Preface

This is a series of lecture notes and problems on “Essential Graduate Physics”, consisting of the following four parts:

- **CM**: Classical Mechanics (for a 1-semester course),
- **EM**: Classical Electrodynamics (2 semesters),
- **QM**: Quantum Mechanics (2 semesters), and
- **SM**: Statistical Mechanics (1 semester).

The parts share a teaching style, structure, and (with a few exceptions) notation, and are interlinked by extensive cross-referencing. I believe that due to this unity, the notes may be used for teaching these courses not only in the (preferred) sequence shown above but in almost any order – or in parallel.

Each part is a two-component package consisting of:

(i) *Lecture Notes* chapter texts, with a list of exercise problems in the end of each chapter, and
(ii) *Exercise and Test Problems with Model Solutions* files.

The series also includes this front matter, two brief reference appendices, **MA**: Selected Mathematical Formulas (16 pp.) and **CA**: Selected Physics Constants (2 pp), and a list of references.

The series is a by-product of the so-called core physics courses I taught at Stony Brook University from 1991 to 2013. Reportedly, most physics departments require their graduate students to either take a set of similar courses or pass comprehensive exams based on an approximately similar body of knowledge. This is why I hope that my notes may be useful for both instructors and students of such courses, as well as for individual learners.

The motivation for composing the lecture notes (which had to be typeset because of my horrible handwriting) and their distribution to Stony Brook students was my desperation to find textbooks I could actually use for teaching. First of all, the textbooks I could find, including the most influential *Theoretical Physics* series by Landau and Lifshitz, did not match my class audiences, which included experiment-oriented students, some PhD candidates from other departments, US college graduates with insufficient undergraduate background, and a few advanced undergraduates. Second, for the rigid time restrictions imposed on the core physics courses, most available textbooks are way too long, and using them would mean hopping from one topic to another, picking up a chapter here and a section there, at a high risk of losing the necessary background material and logical connections between course components – and students’ interest with them. On the other hand, many textbooks lack even brief discussions of several traditional and modern topics that I believe are necessary parts of every professional physicist’s education.

---

2 The texts are saved as separate .pdf files of each chapter, optimized for two-page viewing and double-side printing; merged files for each part and the series as a whole, convenient for search purposes, are also provided.

3 To list just a few: statics and dynamics of elastic and fluid continua, basic notions of physical kinetics, turbulence and deterministic chaos, physics of reversible and quantum computation, energy relaxation and dephasing of open quantum systems, the van der Pol method (a.k.a. the Rotating-Wave Approximation, RWA) in classical and quantum mechanics, physics of electrons and holes in semiconductors, the weak-potential and tight-binding approximations in the energy band theory, optical fiber electrodynamics, macroscopic quantum effects in
The main goal of my courses was to make students familiar with the basic notions and ideas of physics (hence the series’ title), and my main effort was to organize the material in a logical sequence the students could readily follow and enjoy, at each new step understanding why exactly they need to swallow the next knowledge pill. As a backside of such a minimalistic goal, I believe that my texts may be used by advanced undergraduate physics students as well. Moreover, I hope that selected parts of the series may be useful for graduate students of other disciplines, including astronomy, chemistry, mechanical engineering, electrical, computer and electronic engineering, and material science.

At least since Confucius and Sophocles, i.e. for the past 2,500 years, teachers have known that students can master a new concept or method only if they have seen its application to at least a few particular situations. This is why in my notes, the range of theoretical physics methods is limited to the approaches that are indeed necessary for the solution of the problems I had time to discuss, and the introduction of every new technique is always accompanied by an application example or two. Additional exercise problems are listed at the end of each chapter of the lecture notes; they may be used for homework assignments. Individual readers are strongly encouraged to solve as many of these problems as possible.\(^5\)

Detailed model solutions of the exercise problems (some with additional expansion of the lecture material), and several shorter problems suitable for tests (also with model solutions), are gathered in six separate files – one per semester. These files are available for both university instructors and individual readers – free of charge, but in return for a signed commitment to avoid unlimited distribution of the solutions – see p. vii below. For instructors, these files are available not only in the Adobe Systems’ Portable Document Format (*.pdf) but also in the Microsoft Office 1997-2003 format (*.doc) free of macros, so that the problem assignments and solutions may be readily grouped, edited, etc., before their distribution to students, using either virtually any version of Microsoft Word or independent software tools – e.g., the public-domain OpenOffice.org.

I know that my texts are far from perfection. In particular, some sacrifices made at the topic selection, always very subjective, were extremely painful. (Most regretfully, I could not find time for even a brief introduction to the general relativity.\(^6\)) Moreover, it is very probable that despite all my effort and the great help from SBU students and teaching assistants, not all typos/errors have been weeded out. This is why all remarks (however candid) and suggestions by the readers would be highly appreciated. All significant contributions will be gratefully acknowledged – both online and in possible future editions of the series.\(^7\)

\(^4\) Recently several high-quality, graduate-level teaching materials became freely available online, including R. Fitzpatrick’s text on *Classical Electromagnetism* (farside.ph.utexas.edu/teaching/jk1/Electromagnetism.pdf), B. Simons’ “lecture shrinks” on *Advanced Quantum Mechanics* (www.tcm.phy.cam.ac.uk/~bds10/aqp.html), and D. Tong’s lecture notes on several topics (www.damtp.cam.ac.uk/user/tong/teaching.html).

\(^5\) The problems that require either longer calculations or more creative approaches (or both :-)\(^5\)\), are marked by asterisks.

\(^7\) *Note added in June 2019*: Revised versions of these lecture notes, and of model solutions of the exercise problems, are now published by the IOP – see the references on the title page of each part. However, in the view of possible future editions, the kind request formulated above remains very much valid.
Disclaimer

Since these materials are available free of charge, it is hard to imagine somebody blaming their author for deceiving “customers” for his commercial gain. Still, I would like to go a little bit beyond the usual litigation-avoiding claims, and offer a word of caution to potential readers, to preempt their possible later disappointment.

This is NOT a course of theoretical physics – at least in the contemporary sense of the term

Though much of the included material is similar to that in textbooks on “theoretical physics” (most notably in the famous series by L. Landau and E. Lifshitz), this lecture note series is different from them by its focus on the basic concepts and ideas of physics, their relation to experimental data, and most important applications – rather than on sophisticated theoretical techniques. Indeed, the set of theoretical methods discussed in the notes is limited to the minimum necessary for quantitative understanding of the key notions of physics and for solving a few (or rather about a thousand :-) core problems. Moreover, because of the notes’ shortness, I have not been able to cover some key fields of theoretical physics, most notably the general relativity and the quantum field theory – beyond some introductory elements of quantum electrodynamics in QM Chapter 9. If you want to work in modern theoretical physics, you need to know much more than this series teaches!

Moreover, this is NOT a textbook – at least not the usual one

A usual textbook tries (though most commonly fails) to cover virtually all aspects of the addressed field. As a result, it is typically way too long for being fully read and understood by students during the time allocated for the corresponding course, so that the instructors are forced to pick up selected chapters and sections, frequently losing the narrative’s logic lines. In contrast, these notes are much shorter (about 200 pages per semester), enabling their thorough reading – perhaps with just a few later sections dropped, depending on the reader’s interests. I have tried to mitigate the losses due to this minimalistic approach by providing extensive further reading recommendations on the topics I had no time to cover. The reader is highly encouraged to use these sources (and/or the corresponding chapters of more detailed textbooks) on any topics of their special interest.

Then, what these notes ARE and why you may like to use them (I think)

By tradition, graduate physics education consists of two main components: research experience and advanced physics courses. Unfortunately, the latter component is currently under pressure in many physics departments, apparently because of two reasons. On one hand, the average knowledge level of the students entering graduate school is not improving, so that bringing them up to the level of contemporary research becomes increasingly difficult. On the other hand, the research itself is becoming more fragmented, so that the students frequently do not feel an immediate need for a broad physics

---

8 Yes Virginia, these notes represent only my personal opinions, not necessarily those of the Department of Physics and Astronomy of Stony Brook University, the SBU at large, the SUNY system as a whole, the Empire State of New York, the federal agencies and private companies that funded my group’s research, etc. No dear, I cannot be held responsible for any harm, either bodily or mental, their reading may (?) cause.
knowledge base for their PhD project success. Some thesis advisors, trying to maximize the time they could use their students as cheap laboratory workforce, do not help.

I believe that this trend toward the reduction of broad physics education in graduate school is irresponsible. Experience shows that during their future research career, a typical current student will change research fields several times. Starting from scratch in a new field is hard – terribly hard in advanced age (believe me :-). However, physics is fortunate to have a hard core of knowledge, which many other sciences lack. With this knowledge, students will always feel in physics at home, while without it, they may not be able even to understand research literature in the new field, and would risk being reduced to auxiliary work roles – if any at all.

I have seen the main objective of my Stony Brook courses to give an introduction to this hard core of physics, at the same time trying to convey my own enchantment by the unparalleled beauty of the concepts and ideas of this science, and the remarkable logic of their fusion into a wonderful single construct. Let me hope that these notes relay not only the knowledge as such but also at least a part of this enchantment.

Acknowledgments

I am extremely grateful to my faculty colleagues and other readers who commented on certain sections of the notes; here is their list (in the alphabetic order):9

(Evidently, these kind people are not responsible for the remaining deficiencies.)

The Department of Physics and Astronomy of Stony Brook University was very responsive to my kind requests of certain time ordering of my teaching assignments, that was beneficial for note writing and editing. The department, and the university as a whole, also provided a very friendly general environment for my work during the past 25+ years.

A large part of my scientific background and experience, reflected in these materials, came from my education (and then research work) in the Department of Physics of Moscow State University.

And last but not least, I would like to thank my wife Lioudmila for several good bits of advice on aesthetic aspects of note typesetting, and more importantly for all her love, care, and patience – without them, this writing project would be impossible.

konstantin.likharev@stonybrook.edu

9 I am very much sorry that I have not kept proper records from the beginning of my lectures at Stony Brook, so I cannot list all the numerous students and TAs who had kindly attracted my attention to typos in earlier versions of these notes. Needless to say, I am very grateful to them all as well.
Problem Solution Request Templates

Requests should be sent to either konstantin.likharev@stonybrook.edu or klikharev@gmail.com in either of the following forms:

- an e-mail from a valid university address,
- a scanned copy of a signed letter – as an e-mail attachment.

Approximate contents:

A. Request from a Prospective Instructor

Dear Dr. Likharev,

I plan to use your lecture notes and problems of the Essential Graduate Physics series, part(s) <select: CM, EM, QM, SM>, in my course <title> during <semester, year> in the <department, university>. I would appreciate sending me the file(s) Exercise and Test Problems with Model Solutions of that part(s) of the series in the <select: .pdf, both .doc and .pdf> format(s).

I will avoid unlimited distribution of the solutions, in particular their posting on externally searchable websites. If I distribute the solutions among my students, I will ask them to adhere to the same restraint.

I will let you know of any significant typos/deficiencies I may find.

Sincerely, <signature, full name, university position, work phone number>

B. Request from an Individual Learner

Dear Dr. Likharev,

I plan to use your lecture notes and problems of the Essential Graduate Physics series, part(s) <select: CM, EM, QM, SM>, for my personal education. I would appreciate sending me the file(s) Exercise and Test Problems with Model Solutions of that part(s) of the series.

I will not share the material with anyone, and will not use it for passing courses that are officially based on your series.

I will let you know of any significant typos/deficiencies I may find.

Sincerely, <signature, full name, present home address (in English), acting phone number>

### Parts of the series

- CM: Classical Mechanics
- EM: Classical Electrodynamics
- QM: Quantum Mechanics
- SM: Statistical Mechanics

### Appendices

- MA: Selected Mathematical Formulas
- CA: Selected Physical Constants

### Prime signs

The prime signs (′, ″, etc) are used to distinguish similar variables or indices (such as \(j\) and \(j'\) in the matrix element above), rather than to denote derivatives.

### Formulas

The most general and/or important formulas are highlighted with blue frames and short titles on the margins.

### Numbering

Chapter numbers are dropped in all references to formulas, figures, footnotes, and problems within the same chapter.

\(^{10}\) The same letter, typeset in different fonts, typically denotes different variables.

Table of Contents

Chapter 1. Review of Fundamentals (14 pp.)
1.0. Terminology: Mechanics and dynamics
1.1. Kinematics: Basic notions
1.2. Dynamics: Newton laws
1.3. Conservation laws
1.4. Potential energy and equilibrium
1.5. OK, can we go home now?
1.6. Self-test problems (12)

Chapter 2. Lagrangian Analytical Mechanics (14 pp.)
2.1. Lagrange equation
2.2. Three simple examples
2.3. Hamiltonian function and energy
2.4. Other conservation laws
2.5. Exercise problems (11)

Chapter 3. A Few Simple Problems (20 pp.)
3.1. One-dimensional and 1D-reducible systems
3.2. Equilibrium and stability
3.3. Hamiltonian 1D systems
3.4. Planetary problems
3.5. Elastic scattering
3.6. Exercise problems (18)

Chapter 4. Rigid Body Motion (30 pp.)
4.1. Translation and rotation
4.2. Inertia tensor
4.3. Fixed-axis rotation
4.4. Free rotation
4.5. Torque-induced precession
4.6. Non-inertial reference frames
4.7. Exercise problems (23)

Chapter 5. Oscillations (34 pp.)
5.1. Free and forced oscillations
5.2. Weakly nonlinear oscillations
5.3. Reduced equations
5.4. Self-oscillations and phase locking
5.5. Parametric excitation
5.6. Fixed point classification
5.7. Numerical approaches
5.8. Harmonic and subharmonic oscillations
5.9. Exercise problems (16)
### Chapter 6. From Oscillations to Waves (28 pp.)
- 6.1. Two coupled oscillators
- 6.2. $N$ coupled oscillators
- 6.3. 1D waves
- 6.4. Acoustic waves
- 6.5. Standing waves
- 6.6. Wave decay and attenuation
- 6.7. Nonlinear and parametric effects
- 6.8. Exercise problems (20)

### Chapter 7. Deformations and Elasticity (38 pp.)
- 7.1. Strain
- 7.2. Stress
- 7.3. Hooke’s law
- 7.4. Equilibrium
- 7.5. Rod bending
- 7.6. Rod torsion
- 7.7. 3D acoustic waves
- 7.8. Elastic waves in thin rods
- 7.9. Exercise problems (17)

### Chapter 8. Fluid Mechanics (28 pp.)
- 8.1. Hydrostatics
- 8.2. Surface tension effects
- 8.3. Kinematics
- 8.4. Dynamics: Ideal fluids
- 8.5. Dynamics: Viscous fluids
- 8.6. Turbulence
- 8.7. Exercise problems (19)

### Chapter 9. Deterministic Chaos (14 pp.)
- 9.1. Chaos in maps
- 9.2. Chaos in dynamic systems
- 9.3. Chaos in Hamiltonian systems
- 9.4. Chaos and turbulence
- 9.5. Exercise problems (4)

### Chapter 10. A Bit More of Analytical Mechanics (16 pp.)
- 10.1. Hamilton equations
- 10.2. Adiabatic invariance
- 10.3. The Hamilton principle
- 10.4. The Hamilton-Jacobi equation
- 10.5. Exercise problems (9)

**Exercise and Test Problems with Model Solutions** (149 + 32 = 181 problems; 240 pp.)
Chapter 1. Review of Fundamentals

After elaborating a bit on the title and contents of the course, this short introductory chapter reviews the basic notions and facts of the non-relativistic classical mechanics, that are supposed to be known to the readers from undergraduate studies.\footnote{The reader is advised to perform (perhaps after reading this chapter as a reminder) a self-check by solving a few problems of the dozen listed in Sec. 1.6. If the results are not satisfactory, it may make sense to start from some remedial reading. For that, I could recommend, for example (in the alphabetical order):
- K. Symon, \textit{Mechanics}, 3rd ed., Addison-Wesley, 1971.} Due to this reason, the discussion is very brief.

1.0. Terminology: Mechanics and dynamics

A more fair title of this course would be \textit{Classical Mechanics and Dynamics}, because the notions of mechanics and dynamics, though much intertwined, are still somewhat different. The term \textit{mechanics}, in its narrow sense, means deriving the equations of motion of point-like particles and their systems (including solids and fluids), solution of these equations, and interpretation of the results. \textit{Dynamics} is a more ambiguous term; it may mean, in particular:

\begin{enumerate}
\item the part of physics that deals with motion (in contrast to \textit{statics});
\item the part of physics that deals with reasons for motion (in contrast to \textit{kinematics});
\item the part of mechanics that focuses on its two last tasks, i.e. the solution of the equations of motion and discussion of the results.\footnote{The reader may have noticed that the last definition of dynamics is suspiciously close to the part of mathematics devoted to the differential equation analysis; what is the difference? An important bit of philosophy: physics may be defined as an art (and a bit of science :-) of describing Mother Nature by mathematical means; hence in many cases the approaches of a mathematician and a physicist to a problem are very similar. The main difference between them is that physicists try to express the results of their analyses in terms of properties of the systems under study, rather than the \textit{functions} describing them, and as a result develop a sort of intuition ("gut feeling") about how other similar systems may behave, even if their exact equations of motion are somewhat different - or not known at all. The intuition so developed has an enormous heuristic power, and most discoveries in physics have been made through gut-feeling-based insights rather than by just plugging one formula into another one.}
\end{enumerate}

Because of this ambiguity, after some hesitation, I have opted to use the traditional name \textit{Classical Mechanics}, implying its broader meaning that includes (similarly to \textit{Quantum Mechanics} and \textit{Statistical Mechanics}) studies of dynamics of some non-mechanical systems as well.

1.1. Kinematics: Basic notions

The basic notions of kinematics may be defined in various ways, and some mathematicians pay much attention to analyzing such systems of axioms, and relations between them. In physics, we typically stick to less rigorous ways (in order to proceed faster to particular problems) and end debating any definition as soon as "everybody in the room" agrees that we are all speaking about the same thing –
at least in the context they are discussed. Let me hope that the following notions used in classical mechanics do satisfy this criterion in our “room”:

(i) All the Euclidean geometry notions, including the point, the straight line, the plane, etc.

(ii) Reference frames: platforms for observation and mathematical description of physical phenomena. A reference frame includes a coordinate system used for measuring the point’s position (namely, its radius vector \( \mathbf{r} \) that connects the coordinate origin to the point – see Fig. 1) and a clock that measures time \( t \). A coordinate system may be understood as a certain method of expressing the radius vector \( \mathbf{r} \) of a point as a set of its scalar coordinates. The most important of such systems (but by no means the only one) are the Cartesian (orthogonal, linear) coordinates \( r_j \) of a point, in which its radius vector may be represented as the following sum:

\[
\mathbf{r} = \sum_{j=1}^{3} n_j r_j ,
\]

where \( n_1, n_2, \) and \( n_3 \) are unit vectors directed along the coordinate axis – see Fig. 1.\(^4\)

(iii) The absolute (“Newtonian”) space/time,\(^5\) which does not depend on the matter distribution. The space is assumed to have the Euclidean metric, which may be expressed as the following relation between the length \( r \) of any radius vector \( \mathbf{r} \) and its Cartesian coordinates:

\[
 r \equiv |\mathbf{r}| = \left( \sum_{j=1}^{3} r_j^2 \right)^{1/2} ,
\]

while time \( t \) is assumed to runs similarly in all reference frames.

(iv) The (instant) velocity of the point,

---

\(^{3}\) In this series, the Cartesian coordinates (introduced in 1637 by René Descartes, a.k.a. Cartesius) are denoted either as either \( \{r_1, r_2, r_3\} \) or \( \{x, y, z\} \), depending on convenience in each particular case. Note that axis numbering is important for operations like the vector (“cross”) product; the “correct” (meaning generally accepted) numbering order is such that the rotation \( n_1 \rightarrow n_2 \rightarrow n_3 \rightarrow n_1 \cdots \) looks counterclockwise if watched from a point with all \( r_j > 0 \) – like that shown in Fig. 1.

\(^{4}\) Note that the representation (1) is also possible for locally-orthogonal but curvilinear (for example, cylindrical/polar and spherical) coordinates, which will be extensively used in this series. However, such coordinates are not Cartesian, and for them some of the relations given below are invalid - see, e.g., MA Sec. 10.

\(^{5}\) These notions were formally introduced by Sir Isaac Newton in his main work, the three-volume Philosophiae Naturalis Principia Mathematica published in 1686-1687, but are rooted in earlier ideas by Galileo Galilei, published in 1632.
and its acceleration:

\[ a(t) \equiv \frac{d\vec{v}}{dt} \equiv \ddot{\vec{v}} = \ddot{\vec{r}}. \]  

(v) Transfer between reference frames. The above definitions of vectors \( \vec{r}, \vec{v}, \) and \( \vec{a} \) depend on the chosen reference frame (are “reference-frame-specific”), and we frequently need to relate those vectors as observed in different frames. Within the Euclidean geometry, the relation between the radius vectors in two frames with the corresponding axes parallel in the moment of interest (Fig. 2), is very simple:

\[ \vec{r}|_{\text{in } 0'} = \vec{r}|_{\text{in } 0} + \vec{r}_0|_{\text{in } 0'} . \]  

If the frames move versus each other by translation only (no mutual rotation!), similar relations are valid for the velocity and the acceleration as well:

\[ \vec{v}|_{\text{in } 0'} = \vec{v}|_{\text{in } 0} + \vec{v}_0|_{\text{in } 0'} , \]  

\[ \vec{a}|_{\text{in } 0'} = \vec{a}|_{\text{in } 0} + \vec{a}_0|_{\text{in } 0'} . \]  

Note that in the case of mutual rotation of the reference frames, the transfer laws for velocities and accelerations are more complex than those given by Eqs. (6) and (7). Indeed, in this case the notions like \( \vec{v}_0|_{\text{in } 0'} \) are not well defined: different points of an imaginary rigid body connected to frame 0 may have different velocities when observed in frame 0’. It will be more natural for me to discuss these more general relations in the end of Chapter 4, devoted to rigid body motion.

(vi) A particle (or “point particle”): a localized physical object whose size is negligible, and the shape is irrelevant for the given problem. Note that the last qualification is extremely important. For example, the size and shape of a spaceship are not too important for the discussion of its orbital motion but are paramount when its landing procedures are being developed. Since classical mechanics neglects the quantum mechanical uncertainties, in it the position of a particle, at any particular instant \( t \), may be identified with a single geometrical point, i.e. with a single radius vector \( \vec{r}(t) \). The formal final goal of classical mechanics is finding the laws of motion \( \vec{r}(t) \) of all particles participating in the given problem.

---

6 This approximation is legitimate when the product of the coordinate and momentum scales of the particle motion is much larger than Planck’s constant \( \hbar \sim 10^{-34} \text{ J.s} \). More detailed conditions of the classical mechanics’ applicability depend on a particular system – see, e.g., the QM part of this series.
1.2. Dynamics: Newton laws

Generally, the classical dynamics is fully described (in addition to the kinematic relations discussed above) by three *Newton laws*. In contrast to the impression some textbooks on theoretical physics try to create, these laws are experimental in nature, and cannot be derived from purely theoretical arguments.

I am confident that the reader of these notes is already familiar with the Newton laws, in one or another formulation. Let me note only that in some formulations, the 1<sup>st</sup> *Newton law* looks just as a particular case of the 2<sup>nd</sup> law – when the net force acting on a particle equals zero. To avoid this duplication, the 1<sup>st</sup> law may be formulated as the following postulate:

There exists at least one reference frame, called *inertial*, in which any *free particle* (i.e. a particle fully isolated from the rest of the Universe) moves with \( v = \text{const} \), i.e. with \( a = 0 \).

Note that according to Eq. (7), this postulate immediately means that there is also an infinite number of inertial frames because all frames moving without rotation or acceleration relative to the postulated inertial frame 0 (i.e. having \( a_0 = 0 \)) are also inertial.

On the other hand, the 2<sup>nd</sup> and 3<sup>rd</sup> Newton laws may be postulated together in the following elegant way. Each particle, say number \( k \), may be characterized by a scalar constant (called *mass* \( m_k \)), such that at any interaction of \( N \) particles (isolated from the rest of the Universe), in any inertial system,

\[
P \equiv \sum_{k=1}^{N} p_k \equiv \sum_{k=1}^{N} m_k v_k = \text{const.} \tag{1.8}
\]

(Each component of this sum,

\[
p_k \equiv m_k v_k, \tag{1.9}
\]

is called the *mechanical momentum*\(^8\) of the corresponding particle, while the sum \( P \), the *total momentum* of the system.)

Let us apply this postulate to just two interacting particles. Differentiating Eq. (8), written for this case, over time, we get

\[
\dot{p}_1 = -\dot{p}_2. \tag{1.10}
\]

Let us give the derivative \( \dot{p}_1 \) (which is a vector) the name of *force* \( F \) exerted on particle 1. In our current case, when the only possible source of the force is particle 2, it may be denoted as \( F_{12} : \dot{p}_1 \equiv F_{12} \).

Similarly, \( F_{21} \equiv \dot{p}_2 \), so that Eq. (10) becomes the 3<sup>rd</sup> *Newton law*

\[
F_{12} = -F_{21}. \tag{1.11}
\]

---

\(^7\) Due to the genius of Sir Isaac, these laws were formulated in the same *Principia* (1687), well ahead of the physics of his time.

\(^8\) The more extended term *linear momentum* is typically used only in cases when there is a chance of its confusion with the *angular momentum* of the same particle/system – see below. The present-day definition of the linear momentum and the term itself belong to John Wallis (1670), but the concept may be traced back to more vague notions of several previous scientists – all the way back to at least a 570 AD work by John Philoponus.
Plugging Eq. (1.9) into these force definitions, and differentiating the products $m_k \dot{v}_k$, taking into account that particle masses are constants,\(^9\) we get that for $k$ and $k'$ taking any of values 1, 2,

\[
m_k \dot{v}_k \equiv m_k \mathbf{a}_k = F_{kk'}, \quad \text{where } k' \neq k. \quad (1.12)
\]

Now, returning to the general case of several interacting particles, and making an additional (but very natural) assumption that all partial forces $F_{kk'}$ acting on particle $k$ add up as vectors, we may generalize Eq. (12) into the 2\textsuperscript{nd} Newton law

\[
m_k \mathbf{a}_k \equiv \dot{p}_k = \sum_{k' \neq k} F_{kk'}, \quad (1.13)
\]

that allows a clear interpretation of the mass as a measure of particle’s inertia.

As a matter of principle, if the dependence of all pair forces $F_{kk'}$ of particle positions (and generally of time as well) is known, Eq. (13), augmented with the kinematic relations (2) and (3), allows calculation of the laws of motion $\mathbf{r}_k(t)$ of all particles of the system. For example, for one particle the 2\textsuperscript{nd} law (13) gives an ordinary differential equation of the second order,

\[
m \ddot{r} = F(r, t), \quad (1.14)
\]

which may be integrated – either analytically or numerically.

In certain cases, this is very simple. As an elementary example, Newton’s gravity force\(^10\)

\[
F = -G \frac{mm'}{R^2} \mathbf{R} \quad (1.15)
\]

(where $\mathbf{R} \equiv \mathbf{r} - \mathbf{r}'$ is the distance between particles of masses $m$ and $m'$)\(^11\), is virtually uniform and may be approximated as

\[
F = mg, \quad (1.16)
\]

with the vector $\mathbf{g} \equiv (Gm' / r^3) \mathbf{r}'$ being constant, for local motions with $r \ll r'$.\(^12\) As a result, $m$ in Eq. (13) cancels, it is reduced to just $\ddot{\mathbf{r}} = \mathbf{g} = \text{const}$, and may be easily integrated twice:

\[
\ddot{r}(t) \equiv \dot{v}(t) = \int_0^t \mathbf{g} \, dt' + v(0) = g t + v(0), \quad \mathbf{r}(t) = \int_0^t \dot{v}(t') dt' + \mathbf{r}(0) = g\frac{t^2}{2} + v(0)t + \mathbf{r}(0), \quad (1.17)
\]

---

\(^9\) Note that this may not be true for composite bodies of varying total mass $M$ (e.g., rockets emitting jets, see Problem 11), in these cases the momentum’s derivative may differ from $Ma$.

\(^10\) Introduced in the same famous Principia!

\(^11\) The fact that the masses participating in Eqs. (14) and (16) are equal, the so-called weak equivalence principle, is actually highly nontrivial, but has been repeatedly verified experimentally with gradually improved relative accuracy, currently reaching $\sim 10^{-14}$ – see P. Touboul \textit{et al}., \textit{Phys. Rev. Lett.} \textbf{119}, 231101 (2017).

\(^12\) Of course, the most important particular case of Eq. (16) is the motion of objects near the Earth’s surface. In this case, using the fact that Eq. (15) remains valid for the gravity field created by a heavy sphere, we get $g = GM_E / R_E^2$, where $M_E$ and $R_E$ are the Earth’s mass and radius. Plugging in their values, $M_E \approx 5.97 \times 10^{24}$ kg and $R_E \approx 6.37 \times 10^6$ m, we get $g \approx 9.82$ m/s\(^2\). The experimental value of $g$ varies from 9.78 to 9.83 m/s\(^2\) at various locations on Earth’s surface (due to the deviations of Earth’s shape from a sphere, and the location-dependent effect of the centrifugal “inertial force” – see Sec. 4.5 below), with an average value of $g \approx 9.807$ m/s\(^2\).
thus giving the generic solution of all those undergraduate problems on the projectile motion, which
should be so familiar to the reader.

All this looks (and indeed is) very simple, but in most other cases, Eq. (13) leads to more
complex calculations. As an example, let us think about would we use it to solve another simple
problem: a bead of mass \( m \) sliding, without friction, along a round ring of radius \( R \) in a gravity field
obeying Eq. (16) – see Fig. 3. (This system is equivalent to the usual point pendulum, i.e. a point mass
suspended from point 0 on a light rod or string, and constrained to move in one vertical plane.)

Suppose we are only interested in the bead’s velocity \( v \) at the lowest point, after it has been
dropped from the rest at the rightmost position. If we want to solve this problem using only the Newton
laws, we have to make the following steps:

(i) consider the bead in an arbitrary intermediate position on a ring, described, for example by
the angle \( \theta \) shown in Fig. 3;
(ii) draw all the forces acting on the particle – in our current case, the gravity force \( mg \) and the
reaction force \( N \) exerted by the ring – see Fig. 3 above
(iii) write the Cartesian components of the 2nd Newton law (14) for the bead acceleration: \( ma_x = N_x, ma_y = N_y - mg, \)
(iv) recognize that in the absence of friction, the force \( N \) should be normal to the ring, so that we
can use two additional equations, \( N_x = -N \sin \theta \) and \( N_y = N \cos \theta; \)
(v) eliminate unknown variables \( N, N_x, \) and \( N_y \) from the resulting system of four equations, thus
getting a single second-order differential equation for one variable, for example \( \theta; \)

\[
mR \ddot{\theta} = -mg \sin \theta; \tag{1.18}
\]

(vi) use the mathematical identity \( \dot{\theta} = \left( \frac{d\theta}{d\theta} \right) \dot{\theta} \) to integrate this equation over \( \theta \) once to get an
expression relating the velocity \( \dot{\theta} \) and the angle \( \theta \); and, finally,
(vii) using our specific initial condition ( \( \dot{\theta} = 0 \) at \( \theta = \pi/2 \), find the final velocity as \( v = R \dot{\theta} \) at
\( \theta = 0 \).

All this is very much doable, but please agree that the procedure it too cumbersome for such a
simple problem. Moreover, in many other cases even writing equations of motion along relevant
coordinates is very complex, and any help the general theory may provide is highly valuable. In many
cases, such help is given by conservation laws; let us review the most general of them.
1.3. Conservation laws

(i) **Energy** conservation is arguably the most general law of physics, but in mechanics, it takes a more humble form of *mechanical energy conservation*, which has limited applicability. To derive it, we first have to define the *kinetic energy* of a particle as

\[ T \equiv \frac{m}{2} v^2, \tag{1.19} \]

and then recast its differential as

\[ dT \equiv d\left(\frac{m}{2} v^2\right) \equiv d\left(\frac{m}{2} \mathbf{v} \cdot \mathbf{v}\right) = m \mathbf{v} \cdot d\mathbf{v} = m \frac{d\mathbf{r} \cdot d\mathbf{v}}{dt} = d\mathbf{r} \cdot \frac{d\mathbf{p}}{dt}. \tag{1.20} \]

Now plugging in the momentum’s derivative from the 2\textsuperscript{nd} Newton law, \( d\mathbf{p}/dt = \mathbf{F}\), where \( \mathbf{F} \) is the full force acting on the particle, we get \( dT = \mathbf{F} \cdot d\mathbf{r} \). The integration of this equality along the particle’s trajectory connecting some points A and B gives the formula that is sometimes called the work-energy principle:

\[ \Delta T \equiv T(\mathbf{r}_B) - T(\mathbf{r}_A) = \int_A^B \mathbf{F} \cdot d\mathbf{r}, \tag{1.21} \]

where the integral on the right-hand side is called the work of the force \( \mathbf{F} \) on the path from A to B.

The following step may be made only for a *potential* (also called “conservative”) force that may be represented as the (minus) gradient of some scalar function \( U(\mathbf{r}) \), called the *potential energy*.\(^{15}\) The vector operator \( \nabla \) (called either *del* or *nabla*) of spatial differentiation\(^{16}\) allows a very compact expression of this fact:

\[ \mathbf{F} = -\nabla U. \tag{1.22} \]

For example, for the uniform gravity field (16),

\[ U = mgh + \text{const}, \tag{1.23} \]

where \( h \) is the vertical coordinate directed “up” – opposite to the direction of the vector \( \mathbf{g} \).

Integrating the tangential component \( F_t \) of the vector \( \mathbf{F} \) given by Eq. (22), along an arbitrary path connecting the points A and B, we get

\[ \int_A^B F_t \, dr \equiv \int_A^B \mathbf{F} \cdot d\mathbf{r} = U(\mathbf{r}_A) - U(\mathbf{r}_B), \tag{1.24} \]

\(^{13}\) In such quantitative form, the kinetic energy was introduced (under the name “living force”) by Gottfried Leibniz and Johann Bernoulli (circa 1700), though its main properties (21) and (27) had not been clearly revealed until an 1829 work by Gaspard-Gustave de Coriolis. The modern term “kinetic energy” was coined only in 1849-1851 by Lord Kelvin (born William Thomson).

\(^{14}\) In these notes, \( \mathbf{a} \cdot \mathbf{b} \) denotes the scalar (or “dot-”) product of vectors \( \mathbf{a} \) and \( \mathbf{b} \) - see, e.g., MA Eq. (7.1).

\(^{15}\) Note that because of its definition via the gradient, the potential energy is only defined to an arbitrary additive constant. This notion had essentially been used already by G. Leibniz, though the term we are using for it now was introduced much later (in the mid-19\textsuperscript{th} century) by William Rankine.

\(^{16}\) Its basic properties are listed in MA Sec. 8.
i.e. work of potential forces may be represented as the difference of values of the function $U(r)$ in the initial and final points of the path. (Note that according to Eq. (24), the work of a potential force on any closed path, with $r_A = r_B$, is zero.)

Now returning to Eq. (21) and comparing it with Eq. (24), we see that

$$T(r_B) - T(r_A) = U(r_A) - U(r_B), \quad \text{i.e. } T(r_A) + U(r_A) = T(r_A) + U(r_A),$$

so that the total mechanical energy $E$, defined as

$$E \equiv T + U,$$

is indeed conserved:

$$E(r_A) \equiv E(r_B),$$

but for conservative forces only. (Non-conservative forces may change $E$ by either transferring energy from its mechanical form to another form, e.g., to heat in the case of friction, or by pumping the energy into the system under consideration from another, “external” system.)

The mechanical energy conservation allows us to return for a second to the problem shown in Fig. 3 and solve it in one shot by writing Eq. (27) for the initial and final points:

$$v^2 + mgR = \frac{m}{2}v^2 + 0.$$ (1.28)

The (elementary) solution of Eq. (28) for $v$ immediately gives us the desired answer. Let me hope that the reader agrees that this way of problem’s solution is much simpler, and I have earned their attention to discuss other conservation laws – which may be equally effective.

(ii) Linear momentum. The conservation of the full linear momentum of any system of particles isolated from the rest of the world was already discussed in the previous section, and may serve as the basic postulate of classical dynamics – see Eq. (8). In the case of one free particle, the law is reduced to the trivial result $p = \text{const}$, i.e. $v = \text{const}$. If a system of $N$ particles is affected by external forces $F^{(\text{ext})}$, we may write

$$F_k = F_k^{(\text{ext})} + \sum_{k'=1}^N F_{kk'},$$

If we sum up the resulting Eqs. (13) for all particles of the system then, due to the 3rd Newton law (11), valid for any indices $k \neq k'$, the contributions of all internal forces $F_{kk'}$ to the resulting double sum on the right-hand side cancel, and we get the following equation:

$$\dot{P} = F^{(\text{ext})}, \quad \text{where } F^{(\text{ext})} \equiv \sum_{k=1}^N F_k^{(\text{ext})}.$$ (1.30)

It tells us that the translational motion of the system as the whole is similar to that of a single particle, under the effect of the net external force $F^{(\text{ext})}$. As a simple sanity check, if the external forces have a zero sum, we return to the postulate (8). Just one reminder: Eq. (30), as its precursor Eq. (13), is only valid in an inertial reference frame.

---

17 Here the arbitrary constant in Eq. (23) is chosen so that the potential energy is zero in the final point.
I hope that the reader knows numerous examples of application of the linear momentum’s conservation law, including all these undergraduate problems on car collisions, where the large collision forces are typically not known so that the direct application of Eq. (13) to each car is impracticable.

(iii) The angular momentum of a particle is defined as the following vector:

\[
\mathbf{L} = \mathbf{r} \times \mathbf{p},
\]  
(1.31)

where \( \mathbf{a} \times \mathbf{b} \) means the vector (or “cross-“) product of the vector operands. Differentiating Eq. (31) over time, we get

\[
\dot{\mathbf{L}} = \dot{\mathbf{r}} \times \mathbf{p} + \dot{\mathbf{r}} \times \mathbf{p}.
\]  
(1.32)

In the first product, \( \dot{\mathbf{r}} \) is just the velocity vector \( \mathbf{v} \), parallel to the particle momentum \( \mathbf{p} = m\mathbf{v} \), so that this term vanishes since the vector product of any two parallel vectors equals zero. In the second product, \( \dot{\mathbf{p}} \) is equal to the full force \( \mathbf{F} \) acting on the particle, so that Eq. (32) is reduced to

\[
\mathbf{\tau} = \dot{\mathbf{L}},
\]  
(1.33)

where the vector

\[
\mathbf{\tau} = \mathbf{r} \times \mathbf{F},
\]  
(1.34)

is called the torque exerted by force \( \mathbf{F} \). (Note that the torque is reference-frame specific – and again, the frame has to be inertial for Eq. (33) to be valid, because we have used Eq. (13) for its derivation.)

For an important particular case of a central force \( \mathbf{F} \) that is directed along the radius vector \( \mathbf{r} \) of a particle, the torque vanishes, so that (in that particular reference frame only!) the angular momentum is conserved:

\[
\mathbf{L} = \text{const.}
\]  
(1.35)

For a system of \( N \) particles, the total angular momentum is naturally defined as

\[
\mathbf{L} \equiv \sum_{k=1}^{N} \mathbf{L}_k.
\]  
(1.36)

Differentiating this equation over time, using Eq. (33) for each \( \dot{\mathbf{L}}_k \), and again partitioning each force per Eq. (29), we get

\[
\dot{\mathbf{L}} = \sum_{k=1}^{N} \mathbf{r}_k \times \mathbf{F}_{k} + \mathbf{\tau}^{(\text{ext})}, \quad \text{where} \quad \mathbf{\tau}^{(\text{ext})} \equiv \sum_{k=1}^{N} \mathbf{r}_k \times \mathbf{F}_k^{(\text{ext})}.
\]  
(1.37)

The first (double) sum may be always divided into pairs of the type \( \mathbf{r}_k \times \mathbf{F}_{kk'} + \mathbf{r}_{k'} \times \mathbf{F}_{kk'} \). With a natural assumption of the central forces, \( \mathbf{F}_{kk'} \parallel (\mathbf{r}_k - \mathbf{r}_{k'}) \), each of these pairs equals zero. Indeed, in this case,

---

18 Here we imply that the internal motions of the particle, including its rotation about its axis, are negligible. (Otherwise, it could not be represented by a point, as was postulated in Sec. 1.)

19 Such explicit definition of the angular momentum (in different mathematical forms, and under the name of “moment of rotational motion”) has appeared in scientific publications only in the 1740s, though the fact of its conservation (35) in the field of central forces, in the form of the 2nd Kepler law (see Fig. 3.4 below), was proved by I. Newton in his Principia.

20 See, e.g., MA Eq. (7.3).

21 Alternatively, especially in mechanical engineering, torque is called the force moment. This notion may be traced all the way back to Archimedes’ theory of levers developed in the 3rd century BC.
each component of the pair is a vector perpendicular to the plane containing the positions of both particles and the reference frame origin, i.e. to the plane of the drawing of Fig. 4.

Also, due to the 3rd Newton law (11), these two forces are equal and opposite, and the magnitude of each term in the sum may be represented as $|F_{kk'}| \, h_{kk'}$, with equal to the “lever arms” $h_{kk'} = h_{k'k}$. As a result, each sum $(r_k \times F_{kk'} + r_{k'} \times F_{k'k})$, and hence the whole double sum in Eq. (37) vanish, and it is reduced to a very simple result,

$$\dot{\mathbf{L}} = \tau^{(\text{ext})}, \quad (1.38)$$

which is similar to Eq. (33) for a single particle, and is the angular analog of Eq. (30).

In particular, Eq. (38) shows that if the full external torque $\tau^{(\text{ext})}$ vanishes by some reason (e.g., if the system of particles is isolated from the rest of the Universe), the conservation law (35) is valid for the full angular momentum $\mathbf{L}$, even if its individual components $L_k$ are not conserved due to inter-particle interactions.

Note again that since the conservation laws may be derived from the Newton laws (as was done above), they do not introduce anything absolutely new to the dynamics of any system. Indeed, from the mathematical point of view, the conservation laws discussed above are just the first integrals of the second-order differential equations of motion following from the Newton laws, which may liberate us from the necessity to integrate the equations twice.

### 1.4. Potential energy and equilibrium

Another important role of the potential energy $U$, especially for dissipative systems whose total mechanical energy $E$ is not conserved because it may be drained to the environment, is finding the positions of equilibrium (sometimes called the fixed points of the system under analysis) and analyzing their stability with respect to small perturbations. For a single particle, this is very simple: the force (22) vanishes at each extremum (either minimum or maximum) of the potential energy. Of those fixed points, only the minimums of $U(\mathbf{r})$ are stable – see Sec. 3.2 below for a discussion of this point.

A slightly more subtle case is a particle with potential energy $U(\mathbf{r})$, subjected to an additional external force $F^{(\text{ext})}(\mathbf{r})$. In this case, the stable equilibrium is reached at the minimum of not the function $U(\mathbf{r})$, but of what is sometimes called the Gibbs potential energy

---

22 Assuming that the additional, non-conservative forces (such as viscosity) responsible for the mechanical energy drain, vanish at equilibrium – as they typically do. (The static friction is one counter-example.)
which is defined, just as \( U(\mathbf{r}) \) is, to an arbitrary additive constant. The proof of Eq. (39) is very simple: in an extremum of this function, the total force acting on the particle,

\[
\mathbf{F}^{(\text{tot})} = \mathbf{F} + \mathbf{F}^{(\text{ext})} = -\nabla U + \mathbf{r}^T \mathbf{F}^{(\text{ext})} = -\nabla U_G,
\]

vanishes, as it should.

Physically, the difference \( U_G - U \) specified by Eq. (39) is the \( \mathbf{r} \)-dependent part of the potential energy \( U^{(\text{ext})} \) of the external system responsible for the force \( \mathbf{F}^{(\text{ext})} \), so that \( U_G \) is just the total potential energy \( U + U^{(\text{ext})} \), excluding its part that does not depend on \( \mathbf{r} \) and hence is irrelevant for the analysis. According to the 3rd Newton law, the force exerted by the particle on the external system equals \(-\mathbf{F}^{(\text{ext})}\), so that its work (and hence the change of \( U^{(\text{ext})} \) due to the change of \( \mathbf{r} \)) is given by the second term on the right-hand side of Eq. (39). Thus the condition of equilibrium, \(-\nabla U_G = 0\), is just the condition of an extremum of the total potential energy, \( U + U^{(\text{ext})} + \text{const} \), of the two interacting systems.

For the simplest (and very frequent) case when the applied force is independent of the particle’s position, the Gibbs potential energy (39) is just

\[
U_G(\mathbf{r}) = U(\mathbf{r}) - \mathbf{r}^T \mathbf{F}^{(\text{ext})} + \text{const}.
\]

As the simplest example, consider a 1D deformation of the usual elastic spring providing the returning force \(-\kappa x\), where \( x \) is the deviation from its equilibrium. As follows from Eq. (22), its potential energy is \( U = \kappa x^2/2 + \text{const} \), so that its minimum corresponds to \( x = 0 \). Now let us apply an additional external force \( F \), say independent of \( x \). Then the equilibrium deformation of the spring, \( x_0 = F/\kappa \), corresponds to the minimum of not \( U \), but rather of the Gibbs potential energy (41), in our particular case taking the form

\[
U_G = U - Fx = \frac{\kappa x^2}{2} - Fx.
\]

1.5. OK, we’ve got it – can we go home now?

Sorry, not yet. In many cases, the conservation laws discussed above provide little help, even in systems without dissipation. Consider for example a generalization of the bead-on-the-ring problem shown in Fig. 3, in which the ring is rotated by external forces, with a constant angular velocity \( \omega \), about its vertical diameter. In this problem (to which I will repeatedly return below, using it as an

\[23\] Unfortunately, in most textbooks, the association of the (unavoidably used) notion of \( U_G \) with the glorious name of Josiah Willard Gibbs is postponed until a course of statistical mechanics and/or thermodynamics, where \( U_G \) is a part of the Gibbs free energy, in contrast to \( U \), which is a part of the Helmholtz free energy - see, e.g., SM Sec. 1.4. I use this notion throughout my series, because the difference between \( U_G \) and \( U \), and hence that between the Gibbs and Helmholtz free energies, has nothing to do with statistics or thermal motion, and belongs to the whole physics, including not only mechanics but also electrodynamics and quantum mechanics.

\[24\] Note that Eq. (41) is a particular case of what mathematicians call the Legendre transformations.

\[25\] This is essentially a simplified model of the mechanical control device called the centrifugal (or “flyball”, or “centrifugal flyball”) governor – see, e.g., http://en.wikipedia.org/wiki/Centrifugal_governor. (Sometimes the
analytical mechanics “testbed”), none of the three conservation laws listed in the last section, holds. In particular, bead’s energy,

\[ E = \frac{m}{2} v^2 + mgh , \]  

(1.43)
is not constant, because the external forces rotating the ring may change it. Of course, we still can solve the problem using the Newton laws, but this is even more complex than for the above case of the ring at rest, in particular because the force \( \mathbf{N} \) exerted on the bead by the ring now may have three rather than two Cartesian components, which are not simply related. On the other hand, it is clear that the bead still has just one degree of freedom (angle \( \theta \)), so that its dynamics should not be too complicated.

This fact gives the clue how situations like this one could be simplified: if we only could exclude the so-called reaction forces such as \( \mathbf{N} \), that take into account the external constraints imposed on the particle motion, in advance, that should help a lot. Such a constraint exclusion may be provided by analytical mechanics, in particular its Lagrangian formulation, to which we will now proceed.

Of course, the value of the Lagrangian approach goes far beyond simple systems such as the bead on a rotating ring. Indeed, this system has just two externally imposed constraints: the fixed distance of the bead from the center of the ring, and the instant angle of rotation of the ring about its vertical diameter. Now let us consider the motion of a rigid body. It is essentially a system of a very large number, \( N \gg 1 \), of particles (~10^{23} of them if we think about atoms in a 1-cm-scale body). If the only way to analyze its motion would be to write the Newton laws for each of the particles, the situation would be completely hopeless. Fortunately, the number of constraints imposed on its motion is almost similarly huge. (At negligible deformations of the body, the distances between each pair of its particles should be constant.) As a result, the number of actual degrees of freedom of such a body is small (at negligible deformations, just six – see Sec. 6.1), so that with the kind help from analytical mechanics, the motion of the body may be, in many important cases, analyzed even without numerical calculations.

One more important motivation for analytical mechanics is given by dynamics of “non-mechanical” systems, for example, of the electromagnetic field – possibly interacting with charged particles, conducting bodies, etc. In many such systems, the easiest (and sometimes the only practicable) way to find the equations of motion is to derive them from either the Lagrangian or Hamiltonian function of the system. Moreover, the Hamiltonian formulation of the analytical mechanics (to be discussed in Chapter 10) offers a direct pathway to deriving quantum-mechanical Hamiltonian operators of various systems, which are necessary for the analysis of their quantum properties.

1.6. Self-test problems

1.1. A bicycle, ridden with velocity \( v \) on a wet pavement, has no mudguards on its wheels. How far behind should the following biker ride to avoid being splashed over? Neglect the air resistance effects.

---

device is called the “Watt’s governor”, after the famous James Watts who used it in 1788 in one of his first steam engines, but it had been used in European windmills at least since the early 1600s.) Just as a curiosity: the now-ubiquitous term cybernetics was coined by Norbert Wiener in 1948 from the word “governor” (or rather from its ancient-Greek original κυβερνήτης) exactly in this meaning because it had been the first well-studied control device.
1.2. Two round disks of radius $R$ are firmly connected with a coaxial cylinder of a smaller radius $r$, and a thread is wound on the resulting spool. The spool is placed on a horizontal surface, and the thread’s end is being pooled out at angle $\varphi$ – see the figure on the right. Assuming that the spool does not slip on the surface, what direction would it roll?

1.3. Calculate the equilibrium shape of a flexible, heavy rope of length $l$, with a constant mass $\mu$ per unit length, if it is hung in a uniform gravity field between two points separated by a horizontal distance $d$ – see the figure on the right.

1.4. A uniform, long, thin bar is placed horizontally on two similar round cylinders rotating toward each other with the same angular velocity $\omega$ and displaced by distance $d$ – see the figure on the right. Calculate the laws of relatively slow horizontal motion of the bar within the plane of the drawing, for both possible directions of cylinder rotation, assuming that the friction force between the slipping surfaces of the bar and each cylinder obeys the simple Coulomb approximation

$$|F| = \mu N,$$

where $N$ is the normal pressure force between them, and $\mu$ is a constant (velocity-independent) coefficient. Formulate the condition of validity of your result.

1.5. A small block slides, without friction, down a smooth slide that ends with a round loop of radius $R$ – see the figure on the right. What smallest initial height $h$ allows the block to make its way around the loop without dropping from the slide if it is launched with negligible initial velocity?

1.6. A satellite of mass $m$ is being launched from height $H$ over the surface of a spherical planet with radius $R$ and mass $M >> m$ – see the figure on the right. Find the range of initial velocities $v_0$ (normal to the radius) providing closed orbits above the planet’s surface.

1.7. Prove that the thin-uniform-disk model of a galaxy describes small harmonic oscillations of stars inside it along the direction normal to the disk, and calculate the frequency of these oscillations in terms of Newton’s gravitational constant $G$ and density $\rho$ of the disk’s matter.

---

26 It was suggested in 1785 by the same Charles-Augustin de Coulomb who has discovered the famous Coulomb law of electrostatics, and hence pioneered the whole quantitative science of electricity – see EM Ch. 1.
1.8. Derive differential equations of motion for small oscillations of two similar pendula coupled with a spring (see the figure on the right), within their common vertical plane. Assume that at the vertical position of both pendula, the spring is not stretched ($\Delta L = 0$).

1.9. One of the popular futuristic concepts of travel is digging a straight railway tunnel through the Earth and letting a train go through it, without initial velocity – driven only by gravity. Calculate the train’s travel time through such a tunnel, assuming that the Earth’s density $\rho$ is constant, and neglecting the friction and planet-rotation effects.

1.10. A small bead of mass $m$ may slide, without friction, along a light string, stretched with a force $F > mg$, between two points separated by a horizontal distance $2d$ – see the figure on the right. Calculate the frequency of horizontal oscillations of the bead about its equilibrium position.

1.11. For a rocket accelerating due to its working jet motor (and hence spending the jet fuel), calculate the relation between its velocity and the remaining mass.

*Hint:* For the sake of simplicity, consider the 1D motion.

1.12. Prove the following virial theorem:$^{27}$ for a set of $N$ particles performing a periodic motion,

$$\bar{T} = -\frac{1}{2} \sum_{k=1}^{N} \mathbf{F}_k \cdot \mathbf{r}_k,$$

where the top bar means time averaging – in this case over the motion period. What does the virial theorem say about:

(i) a 1D motion of a particle in the confining potential$^{28} U(x) = ax^s$, with $a > 0$ and $s > 0$, and

(ii) an orbital motion of a particle in the central potential $U(r) = -C/r$?

*Hint:* Explore the time derivative of the following scalar function of time: $G(t) = \sum_{k=1}^{N} \mathbf{p}_k \cdot \mathbf{r}_k$.

$^{27}$ It was first stated by Rudolf Clausius in 1870.

$^{28}$ Here and below I am following the (regretful) custom of using the single word “potential” for the potential energy of the particle - just for brevity. This custom is also common in quantum mechanics, but in electrodynamics these two notions should be clearly distinguished – as they are in the QM part of this series.
Chapter 2. Lagrangian Analytical Mechanics

The goal of this chapter is to describe the Lagrangian formalism of analytical mechanics, which is extremely useful for obtaining the differential equations of motion (and sometimes their first integrals) not only for mechanical systems with holonomic constraints but also some other dynamic systems.

2.1. Lagrange equations

In many cases, the constraints imposed on the 3D motion of a system of \( N \) particles may be described by \( N \) vector (i.e. \( 3N \) scalar) algebraic equations

\[
\mathbf{r}_k = \mathbf{r}_k(q_1, q_2, \ldots, q_j, \ldots, q_J, t), \quad \text{with } 1 \leq k \leq N, \quad (2.1)
\]

where \( q_j \) are certain \textit{generalized coordinates} that (together with constraints) completely define the system position. Their number \( J \leq 3N \) is called the number of the actual \textit{degrees of freedom} of the system. The constraints that allow such description are called \textit{holonomic}.\footnote{Possibly, the simplest counter-example of a \textit{non-holonomic} constraint is a set of inequalities describing the hard walls confining the motion of particles in a closed volume. Non-holonomic constraints are better dealt with other methods, e.g., by imposing proper boundary conditions on the (otherwise unconstrained) motion.}

For example, for the problem discussed briefly in Section 1.5, namely the bead sliding along a rotating ring (Fig. 1), \( J = 1 \), because with the constraints imposed by the ring, the bead’s position is uniquely determined by just one generalized coordinate – for example, its polar angle \( \theta \).

Indeed, selecting the reference frame as shown in Fig. 1 and using the well-known formulas for the spherical coordinates,\footnote{See, e.g., MA Eq. (10.7).} we see that in this case, Eq. (1) has the form

\[
\mathbf{r} = \{x, y, z\} = \{R \sin \theta \cos \varphi, R \sin \theta \sin \varphi, R \cos \theta\}, \quad \text{where } \varphi = \omega t + \text{const}, \quad (2.2)
\]

with the last constant depending on the exact selection of the axes \( x \) and \( y \) and the time origin. Since the angle \( \varphi \), in this case, is a fixed function of time, and \( R \) is a fixed constant, the particle’s position in space...
at any instant $t$ is completely determined by the value of its only generalized coordinate $\theta$. (Note that its dimensionality is different from that of Cartesian coordinates!)

Now returning to the general case of $J$ degrees of freedom, let us consider a set of small variations (alternatively called “virtual displacements”) $\delta q_j$ allowed by the constraints. Virtual displacements differ from the actual small displacements (described by differentials $dq_j$ proportional to time variation $dt$) in that $\delta q_j$ describes not the system’s motion as such, but rather its possible variation – see Fig. 1.

![Fig. 2.2. Actual displacement $dq_j$ vs. the virtual one (i.e. variation) $\delta q_j$.](image)

Generally, operations with variations are the subject of a special field of mathematics, the calculus of variations. However, the only math background necessary for our current purposes is the understanding that operations with variations are similar to those with the usual differentials, though we need to watch carefully what each variable is a function of. For example, if we consider the variation of the radius vectors (1), at a fixed time $t$, as a function of independent variations $\delta q_j$, we may use the usual formula for the differentiation of a function of several arguments:

$$\delta \mathbf{r}_k = \sum_j \frac{\partial \mathbf{r}_k}{\partial q_j} \delta q_j.$$  \hspace{1cm} \text{(2.3)}

Now let us break the force acting upon the $k^{th}$ particle into two parts: the frictionless, constraining part $N_k$ of the reaction force and the remaining part $F_k$ – including the forces from other sources and possibly the friction part of the reaction force. Then the 2\textsuperscript{nd} Newton law for the $k^{th}$ particle of the system may be rewritten as

$$m_k \ddot{\mathbf{r}}_k - F_k = N_k.$$ \hspace{1cm} \text{(2.4)}

Since any variation of the motion has to be allowed by the constraints, its $3N$-dimensional vector with $N$ 3D-vector components $\delta \mathbf{r}_k$ has to be perpendicular to the $3N$-dimensional vector of the constraining forces, also with $N$ 3D-vector components $N_k$. (For example, for the problem shown in Fig. 2.1, the virtual displacement vector $\delta \mathbf{r}_k$ may be directed only along the ring, while the constraining force $N$, exerted by the ring, has to be perpendicular to that direction.) This condition may be expressed as

3 For a concise introduction to the field see, e.g., either I. Gelfand and S. Fomin, Calculus of Variations, Dover, 2000, or L. Elsgolc, Calculus of Variations, Dover, 2007. An even shorter review may be found in Chapter 17 of Arfken and Weber – see MA Sec. 16. For a more detailed discussion, using many examples from physics, see R. Weinstock, Calculus of Variations, Dover, 2007.

4 See, e.g., MA Eq. (4.2). In all formulas of this section, all summations over $j$ are from 1 to $J$, while those over the particle number $k$ are from 1 to $N$, so that for the sake of brevity, these limits are not explicitly specified.
\[ \sum_k N_k \cdot \delta r_k = 0, \]  
(2.5)

where the scalar product of 3N-dimensional vectors is defined exactly like that of 3D vectors, i.e. as the sum of the products of the corresponding components of the operands. The substitution of Eq. (4) into Eq. (5) results in the so-called D’Alembert principle:5

\[ \sum_k (m_k \dot{v}_k - F_k) \cdot \delta r_k = 0. \]  
(2.6)

Now we may plug Eq. (3) into Eq. (6) to get

\[ \sum_j \left( \sum_k m_k \dot{v}_k \cdot \frac{\partial r_k}{\partial q_j} - \mathcal{F}_j \right) \delta q_j = 0, \]  
(2.7)

where the scalars \( \mathcal{F}_j \), called the generalized forces, are defined as follows:6

\[ \mathcal{F}_j = \sum_k F_k \cdot \frac{\partial r_k}{\partial q_j}. \]  
(2.8)

Now we may use the standard argument of the calculus of variations: for the left-hand side of Eq. (7) to be zero for an arbitrary selection of independent variations \( \delta q_j \), the expressions in the curly brackets, for every \( j \), should equal zero. This gives us the desired set of \( J \leq 3N \) equations

\[ \sum_k m_k \dot{v}_k \cdot \frac{\partial r_k}{\partial q_j} - \mathcal{F}_j = 0; \]  
(2.9)

what remains is just to recast them in a more convenient form.

First, using the differentiation by parts to calculate the following time derivative:

\[ \frac{d}{dt} \left( \dot{v}_k \cdot \frac{\partial r_k}{\partial q_j} \right) = \ddot{v}_k \cdot \frac{\partial r_k}{\partial q_j} + \dot{v}_k \cdot \frac{d}{dt} \left( \frac{\partial r_k}{\partial q_j} \right), \]  
(2.10)

we may notice that the first term on the right-hand side is exactly the scalar product in the first term of Eq. (9).

Second, let us use another key fact of the calculus of variations (which is, essentially, evident from Fig. 3): the differentiation of a variable over time and over the generalized coordinate variation (at a fixed time) are interchangeable operations. As a result, in the second term on the right-hand side of Eq. (10) we may write

\[ \frac{d}{dt} \left( \frac{\partial r_k}{\partial q_j} \right) = \frac{\partial}{\partial q_j} \left( \frac{d r_k}{dt} \right) \equiv \partial v_k \cdot \frac{\partial}{\partial q_j}. \]  
(2.11)

---

5 It was spelled out in a 1743 work by Jean le Rond d’Alembert, though the core of this result has been traced to an earlier work by Jacob (Jean) Bernoulli (1667 – 1748) – not to be confused with his son Daniel Bernoulli (1700-1782) who is credited, in particular, for the Bernoulli equation for ideal fluids, to be discussed in Sec. 8.4 below.

6 Note that since the dimensionality of generalized coordinates may be arbitrary, that of generalized forces may also differ from the newton.
Finally, let us differentiate Eq. (1) over time:

$$v_k \equiv \frac{dr_k}{dt} = \sum_j \frac{\partial r_k}{\partial q_j} \dot{q}_j + \frac{\partial r_k}{\partial t}.$$  \hfill (2.12)

This equation shows that particle velocities $v_k$ may be considered to be linear functions of the generalized velocities $\dot{q}_j$, considered as independent variables, with proportionality coefficients

$$\frac{\partial v_k}{\partial q_j} = \frac{\partial r_k}{\partial q_j}.$$  \hfill (2.13)

With the account of Eqs. (10), (11), and (13), Eq. (9) turns into

$$\frac{d}{dt} \sum_k m_k \mathbf{v}_k \cdot \mathbf{v}_k - \sum_k m_k \mathbf{v}_k \cdot \frac{\partial \mathbf{v}_k}{\partial q_j} - F_j = 0.$$  \hfill (2.14)

This result may be further simplified by making, for the total kinetic energy of the system,

$$T \equiv \sum_k \frac{m_k}{2} v_k^2 = \frac{1}{2} \sum_k m_k \mathbf{v}_k \cdot \mathbf{v}_k,$$  \hfill (2.15)

the same commitment as for $v_k$, i.e. considering $T$ a function of not only the generalized coordinates $q_j$ and time $t$ but also of the generalized velocities $\dot{q}_j$ – as variables independent of $q_j$ and $t$. Then we may calculate the partial derivatives of $T$ as

$$\frac{\partial T}{\partial q_j} = \sum_k m_k \mathbf{v}_k \cdot \frac{\partial \mathbf{v}_k}{\partial q_j}, \quad \frac{\partial T}{\partial \dot{q}_j} = \sum_k m_k \mathbf{v}_k \cdot \frac{\partial \mathbf{v}_k}{\partial \dot{q}_j},$$  \hfill (2.16)

and notice that they are exactly the two sums participating in Eq. (14). As a result, we get a system of $J$ Lagrange equations,$^7$

$$\frac{d}{dt} \frac{\partial T}{\partial \dot{q}_j} - \frac{\partial T}{\partial q_j} - F_j = 0, \quad \text{for } j = 1, 2, \ldots, J.$$  \hfill (2.17)

Their big advantage over the initial Newton law equations (4) is that the Lagrange equations do not include the constraining forces $N_k$, and thus there are only $J$ of them – typically much fewer than $3N$.

$^7$ They were derived in 1788 by Joseph-Louis Lagrange, who pioneered the whole field of analytical mechanics – not to mention his key contributions to the number theory and celestial mechanics.
This is as far as we can go for arbitrary forces. However, if all the forces may be expressed in the form similar to, but somewhat more general than Eq. (1.22), \( \mathbf{F}_k = -\nabla_k U(\mathbf{r}_1, \mathbf{r}_2, \ldots, \mathbf{r}_N, t) \), where \( U \) is the effective potential energy of the system\(^{8} \) and \( \nabla_k \) denotes the spatial differentiation over coordinates of the \( k^{\text{th}} \) particle, we may recast Eq. (8) into a simpler form:

\[
\mathcal{F}_j \equiv \sum_k \mathbf{F}_k \cdot \frac{\partial \mathbf{r}_k}{\partial q_j} = -\sum_k \left( \frac{\partial U}{\partial x_k} \frac{\partial x_k}{\partial q_j} + \frac{\partial U}{\partial y_k} \frac{\partial y_k}{\partial q_j} + \frac{\partial U}{\partial z_k} \frac{\partial z_k}{\partial q_j} \right) \equiv -\frac{\partial U}{\partial q_j}. \tag{2.18}
\]

Since we assume that \( U \) depends only on particle coordinates (and possibly time), but not velocities: \( \frac{\partial U}{\partial \dot{q}_j} = 0 \), with the substitution of Eq. (18), the Lagrange equation (17) may be represented in the so-called canonical form:

\[
\frac{d}{dt} \frac{\partial L}{\partial \dot{q}_j} - \frac{\partial L}{\partial q_j} = 0, \tag{2.19a}
\]

where \( L \) is the Lagrangian function (sometimes called just the “Lagrangian”), defined as

\[
L \equiv T - U. \tag{2.19b}
\]

(It is crucial to distinguish this function from the mechanical energy (1.26), \( E = T + U \).

Note also that according to Eq. (2.18), for a system under the effect of an additional generalized external force \( \mathcal{F}(t) \) we have to use, in all these relations, not the internal potential energy \( U^{(\text{int})} \) of the system, but its Gibbs potential energy \( U \equiv U^{(\text{int})} - \mathcal{F}\dot{q}_j \) – see the discussion in Sec. 1.4.

Using the Lagrangian approach in practice, the reader should always remember that, first, each system has only one Lagrange function (19b), but is described by \( J \geq 1 \) Lagrange equations (19a), with \( j \) taking values 1, 2, \ldots, \( J \), and second, that differentiating the function \( L \), we have to consider the generalized velocities as its independent arguments, ignoring the fact they are actually the time derivatives of the generalized coordinates.

### 2.2. Three simple examples

As the first, simplest example, consider a particle constrained to move along one axis (say, \( x \)):

\[
T = \frac{m}{2} \dot{x}^2, \quad U = U(x, t). \tag{2.20}
\]

In this case, it is natural to consider \( x \) as the (only) generalized coordinate, and \( \dot{x} \) as the generalized velocity, so that

\[
L \equiv T - U = \frac{m}{2} \dot{x}^2 - U(x, t). \tag{2.21}
\]

Considering \( \dot{x} \) as an independent variable, we get \( \partial L / \partial \dot{x} = m \dot{x} \), and \( \partial L / \partial x = -\partial U / \partial x \), so that Eq. (19) (the only Lagrange equation in this case of the single degree of freedom!) yields

\[^{8}\text{Note that due to the possible time dependence of } U, \text{ Eq. (17) does not mean that the forces } \mathbf{F}_k \text{ have to be conservative – see the next section for more discussion. With this understanding, I will still use for function } U \text{ the convenient name of "potential energy".} \]
\[
\frac{d}{dt}(m\ddot{x}) - \left( -\frac{\partial U}{\partial x} \right) = 0,
\]

(2.22)
evidently the same result as the \(x\)-component of the 2nd Newton law with \(F_x = -\frac{\partial U}{\partial x}\). This example is a good sanity check, but it also shows that the Lagrange formalism does not provide too much advantage in this particular case.

Such an advantage is, however, evident for our testbed problem – see Fig. 1. Indeed, taking the polar angle \(\theta\) for the (only) generalized coordinate, we see that in this case, the kinetic energy depends not only on the generalized velocity but also on the generalized coordinate:

\[
T = \frac{m}{2} R^2 (\dot{\theta}^2 + \omega^2 \sin^2 \theta), \quad U = -mgz + \text{const} \equiv -mgR \cos \theta + \text{const},
\]

(2.23)
\[
L \equiv T - U = \frac{m}{2} R^2 (\dot{\theta}^2 + \omega^2 \sin^2 \theta) + mgR \cos \theta + \text{const}.
\]

Here it is especially important to remember that at substantiating the Lagrange equation, \(\theta\) and \(\dot{\theta}\) have to be treated as independent arguments of \(L\), so that

\[
\frac{\partial L}{\partial \theta} = mR^2 \dot{\theta}, \quad \frac{\partial L}{\partial \dot{\theta}} = mR^2 \omega \sin \theta \cos \theta - mgR \sin \theta,
\]

(2.24)
giving us the following equation of motion:

\[
\frac{d}{dt}(mR^2 \ddot{\theta}) - (mR^2 \omega^2 \sin \theta \cos \theta - mgR \sin \theta) = 0.
\]

(2.25)
As a sanity check, at \(\omega = 0\), Eq. (25) is reduced to the equation (1.18) of the usual pendulum:

\[
\ddot{\theta} + \Omega^2 \sin \theta = 0, \quad \text{where } \Omega \equiv \left( \frac{g}{R} \right)^{1/2}.
\]

(2.26)
We will explore the full dynamic equation (25) in more detail later, but please note how simple its derivation was – in comparison with writing the 3D Newton law and then excluding the reaction force.

Next, though the Lagrangian formalism was derived from the Newton law for mechanical systems, the resulting equations (19) are applicable to other dynamic systems, especially those for which the kinetic and potential energies may be readily expressed via some generalized coordinates. As the simplest example, consider the well-known connection (Fig. 4) of a capacitor with capacitance \(C\) to an inductive coil with self-inductance \(L\)\(^{\text{10}}\) (Electrical engineers frequently call it the \textit{LC tank circuit}.)

\[\text{Fig. 2.4. \textit{LC tank circuit.}}\]

---

\(^9\) The above expression for \(T \equiv (m/2)(\dot{x}^2 + \dot{y}^2 + \dot{z}^2)\) may be readily obtained either by the formal differentiation of Eq. (2) over time, or just by noticing that the velocity vector has two perpendicular components: one (of magnitude \(R\dot{\theta}\)) along the ring, and another one (of magnitude \(\omega \rho = \omega R \sin \theta\)) normal to the ring’s plane.

\(^{10}\) A fancy font is used here to avoid any chance of confusion between the inductance and the Lagrange function.
As the reader (hopefully :-) knows, at relatively low frequencies we may use the so-called lumped-circuit approximation, in which the total energy of the system is the sum of two components, the electric energy $E_e$ localized inside the capacitor, and the magnetic energy $E_m$ localized inside the inductance coil:

$$E_e = \frac{Q^2}{2C}, \quad E_m = \frac{L I^2}{2}. \quad (2.27)$$

Since the electric current $I$ through the coil and the electric charge $Q$ on the capacitor are connected by the charge continuity equation $dQ/dt = I$ (evident from Fig. 4), it is natural to declare the charge the generalized coordinate of the system, and the current, its generalized velocity. With this choice, the electrostatic energy $E_e(Q)$ may be treated as the potential energy $U$ of the system, and the magnetic energy $E_m(I)$, as its kinetic energy $T$. With this attribution, we get

$$\frac{\partial T}{\partial \dot{q}} = \frac{\partial E_m}{\partial I} \equiv L \dot{I} \equiv L \dot{Q}, \quad \frac{\partial T}{\partial q} = \frac{\partial E_m}{\partial Q} = 0, \quad \frac{\partial U}{\partial q} = \frac{\partial E_e}{\partial Q} \equiv \frac{Q}{C}, \quad \frac{\partial U}{\partial \dot{q}} = \frac{\partial E_e}{\partial \dot{Q}} = 0, \quad (2.28)$$

so that the Lagrange equation (19) becomes

$$\frac{d}{dt} \left( \frac{\partial T}{\partial \dot{q}} - \frac{\partial U}{\partial q} \right) = 0. \quad (2.29)$$

Note, however, that the above choice of the generalized coordinate and velocity is not unique. Instead, one can use, as the generalized coordinate, the magnetic flux $\Phi$ through the inductive coil, related to the common voltage $V$ across the circuit (Fig. 4) by Faraday’s induction law $V = -d\Phi/dt$. With this choice, $(-V)$ becomes the generalized velocity, $E_m = \Phi^2/2L$ should be understood as the potential energy, and $E_e = CV^2/2$ treated as the kinetic energy. For this choice, the resulting Lagrange equation of motion is equivalent to Eq. (29). If both parameters of the circuit, $L$ and $C$, are constant in time, Eq. (29) is just the harmonic oscillator equation and describes sinusoidal oscillations with the frequency

$$\omega_0 = \frac{1}{(2\sqrt{L}C)^{1/2}}. \quad (2.30)$$

This is of course a well-known result, which may be derived in a more standard way – by equating the voltage drops across the capacitor ($V = Q/C$) and the inductor ($V = -LdI/dt = -Ld^2Q/dt^2$). However, the Lagrangian approach is much more convenient for more complex systems – for example, for the general description of the electromagnetic field and its interaction with charged particles.\(^\text{11}\)

2.3. Hamiltonian function and energy

The canonical form (19) of the Lagrange equation has been derived using Eq. (18), which is formally similar to Eq. (1.22) for a potential force. Does this mean that the system described by Eq. (19) always conserves energy? Not necessarily, because the “potential energy” $U$ that participates in Eq. (18), may depend not only on the generalized coordinates but on time as well. Let us start the analysis of this issue with the introduction of two new (and very important!) notions: the generalized momentum corresponding to each generalized coordinate $q_j$.

\(^{11}\) See, e.g., EM Secs. 9.7 and 9.8.
and the Hamiltonian function\(^{12}\)

\[
H = \sum_j \frac{\partial L}{\partial \dot{q}_j} \dot{q}_j - L = \sum_j p_j \dot{q}_j - L. \tag{2.32}
\]

To see whether the Hamiltonian function is conserved during the motion, let us differentiate both sides of its definition (32) over time:

\[
\frac{dH}{dt} = \sum_j \left[ \frac{d}{dt} \left( \frac{\partial L}{\partial \dot{q}_j} \right) \dot{q}_j + \frac{\partial L}{\partial \ddot{q}_j} \ddot{q}_j \right] - \frac{dL}{dt}. \tag{2.33}
\]

If we want to make use of the Lagrange equation (19), the last derivative has to be calculated considering \(L\) as a function of independent arguments \(q_j, \dot{q}_j, \text{and } t\), so that

\[
\frac{dL}{dt} = \sum_j \left( \frac{\partial L}{\partial q_j} \dot{q}_j + \frac{\partial L}{\partial \dot{q}_j} \ddot{q}_j + \frac{\partial L}{\partial t} \right), \tag{2.34}
\]

where the last term is the derivative of \(L\) as an explicit function of time. We see that the last term in the square brackets of Eq. (33) immediately cancels with the last term in the parentheses of Eq. (34). Moreover, using the Lagrange equation (19a) for the first term in the square brackets of Eq. (33), we see that it cancels with the first term in the parentheses of Eq. (34). As a result, we arrive at a very simple and important result:

\[
\frac{dH}{dt} = -\frac{\partial L}{\partial t}. \tag{2.35}
\]

The most important corollary of this formula is that if the Lagrangian function does not depend on time explicitly (\(\frac{\partial L}{\partial t} = 0\)), the Hamiltonian function is an integral of motion:

\[
H = \text{const.} \tag{2.36}
\]

Let us see how this works, using the first two examples discussed in the previous section. For a 1D particle, the definition (31) of the generalized momentum yields

\[
p_x = \frac{\partial L}{\partial \dot{x}} = m\dot{x}, \tag{2.37}
\]

so that it coincides with the usual linear momentum – or rather with its \(x\)-component. According to Eq. (32), the Hamiltonian function for this case (with just one degree of freedom) is

\[
H \equiv p_x \dot{x} - L = p_x \frac{p_x}{m} - \left( \frac{m}{2} \dot{x}^2 - U \right) = \frac{p_x^2}{2m} + U, \tag{2.38}
\]

\(^{12}\) It is named after Sir William Rowan Hamilton, who developed his approach to analytical mechanics in 1833, on the basis of the Lagrangian mechanics. This function is sometimes called just the “Hamiltonian”, but it is advisable to use the full term “Hamiltonian function” in classical mechanics, to distinguish it from the Hamiltonian operator used in quantum mechanics. (Their relation will be discussed in Sec. 10.1 below.)
i.e. coincides with particle’s mechanical energy $E = T + U$. Since the Lagrangian does not depend on time explicitly, both $H$ and $E$ are conserved.

However, it is not always that simple! Indeed, let us return again to our testbed problem (Fig. 1). In this case, the generalized momentum corresponding to the generalized coordinate $\theta$ is

$$p_\theta = \frac{\partial L}{\partial \dot{\theta}} = mR^2 \dot{\theta} ,$$

and Eq. (32) yields:

$$H \equiv p_\theta \dot{\theta} - L = mR^2 \dot{\theta}^2 - \left[ \frac{m}{2} R^2 (\dot{\theta}^2 + \omega^2 \sin^2 \theta) + mgR \cos \theta \right] + \text{const}$$

$$\equiv \frac{m}{2} R^2 (\dot{\theta}^2 - \omega^2 \sin^2 \theta) - mgR \cos \theta + \text{const} .$$

This means that (as soon as $\omega \neq 0$), the Hamiltonian function differs from the mechanical energy

$$E \equiv T + U = \frac{m}{2} R^2 (\dot{\theta}^2 + \omega^2 \sin^2 \theta) - mgR \cos \theta + \text{const} .$$

The difference, $E - H = mR^2 \omega^2 \sin^2 \theta$ (besides an inconsequential constant), may change at bead’s motion along the ring, so that although $H$ is an integral of motion (since $\partial L/\partial t = 0$), the energy is not conserved.

In this context, let us find out when these two functions, $E$ and $H$, do coincide. In mathematics, there is a notion of a homogeneous function $f(x_1, x_2, \ldots)$ of degree $\lambda$, defined in the following way: for an arbitrary constant $a$,

$$f(ax_1, ax_2, \ldots) = a^\lambda f(x_1, x_2, \ldots) .$$

Such functions obey the following Euler theorem:\(^{13}\)

$$\sum_j \frac{\partial f}{\partial x_j} x_j = \lambda f ,$$

which may be readily proved by differentiating both parts of Eq. (42) over $a$ and then setting this parameter to the particular value $a = 1$. Now, consider the case when the kinetic energy is a quadratic form of all generalized velocities $\dot{q}_j$:

$$T = \sum_{j,j'} t_{j,j'} (q_1, q_2, \ldots, t) \dot{q}_j \dot{q}_{j'} ,$$

with no other terms. It is evident that such $T$ satisfies the definition of a homogeneous function of the velocities with $\lambda = 2$,\(^{14}\) so that the Euler theorem (43) gives

$$\sum_j \frac{\partial T}{\partial \dot{q}_j} \dot{q}_j = 2T .$$

---

\(^{13}\) This is just one of many theorems bearing the name of their author – the genius mathematician Leonhard Euler (1707-1783).

\(^{14}\) Such functions are called quadratic-homogeneous.
But since $U$ is independent of the generalized velocities, $\partial L/\partial \dot{q}_j = \partial T/\partial \dot{q}_j$, and the left-hand side of Eq. (45) is exactly the first term in the definition (32) of the Hamiltonian function, so that in this case
\[ H = 2T - L = 2T - (T - U) = T + U = E. \] (2.46)

So, for a system with a kinetic energy of the type (44), for example, a free particle with $T$ considered as a function of its Cartesian velocities,
\[ T = \frac{m}{2} \left( v_x^2 + v_y^2 + v_z^2 \right), \] (2.47)
the notions of the Hamiltonian function and the mechanical energy are identical. Indeed, some textbooks, very regrettably, do not distinguish these notions at all! However, as we have seen from our bead-on-the-rotating-ring example, these variables do not always coincide. For that problem, the kinetic energy, in addition to the term proportional to $\dot{\theta}^2$, has another, velocity-independent term – see the first of Eqs. (23) – and hence is not a quadratic-homogeneous function of the angular velocity, giving $E \neq H$.

Thus, Eq. (36) expresses a new conservation law, generally different from that of mechanical energy conservation.

### 2.4. Other conservation laws

Looking at the Lagrange equation (19), we immediately see that if $L \equiv T - U$ is independent of some generalized coordinate $q_j$, $\partial L/\partial \dot{q}_j = 0$,\(^{15}\) then the corresponding generalized momentum is an integral of motion:\(^{16}\)
\[ p_j = \frac{\partial L}{\partial \dot{q}_j} = \text{const.} \] (2.48)

For example, for a 1D particle with the Lagrangian (21), the momentum $p_x$ is conserved if the potential energy is constant (and hence the $x$-component of force is zero) – of course. As a less obvious example, let us consider a 2D motion of a particle in the field of central forces. If we use polar coordinates $r$ and $\varphi$ in the role of generalized coordinates, the Lagrangian function,\(^{17}\)
\[ L \equiv T - U = \frac{m}{2} \left( \dot{r}^2 + r^2 \dot{\varphi}^2 \right) - U(r), \] (2.49)
is independent of $\varphi$ and hence the corresponding generalized momentum,
\[ p_\varphi = \frac{\partial L}{\partial \dot{\varphi}} = mr^2 \dot{\varphi}, \] (2.50)

\(^{15}\)Such coordinates are frequently called cyclic, because in some cases (like in the second example considered below) they represent periodic coordinates such as angles. However, this terminology is misleading, because some “cyclic” coordinates (e.g., $x$ in our first example) have nothing to do with rotation.

\(^{16}\)This fact may be considered a particular case of a more general mathematical statement called the Noether theorem – named after its author, Emmy Nöther, sometimes called the “greatest woman mathematician ever lived”. Unfortunately, because of time/space restrictions, for its discussion I have to refer the interested reader elsewhere – for example to Sec. 13.7 in H. Goldstein et al., Classical Mechanics, 3rd ed. Addison Wesley, 2002.

\(^{17}\)Note that here $\dot{r}^2$ is the square of the scalar derivative $\dot{r}$, rather than the square of the vector $\dot{\mathbf{r}} = \mathbf{v}$. 

---

1. Such coordinates are frequently called cyclic, because in some cases (like in the second example considered below) they represent periodic coordinates such as angles. However, this terminology is misleading, because some “cyclic” coordinates (e.g., $x$ in our first example) have nothing to do with rotation.
2. This fact may be considered a particular case of a more general mathematical statement called the Noether theorem – named after its author, Emmy Nöther, sometimes called the “greatest woman mathematician ever lived”. Unfortunately, because of time/space restrictions, for its discussion I have to refer the interested reader elsewhere – for example to Sec. 13.7 in H. Goldstein et al., Classical Mechanics, 3rd ed. Addison Wesley, 2002.
3. Note that here $\dot{r}^2$ is the square of the scalar derivative $\dot{r}$, rather than the square of the vector $\dot{\mathbf{r}} = \mathbf{v}$. 

is conserved. This is just a particular (2D) case of the angular momentum conservation – see Eq. (1.24). Indeed, for the 2D motion within the \([x, y]\) plane, the angular momentum vector,

\[
\mathbf{L} \equiv \mathbf{r} \times \mathbf{p} = \begin{vmatrix} n_x & n_y & n_z \\ x & y & z \\ m\dot{x} & m\dot{y} & m\dot{z} \end{vmatrix},
\]

has only one component different from zero, namely the component normal to the motion plane:

\[
L_z = x(m\dot{y}) - y(m\dot{x}).
\]

Differentiating the well-known relations between the polar and Cartesian coordinates,

\[
x = r \cos \varphi, \quad y = r \sin \varphi,
\]

over time, and plugging the result into Eq. (52), we see that

\[
L_z = mr^2 \dot{\varphi} \equiv p_{\varphi}.
\]

Thus the Lagrangian formalism provides a powerful way of searching for non-evident integrals of motion. On the other hand, if such a conserved quantity is evident or known \textit{a priori}, it is helpful for the selection of the most appropriate generalized coordinates, giving the simplest Lagrange equations. For example, in the last problem, if we knew in advance that \(p_{\varphi}\) had to be conserved, this could provide a motivation for using the angle \(\varphi\) as one of generalized coordinates.

\textbf{2.5. Exercise problems}

In each of Problems 2.1-2.11, for the given system:

(i) introduce a set of convenient generalized coordinate(s) \(q_j\),

(ii) write down the Lagrangian \(L\) as a function of \(q_j, \dot{q}_j\), and (if appropriate) time,

(iii) write down the Lagrange equation(s) of motion,

(iv) calculate the Hamiltonian function \(H\); find out whether it is conserved,

(v) calculate energy \(E\); is \(E = H\)?; is the energy conserved?

(vi) any other evident integrals of motion?

\textbf{2.1. A double pendulum} – see the figure on the right. Consider only the motion in the vertical plane containing the suspension point.

\textbf{2.2. A stretchable pendulum} (i.e. a mass hung on an elastic cord that exerts force \(F = -\kappa(l - l_0)\), where \(\kappa\) and \(l_0\) are positive constants), also confined to the vertical plane:
2.3. A fixed-length pendulum hanging from a horizontal support whose motion law $x_0(t)$ is fixed. (No vertical plane constraint here.)

2.4. A pendulum of mass $m$, hung on another point mass $m'$, which may slide, without friction, along a straight horizontal rail – see the figure on the right. The motion is confined to the vertical plane that contains the rail.

2.5. A point-mass pendulum of length $l$, attached to the rim of a disk of radius $R$, which is rotated in a vertical plane with a constant angular velocity $\omega$ – see the figure on the right. (Consider only the motion within the disk’s plane.)

2.6. A bead of mass $m$, sliding without friction along a light string stretched by a fixed force $T$ between two horizontally displaced points – see the figure on the right. Here, in contrast to the similar Problem 1.10, the string tension $T$ may be comparable with the bead’s weight $mg$, and the motion is not restricted to the vertical plane.

2.7. A bead of mass $m$, sliding without friction along a light string of a fixed length $2l$, which is hung between two points, horizontally displaced by distance $2d < 2l$ – see the figure on the right. As in the previous problem, the motion is not restricted to the vertical plane.

2.8. A block of mass $m$ that can slide, without friction, along the inclined plane surface of a heavy wedge with mass $m'$. The wedge is free to move, also without friction, along a horizontal surface – see the figure on the right. (Both motions are within the vertical plane containing the steepest slope line.)

2.9. The two-pendula system that was the subject of Problem 1.8 – see the figure on the right.
2.10. A system of two similar, inductively-coupled LC circuits – see the figure on the right.

2.11. A small Josephson junction – the system consisting of two superconductors (S) weakly coupled by Cooper-pair tunneling through a thin insulating layer (I) that separates them – see the figure on the right.

Hints:

(i) At not very high frequencies (whose quantum $\hbar \omega$ is lower than the binding energy $2\Delta$ of the Cooper pairs), the Josephson effect in a sufficiently small junction may be described by the following coupling energy:

$$U(\varphi) = -E_J \cos \varphi + \text{const},$$

where the constant $E_J$ describes the coupling strength, while the variable $\varphi$ (called the Josephson phase difference) is connected to the voltage $V$ across the junction by the famous frequency-to-voltage relation

$$\frac{d\varphi}{dt} = \frac{2e}{\hbar} V,$$

where $e \approx 1.602 \times 10^{-19}$ C is the fundamental electric charge and $\hbar \approx 1.054 \times 10^{-34}$ J·s is the Planck constant.18

(ii) The junction (as any system of two close conductors) has a substantial electric capacitance $C$.

---

18 More discussion of the Josephson effect and the physical sense of the variable $\varphi$ may be found, for example, in EM Sec. 6.5 and QM Secs. 1.6 and 2.8 of this lecture note series, but the given problem may be solved without that additional information.

Chapter 3. A Few Simple Problems

The objective of this chapter is to solve a few simple but very important particle dynamics problems that may be reduced to 1D motion. They notably include the famous "planetary" problem of two particles interacting via a spherically-symmetric potential, and the classical particle scattering problem. In the process of solution, several methods that will be very essential for the analysis of more complex systems are also discussed.

3.1. One-dimensional and 1D-reducible systems

If a particle is confined to motion along a straight line (say, axis $x$), its position is completely determined by this coordinate. In this case, as we already know, particle’s Lagrangian is given by Eq. (2.21):

$$L = T(\dot{x}) - U(x,t), \quad T(\dot{x}) = \frac{m}{2} \dot{x}^2,$$

so that the Lagrange equation of motion, given by Eq. (2.22),

$$m\ddot{x} = -\frac{\partial U(x,t)}{\partial x},$$

is just the $x$-component of the 2nd Newton law.

It is convenient to discuss the dynamics of such really-1D systems as a part of a more general class of effectively-1D systems, whose position, due to holonomic constraints and/or conservation laws, is also fully determined by one generalized coordinate $q$, and whose Lagrangian may be represented in a form similar to Eq. (1):

$$L = T_{ef}(\dot{q}) - U_{ef}(q,t), \quad T_{ef} = \frac{m_{ef}}{2} \dot{q}^2,$$

where $m_{ef}$ is some constant which may be considered as the effective mass of the system, and the function $U_{ef}$ its effective potential energy. In this case, the Lagrange equation (2.19), describing the system’s dynamics, has a form similar to Eq. (2):

$$m_{ef} \ddot{q} = -\frac{\partial U_{ef}(q,t)}{\partial q}.$$

As an example, let us return again to our testbed system shown in Fig. 2.1. We have already seen that for this system, having one degree of freedom, the genuine kinetic energy $T$, expressed by the first of Eqs. (2.23), is not a quadratically-homogeneous function of the generalized velocity. However, the system’s Lagrangian function (2.23) still may be represented in the form (3),

$$L = \frac{m}{2} R^2 \dot{\theta}^2 + \frac{m}{2} R^2 \omega^2 \sin^2 \theta + mgR \cos \theta + \text{const} = T_{ef} - U_{ef},$$

if we take
\[ T_{\text{ef}} \equiv \frac{m}{2} R^2 \dot{\theta}^2, \quad U_{\text{ef}} \equiv -\frac{m}{2} R^2 \omega^2 \sin^2 \theta - mgR \cos \theta + \text{const.} \quad (3.6) \]

In this new partitioning of the function \( L \), which is legitimate because \( U_{\text{ef}} \) depends only on the generalized coordinate \( \theta \), but not on the corresponding generalized velocity, \( T_{\text{ef}} \) includes only a part of the full kinetic energy \( T \) of the bead, while \( U_{\text{ef}} \) includes not only its real potential energy \( U \) in the gravity field but also an additional term related to ring rotation. (As we will see in Sec. 4.6, this term may be interpreted as the effective potential energy due to the inertial centrifugal “force” arising at the problem’s solution in the non-inertial reference frame rotating with the ring.)

Returning to the general case of effectively-1D systems with Lagrangians of the type (3), let us calculate their Hamiltonian function, using its definition (2.32):

\[ H = \frac{\partial L}{\partial \dot{q}} \dot{q} - L = m_{\text{ef}} \dot{q}^2 - (T_{\text{ef}} - U_{\text{ef}}) = T_{\text{ef}} + U_{\text{ef}}. \quad (3.7) \]

So, \( H \) is expressed via \( T_{\text{ef}} \) and \( U_{\text{ef}} \) exactly as the energy \( E \) is expressed via genuine \( T \) and \( U \).

### 3.2. Equilibrium and stability

**Autonomous** systems are defined as dynamic systems whose equations of motion do not depend on time explicitly. For the effectively-1D (and in particular the really-1D) systems obeying Eq. (4), this means that their function \( U_{\text{ef}} \), and hence the Lagrangian function (3) should not depend on time explicitly. According to Eqs. (2.35), in such systems, the Hamiltonian function (7), i.e. the sum \( T_{\text{ef}} + U_{\text{ef}} \), is an integral of motion. However, be careful! Generally, this conclusion is not valid for the mechanical energy \( E \) of such a system; for example, as we already know from Sec. 2.2, for our testbed problem, with the generalized coordinate \( q = \theta \) (Fig. 2.1), \( E \) is not conserved.

According to Eq. (4), an autonomous system, at appropriate initial conditions, may stay in equilibrium at one or several *stationary* (alternatively called *fixed*) points \( q_n \), corresponding to either the minimum or a maximum of the effective potential energy (see Fig. 1):

\[ \frac{dU_{\text{ef}}}{dq}(q_n) = 0. \quad (3.8) \]

Fig. 3.1. The effective potential energy profile near stable \((q_0, q_2)\) and unstable \((q_1)\) fixed points, and its quadratic approximation (10) near point \(q_0\) — schematically.

In order to explore the *stability* of such fixed points, let us analyze the dynamics of small deviations

\[ \tilde{q}(t) \equiv q(t) - q_n \quad (3.9) \]

from the equilibrium. For that, let us expand the function \( U_{\text{ef}}(q) \) in the Taylor series at a fixed point:
\[ U_{\text{ef}}(q) = U_{\text{ef}}(q_0) + \frac{dU_{\text{ef}}(q_n)}{dq}(\ddot{q}) + \frac{1}{2} \frac{d^2U_{\text{ef}}(q_n)}{dq^2}(\ddot{q})^2 + \ldots \] (3.10)

The first term on the right-hand side, \( U_{\text{ef}}(q_0) \), is arbitrary and does not affect motion. The next term, linear in deviation \( \ddot{q} \), equals zero – see the fixed point’s definition (8). Hence the fixed point stability is determined by the next term, quadratic in \( \ddot{q} \), more exactly by its coefficient,

\[ \kappa_{\text{ef}} \equiv \frac{d^2U_{\text{ef}}(q_n)}{dq^2}, \] (3.11)

which plays the role of the effective spring constant. Indeed, neglecting the higher terms of the Taylor expansion (10), we see that Eq. (4) takes the familiar form:

\[ m_{\text{ef}} \ddot{q} + \kappa_{\text{ef}} \ddot{q} = 0. \] (3.12)

I am confident that the reader of these notes knows everything about this equation, but since we will soon run into similar but more complex equations, let us review the formal procedure of its solution. From the mathematical standpoint, Eq. (12) is an ordinary, linear differential equation of the second order, with constant coefficients. The theory of such equations tells us that its general solution (for any initial conditions) may be represented as

\[ \ddot{q}(t) = c_+ e^{\lambda_+ t} + c_- e^{\lambda_- t}, \] (3.13)

where the constants \( c_\pm \) are determined by initial conditions, while the so-called characteristic exponents \( \lambda_\pm \) are completely defined by the equation itself. To calculate these exponents, it is sufficient to plug just one partial solution, \( e^{\lambda t} \), into the equation. In our simple case (12), this yields the following characteristic equation:

\[ m_{\text{ef}} \lambda^2 + \kappa_{\text{ef}} = 0. \] (3.14)

If the ratio \( k_{\text{ef}}/m_{\text{ef}} \) is positive, i.e. the fixed point corresponds to the minimum of potential energy (e.g., see points \( q_0 \) or \( q_2 \) in Fig. 1), the characteristic equation yields

\[ \lambda_\pm = \pm i \omega_0, \quad \text{with} \quad \omega_0 = \left( \frac{\kappa_{\text{ef}}}{m_{\text{ef}}} \right)^{1/2}, \] (3.15)

(where \( i \) is the imaginary unit, \( i^2 = -1 \)), so that Eq. (13) describes sinusoidal oscillations of the system,\(^2\)

\[ \ddot{q}(t) = c_+ e^{i \omega_0 t} + c_- e^{-i \omega_0 t} = c_\cos \omega_0 t + c_\sin \omega_0 t, \] (3.16)

---

1 Those terms may be important only in very special cases then \( \kappa_{\text{ef}} \) is exactly zero, i.e. when a fixed point is an inflection point of the function \( U_{\text{ef}}(q) \).

2 The reader should not be scared of the first form of (16), i.e. of the representation of a real variable (the deviation from equilibrium) via a sum of two complex functions. Indeed, any real initial conditions give \( c_\neq c_\), so that the sum is real for any \( t \). An even simpler way to deal with such complex representations of real functions will be discussed in the beginning of the next chapter, and then used throughout the series.
with the frequency $\omega_0$, about the fixed point – which is thereby stable.\(^3\) On the other hand, at the potential energy maximum ($k_{ef} < 0$, e.g., at point $q_1$ in Fig. 1), we get

$$\lambda_\pm = \pm \lambda, \quad \lambda \equiv \left(\frac{|K_{ef}|}{m_{ef}}\right)^{1/2}, \quad \ddot{q}(t) = c_+ e^{+\lambda t} + c_- e^{-\lambda t}. \quad (3.17)$$

Since the solution has an exponentially growing part,\(^4\) the fixed point is unstable.

Note that the quadratic expansion of function $U_{ef}(q)$, given by the truncation of Eq. (10) to the three displayed terms, is equivalent to a linear Taylor expansion of the effective force:

$$F_{ef} \equiv -\frac{dU_{ef}}{dq} \approx -K_{ef} \dot{q}, \quad (3.18)$$

immediately resulting in the linear equation (12). Hence, to analyze the stability of a fixed point $q_n$, it is sufficient to linearize the equation of motion with respect to small deviations from the point, and study possible solutions of the resulting linear equation. This linearization procedure is typically simpler to carry out than the quadratic expansion (10).

As an example, let us return to our testbed problem (Fig. 2.1) whose function $U_{ef}$ we already know – see the second of Eqs. (6). With it, the equation of motion (4) becomes

$$mR^2 \ddot{\theta} = -\frac{dU_{ef}}{d\theta} = mR^2 \left(\omega^2 \cos \theta - \Omega^2\right) \sin \theta, \quad \text{i.e.} \quad \ddot{\theta} = \left(\omega^2 \cos \theta - \Omega^2\right) \sin \theta, \quad (3.19)$$

where $\Omega \equiv (g/R)^{1/2}$ is the frequency of small oscillations of the system at $\omega = 0$ – see Eq. (2.26).\(^5\) From requirement (8), we see that on any $2\pi$-long segment of the angle $\theta$,\(^6\) the system may have four fixed points; for example, on the half-open segment ($-\pi, +\pi$] these points are

$$\theta_0 = 0, \quad \theta_1 = \pi, \quad \theta_{2,3} = \pm \cos^{-1} \frac{\Omega^2}{\omega^2}. \quad (3.20)$$

The last two fixed points, corresponding to the bead shifted to either side of the rotating ring, exist only if the angular velocity $\omega$ of the rotation exceeds $\Omega$. (In the limit of very fast rotation, $\omega \gg \Omega$, Eq. (20) yields $\theta_{2,3} \to \pm \pi/2$, i.e. the stationary positions approach the horizontal diameter of the ring – in accordance with our physical intuition.)

To analyze the fixed point stability, we may again use Eq. (9), in the form $\theta = \theta_n + \ddot{\theta}$, plug it into Eq. (19), and Taylor-expand the trigonometric functions of $\theta$ up to the first term in $\ddot{\theta}$:

$$\ddot{\theta} = \left[\omega^2 (\cos \theta_n - \sin \theta_n \ddot{\theta}) - \Omega^2\right] (\sin \theta_n + \cos \theta_n \ddot{\theta}). \quad (3.21)$$

---

\(^3\) This particular type of stability, when the deviation from the equilibrium oscillates with a constant amplitude, neither growing nor decreasing in time, is called either the orbital, or “neutral”, or “indifferent” stability.

\(^4\) Mathematically, the growing part vanishes at some special (exact) initial conditions which give $c_n = 0$. However, the futility of this argument for real physical systems should be obvious for anybody who had ever tried to balance a pencil on its sharp point.

\(^5\) Note that Eq. (19) coincides with Eq. (2.25). This is a good sanity check illustrating that the procedure (5)-(6) of moving of a term from the potential to the kinetic energy within the Lagrangian function is indeed legitimate.

\(^6\) For this particular problem, the values of $\theta$ that differ by a multiple of $2\pi$, are physically equivalent.
Generally, this equation may be linearized further by purging its right-hand side of the term proportional to $\tilde{\theta}^2$; however, in this simple case, Eq. (21) is already convenient for analysis. In particular, for the fixed point $\theta_0 = 0$ (corresponding to the bead’s position at the bottom of the ring), we have $\cos \theta_0 = 1$ and $\sin \theta_0 = 0$, so that Eq. (21) is reduced to a linear differential equation

$$\ddot{\theta} = (\omega^2 - \Omega^2) \tilde{\theta}$$

whose characteristic equation is similar to Eq. (14) and yields

$$\lambda^2 = \omega^2 - \Omega^2, \quad \text{for } \theta \approx \theta_0.$$  

(3.23a)

This result shows that if $\omega < \Omega$, when both roots $\lambda$ are imaginary, this fixed point is orbitally stable. However, if the rotation speed is increased so that $\omega > \Omega$, the roots become real, $\lambda_{\pm} = (\omega^2 - \Omega^2)^{1/2}$, with one of them positive, so that the fixed point becomes unstable beyond this threshold, i.e. as soon as fixed points $\theta_{2,3}$ exist. Absolutely similar calculations for other fixed points yield

$$\lambda^2 = \begin{cases} \Omega^2 + \omega^2 > 0, & \text{for } \theta \approx \theta_1, \\ \Omega^2 - \omega^2, & \text{for } \theta \approx \theta_{2,3}. \end{cases}$$

(3.23b)

These results show that the fixed point $\theta_1$ (bead on the top of the ring) is always unstable – just as we could foresee, while the side fixed points $\theta_{2,3}$ are orbitally stable as soon as they exist (at $\omega > \Omega$).

Thus, our fixed-point analysis may be summarized very simply: an increase of the ring rotation speed $\omega$ beyond a certain threshold value, equal to $\Omega$ given by Eq. (2.26), causes the bead to move to one of the ring sides, oscillating about one of the fixed points $\theta_{2,3}$. Together with the rotation about the vertical axis, this motion yields quite a complex (generally, open) spatial trajectory as observed from a lab frame, so it is fascinating that we could analyze it quantitatively in such a simple way.

Later in this course, we will repeatedly use the linearization of the equations of motion for the analysis of stability of more complex systems, including those with energy dissipation.

### 3.3. Hamiltonian 1D systems

Autonomous systems that are described by time-independent Lagrangians are frequently called Hamiltonian ones because their Hamiltonian function $H$ (again, not necessarily equal to the genuine mechanical energy $E$) is conserved. In our current 1D case, described by Eq. (3),

$$H = \frac{m_{ef}}{2} \dot{q}^2 + U_{ef}(q) = \text{const}.$$  

(3.24)

From the mathematical standpoint, this conservation law is just the first integral of motion. Solving Eq. (24) for $\dot{q}$, we get the first-order differential equation,

$$\frac{dq}{dt} = \pm \left( \frac{2}{m_{ef}} \left[H - U_{ef}(q)\right] \right)^{1/2}, \quad \text{i.e. } \pm \left( \frac{m_{ef}}{2} \right)^{1/2} \frac{dq}{\left[H - U_{ef}(q)\right]^{1/2}} = dt,$$

(3.25)

which may be readily integrated:
\[ \pm \left( \frac{m_{\text{eff}}}{2} \right)^{1/2} \frac{q(t)}{q(t_0)} \int_{q(t_0)}^{q'(t)} \left[ H - U_{\text{ef}}(q') \right]^{1/2} = t - t_0. \]  

(3.26)

Since the constant \( H \) (as well as the proper sign before the integral – see below) is fixed by initial conditions, Eq. (26) gives the reciprocal form, \( t = t(q) \), of the desired law of system motion, \( q(t) \). Of course, for any particular problem the integral in Eq. (26) still has to be worked out, either analytically or numerically, but even the latter procedure is typically much easier than the numerical integration of the initial, second-order differential equation of motion, because at the addition of many values (to which any numerical integration is reduced\(^7\)) the rounding errors are effectively averaged out.

Moreover, Eq. (25) also allows a general classification of 1D system motion. Indeed:

(i) If \( H > U_{\text{ef}}(q) \) in the whole range of interest, the effective kinetic energy \( T_{\text{ef}}(3) \) is always positive. Hence the derivative \( dq/dt \) cannot change its sign, so that the effective velocity retains the sign it had initially. This is an unbound motion in one direction (Fig. 2a).

(ii) Now let the particle approach a classical turning point \( A \) where \( H = U_{\text{ef}}(q) \) – see Fig. 2b.\(^8\) According to Eq. (25), at that point the particle velocity vanishes, while its acceleration, according to Eq. (4), is still finite. This corresponds to the particle reflection from this potential wall, with the change of the velocity sign.

---

\(^7\) See, e.g., MA Eqs. (5.2) and (5.3).

\(^8\) This terminology comes from quantum mechanics, which shows that a particle (or rather its wavefunction) actually can, to a certain extent, penetrate into the “classically forbidden range” where \( H < U_{\text{ef}}(q) \).
(iii) If, after the reflection from point $A$, the particle runs into another classical turning point $B$ (Fig. 2c), the reflection process is repeated again and again, so that the particle is bound to a periodic motion between two turning points.

The last case of periodic oscillations presents a large conceptual and practical interest, and the whole next chapter will be devoted to a detailed analysis of this phenomenon and numerous associated effects. Here I will only note that for an autonomous Hamiltonian system described by Eq. (4), Eq. (26) immediately enables the calculation of the oscillation period:

$$T = 2\left(\frac{m_{\text{eff}}}{2}\right)^{1/2} \int_{B}^{A} \frac{dq}{\sqrt{H - U_{\text{eff}}(q)}}^{1/2},$$

(3.27)

where the additional front factor 2 accounts for two time intervals: of the motion from $B$ to $A$ and back – see Fig. 2c. Indeed, according to Eq. (25), in each classically allowed point $q$, the velocity magnitude is the same so that these time intervals are equal to each other.

(Note that the dependence of points $A$ and $B$ on $H$ is not necessarily continuous. For example, for our testbed problem, whose effective potential energy is plotted in Fig. 2d for a particular value of $\omega > \Omega$, a gradual increase of $H$ leads to a sudden jump, at $H = H_1$, of the point $B$ to a new position $B'$, corresponding to a sudden switch from oscillations about one fixed point $\theta_{2,3}$ to oscillations about two adjacent fixed points – before the beginning of a persistent rotation around the ring at $H > H_2$.)

Now let us consider a particular, but very important limit of Eq. (27). As Fig. 2c shows, if $H$ is reduced to approach $U_{\text{min}}$, the periodic oscillations take place at the very bottom of “potential well”, about a stable fixed point $q_0$. Hence, if the potential energy profile is smooth enough, we may limit the Taylor expansion (10) to the displayed quadratic term. Plugging it into Eq. (27), and using the mirror symmetry of this particular problem about the fixed point $q_0$, we get

$$T = 4\left(\frac{m_{\text{eff}}}{2}\right)^{1/2} \int_{0}^{A} \frac{d\bar{q}}{\sqrt{H - (U_{\text{min}} + \kappa_{\text{eff}} \bar{q}^2 / 2)}}^{1/2} = \frac{4}{\omega_0} I, \quad \text{with } I \equiv \int_{0}^{1} \frac{d\xi}{(1 - \xi^2)^{1/2}},$$

(3.28)

where $\xi \equiv \bar{q} / A$, with $A \equiv (2/\kappa_{\text{eff}})^{1/2}(H - U_{\text{min}})^{1/2}$ being the classical turning point, i.e. the oscillation amplitude, and $\omega_0$ the frequency given by Eq. (15). Taking into account that the elementary integral $I$ in that equation equals $\pi/2$, we finally get

$$T = \frac{2\pi}{\omega_0},$$

(3.29)

as it should be for the harmonic oscillations (16). Note that the oscillation period does not depend on the oscillation amplitude $A$, i.e. on the difference $(H - U_{\text{min}})$ – while it is sufficiently small.

### 3.4. Planetary problems

Leaving a more detailed study of oscillations for Chapter 5, let us now discuss the so-called planetary systems\(^10\) whose description, somewhat surprisingly, may be also reduced to an effectively 1D

---

\(^9\) Indeed, introducing a new variable $\zeta$ as $\xi \equiv \sin \zeta$, we get $d\xi = \cos \zeta d\zeta = (1 - \zeta^2)^{1/2} d\zeta$, so that the function under the integral is just $d\zeta$, and its limits are $\zeta = 0$ and $\zeta = \pi/2$. 

\(^{10}\) Indeed, introducing a new variable $\zeta$ as $\xi \equiv \sin \zeta$, we get $d\xi = \cos \zeta d\zeta = (1 - \zeta^2)^{1/2} d\zeta$, so that the function under the integral is just $d\zeta$, and its limits are $\zeta = 0$ and $\zeta = \pi/2$. 

problem. Consider two particles that interact via a conservative, central force \( F_{21} = -F_{12} = n \cdot F(r) \), where \( r \) and \( n \) are, respectively, the magnitude and direction of the distance vector \( \mathbf{r} = \mathbf{r}_1 - \mathbf{r}_2 \) connecting the two particles (Fig. 3).

![Fig. 3.3. Vectors in the “planetary” problem.]

Generally, two particles moving without constraints in 3D space, have \( 3 + 3 = 6 \) degrees of freedom, which may be described, e.g., by their Cartesian coordinates \( \{x_1, y_1, z_1, x_2, y_2, z_2\} \) However, for this particular form of interaction, the following series of tricks allows the number of essential degrees of freedom to be reduced to just one.

First, the central, conservative force of particle interaction may be described by a time-independent potential energy \( U(r) \), such that \( F(r) = -\frac{\partial U(r)}{\partial r} \). Hence the Lagrangian of the system is

\[
L \equiv T - U(r) = \frac{m_1}{2} \dot{\mathbf{r}}_1^2 + \frac{m_2}{2} \dot{\mathbf{r}}_2^2 - U(r).
\] (3.30)

Let us perform the transfer from the initial six scalar coordinates of the particles to the following six generalized coordinates: three Cartesian components of the distance vector

\[
\mathbf{r} = \mathbf{r}_1 - \mathbf{r}_2,
\] (3.31)

and three scalar components of the following vector:

\[
\mathbf{R} \equiv \frac{m_1 \mathbf{r}_1 + m_2 \mathbf{r}_2}{M} \quad \text{with} \quad M \equiv m_1 + m_2,
\] (3.32)

which defines the position of the center of mass of the system, with the total mass \( M \). Solving the system of two linear equations (31) and (32) for \( \mathbf{r}_1 \) and \( \mathbf{r}_2 \), we get

\[
\mathbf{r}_1 = \mathbf{R} + \frac{m_2}{M} \mathbf{r}, \quad \mathbf{r}_2 = \mathbf{R} - \frac{m_1}{M} \mathbf{r}.
\] (3.33)

Plugging these relations into Eq. (30), we see that it is reduced it to

\[
L = \frac{M}{2} \dot{\mathbf{R}}^2 + \frac{m}{2} \mathbf{r}^2 - U(r),
\] (3.34)

where \( m \) is the so-called reduced mass:

---

10 This name is very conditional, because this group of problems includes, for example, charged particle scattering (see Sec. 3.7 below).

11 See, e.g., MA Eq. (10.8) with \( \partial/\partial \theta = \partial/\partial \varphi = 0 \).
Note that according to Eq. (35), the reduced mass is lower than that of the lightest component of the two-body system. If one of \( m_{1,2} \) is much less than its counterpart (like it is in most star-planet or planet-satellite systems), then with a good precision \( m \approx \min [m_1, m_2] \).

Since the Lagrangian function (34) depends only on \( \dot{\mathbf{R}} \) rather than \( \mathbf{R} \) itself, according to our discussion in Sec. 2.4, all Cartesian components of \( \mathbf{R} \) are cyclic coordinates, and the corresponding generalized momenta are conserved:

\[
P_j \equiv \frac{\partial L}{\partial \dot{R}_j} \equiv M \dot{R}_j = \text{const}, \quad j = 1, 2, 3. \tag{3.36}
\]

Physically, this is just the conservation law for the full momentum \( \mathbf{P} \equiv M \dot{\mathbf{R}} \) of our system, due to the absence of external forces. Actually, in the axiomatics used in Sec. 1.3 this law is postulated – see Eq. (1.10) – but now we may attribute the momentum \( \mathbf{P} \) to a certain geometric point, with the center-of-mass radius vector \( \mathbf{R} \). In particular, since according to Eq. (36) the center moves with a constant velocity in the inertial reference frame used to write Eq. (30), we may consider a new inertial frame with the origin at point \( \mathbf{R} \). In this new frame, \( \mathbf{R} = 0 \), so that the vector \( \mathbf{r} \) (and hence the scalar \( r \)) remain the same as in the old frame (because the frame transfer vector adds equally to \( \mathbf{r}_1 \) and \( \mathbf{r}_2 \), and cancels in \( \mathbf{r} = \mathbf{r}_1 - \mathbf{r}_2 \)), and the Lagrangian (34) is now reduced to

\[
L = \frac{m}{2} \dot{r}^2 - U(r). \tag{3.37}
\]

Thus our initial problem has been reduced to just three degrees of freedom – three scalar components of the vector \( \mathbf{r} \). Moreover, Eq. (37) shows that dynamics of the vector \( \mathbf{r} \) of our initial, two-particle system is identical to that of the radius vector of a single particle with the effective mass \( m \), moving in the central potential field \( U(r) \).

Two more degrees of freedom may be excluded from the planetary problem by noticing that according to Eq. (1.35), the angular momentum \( \mathbf{L} = \mathbf{r} \times \mathbf{p} \) of our effective single particle of mass \( m \) is also conserved, both in magnitude and direction. Since the direction of \( \mathbf{L} \) is, by its definition, perpendicular to both of \( \mathbf{r} \) and \( \mathbf{v} = \mathbf{p}/m \), this means that the particle’s motion is confined to the plane whose orientation is determined by the initial directions of the vectors \( \mathbf{r} \) and \( \mathbf{v} \). Hence we can completely describe particle’s position by just two coordinates in that plane, for example by the distance \( r \) to the origin, and the polar angle \( \varphi \). In these coordinates, Eq. (37) takes the form identical to Eq. (2.49):

\[
L = \frac{m}{2} \left( \dot{r}^2 + r^2 \dot{\varphi}^2 \right) - U(r). \tag{3.38}
\]

Moreover, the latter coordinate, polar angle \( \varphi \), may be also eliminated by using the conservation of angular momentum’s magnitude, in the form of Eq. (2.50):\[12\]

\[
L_z = mr^2 \dot{\varphi} = \text{const.} \tag{3.39}
\]

\[12\] Here index \( z \) stands for the coordinate perpendicular to the motion plane. Since other components of the angular momentum equal zero, the index is not really necessary, but I will still use it – just to make a clear distinction between the angular momentum \( L_z \) and the Lagrangian function \( L \).
A direct corollary of this conservation is the so-called 2nd Kepler law: the radius vector \( r \) sweeps equal areas \( A \) in equal times. Indeed, in the linear approximation in \( dA \ll A \), the area differential \( dA \) is equal to the area of a narrow right triangle with the base being the arc differential \( rd\phi \), and the height equal to \( r \) – see Fig. 4. As a result, according to Eq. (39), the time derivative of the area,

\[
\frac{dA}{dt} = \frac{r(rd\phi)/2}{dt} \equiv \frac{1}{2} r^2 \frac{d\phi}{dt} = \frac{L_z}{2m},
\]

remains constant. Since the factor \( L_z/2m \) is constant, integration of this equation over an arbitrary (not necessarily small!) time interval \( \Delta t \) proves the 2nd Kepler law: \( A \propto \Delta t \).

Now note that since \( \partial L/\partial \dot{t} = 0 \), the Hamiltonian function \( H \) is also conserved, and since, according to Eq. (38), the kinetic energy of the system is a quadratic-homogeneous function of the generalized velocities \( \dot{r} \) and \( \dot{\phi} \), we have \( H = E \), so that the system’s energy \( E \),

\[
E = \frac{m}{2} \dot{r}^2 + \frac{m}{2} r^2 \dot{\phi}^2 + U(r),
\]

is also a first integral of motion. But according to Eq. (39), the second term on the right-hand side of Eq. (41) may be represented as

\[
\frac{m}{2} r^2 \dot{\phi}^2 = \frac{L_z^2}{2mr^2},
\]

so that the energy (41) may be expressed as that of a 1D particle moving along axis \( r \),

\[
E = \frac{m}{2} \dot{r}^2 + U_{\text{ef}}(r),
\]

in the following effective potential:

\[
U_{\text{ef}}(r) \equiv U(r) + \frac{L_z^2}{2mr^2}.
\]

(The physical sense of the second term is similar to that of the first term in the \( U_{\text{ef}} \) spelled out in Eq. (6), and will be discussed again in Sec. 4.6 below.) So the planetary motion problem has been reduced to the dynamics of an effectively-1D system.

---

13 This is one of the three laws deduced, from the extremely detailed astronomical data collected by Tycho Brahe (1546-1601), by Johannes Kepler in the early 17th century. In turn, the three Kepler laws have become the main basis for Newton’s discovery, a few decades later, of the gravity law (1.15). That relentless march of physics…

14 One may argue that this fact should have been evident from the very beginning because the effective particle of mass \( m \) moves in a potential field \( U(r) \), which conserves energy.
Now we may proceed just like we did in Sec. 3, with due respect to the very specific effective potential (44) which, in particular, diverges at $r \to 0$ – besides the very special case of an exactly radial motion, $L_z = 0$. In particular, we may solve Eq. (43) for $dr/dt$ to get

$$\frac{dt}{dr} = \left(\frac{m}{2}\right)^{1/2} \frac{dr}{[E - U_{\text{ef}}(r)]^{1/2}}. \quad (3.45)$$

This equation allows us not only to get a direct relationship between time $t$ and distance $r$, similar to Eq. (26),

$$t = \pm \left(\frac{m}{2}\right)^{1/2} \int \frac{dr}{[E - U_{\text{ef}}(r)]^{1/2}} = \pm \left(\frac{m}{2}\right)^{1/2} \int \frac{dr}{[E - U(r) - L_z^2 / 2mr^2]^{1/2}}, \quad (3.46)$$

but also do a similar calculation of the angle $\varphi$. Indeed, integrating Eq. (39),

$$\varphi \equiv \int \dot{\varphi} \, dt = \frac{L_z}{m} \int \frac{dt}{r^2}, \quad (3.47)$$

and plugging $dt$ from Eq. (45), we get an explicit expression for the particle trajectory $\varphi(r)$:

$$\varphi = \pm \frac{L_z}{(2m)^{1/2}} \int \frac{dr}{r^2[E - U_{\text{ef}}(r)]^{1/2}} = \pm \frac{L_z}{(2m)^{1/2}} \int \frac{dr}{r^2[E - U(r) - L_z^2 / 2mr^2]^{1/2}}. \quad (3.48)$$

Note that according to Eq. (39), the derivative $d\varphi/dt$ does not change sign at the reflection from any classical turning point $r \neq 0$, so that, in contrast to Eq. (46), the sign on the right-hand side of Eq. (48) is uniquely determined by the initial conditions and cannot change during the motion.

Let us use these results, valid for any interaction law $U(r)$, for the planetary motion’s classification. (Following a good tradition, in what follows I will select the arbitrary constant in the potential energy in the way to provide $U \to 0$, and hence $U_{\text{ef}} \to 0$ at $r \to \infty$.) The following cases should be distinguished.

If $U(r) < 0$, i.e. the particle interaction is attractive (as it always is in the case of gravity), and the divergence of the attractive potential at $r \to 0$ is faster than $1/r^2$, then $U_{\text{ef}}(r) \to -\infty$ at $r \to 0$, so that at appropriate initial conditions the particle may drop on the center even if $L_z \neq 0$ – the event called the capture. On the other hand, with $U(r)$ either converging or diverging slower than $1/r^2$, at $r \to 0$, the effective energy profile $U_{\text{ef}}(r)$ has the shape shown schematically in Fig. 5. This is true, in particular, for the very important case

$$U(r) = -\frac{\alpha}{r}, \quad \text{with} \quad \alpha > 0, \quad (3.49)$$

which describes, in particular, the Coulomb (electrostatic) interaction of two particles with electric charges of opposite signs, and the Newton gravity law (1.15). This particular case will be analyzed below, but now let us return to the analysis of an arbitrary attractive potential $U(r) < 0$ leading to the

---

Note that this reduction has been done in a way different from that used for our testbed problem (shown in Fig. 2.1) in Sec. 2 above. (The reader is encouraged to analyze this difference.) To emphasize this fact, I will keep writing $E$ instead of $H$ here, though for the planetary problem we are discussing now, these two notions coincide.
effective potential shown in Fig. 5, when the angular-momentum term in Eq. (44) dominates at small distances $r$.

![Effective potential profile](image)

Fig. 3.5. Effective potential profile of an attractive central field, and two types of motion in it.

According to the analysis in Sec. 3, such potential profile, with a minimum at some distance $r_0$, may sustain two types of motion, depending on the energy $E$ (which is determined by initial conditions):

(i) If $E > 0$, there is only one classical turning point where $E = U_{ef}$, so that the distance $r$ either grows with time from the very beginning or (if the initial value of $\dot{r}$ was negative) first decreases and then, after the reflection from the increasing potential $U_{ef}$, starts to grow indefinitely. The latter case, of course, describes the scattering of the effective particle by the attractive center.16

(ii) On the opposite, if the energy is within the range

\[ U_{ef}(r_0) \leq E < 0, \tag{3.50} \]

the system moves periodically between two classical turning points $r_{min}$ and $r_{max}$ – see Fig. 5. These oscillations of the distance $r$ correspond to the bound orbital motion of our effective particle about the attracting center.

Let us start with the discussion of the bound motion, with the energy within the range (50). If the energy has its minimal possible value,

\[ E = U_{ef}(r_0) = \min[U_{ef}(r)], \tag{3.51} \]

the distance cannot change, $r = r_0 = \text{const}$, so that the orbit is circular, with the radius $r_0$ satisfying the condition $dU_{ef}/dr = 0$. Using Eq. (44), we see that the condition for $r_0$ may be written as

\[ \frac{L_z^2}{mr_0^3} = \left. \frac{dU}{dr} \right|_{r=r_0}. \tag{3.52} \]

Since at circular motion, the velocity $\mathbf{v}$ is perpendicular to the radius vector $\mathbf{r}$, $L_z$ is just $mr_0v$, the left-hand side of Eq. (52) equals $mv^2/r_0$, while its right-hand side is just the magnitude of the attractive force, so that this equality expresses the well-known 2nd Newton law for the circular motion. Plugging this result into Eq. (47), we get a linear law of angle change, $\varphi = \omega t + \text{const}$, with the angular velocity

\[ \omega = \frac{L_z}{mr_0^2} = \frac{v}{r_0}, \tag{3.53} \]

16 In the opposite case when the interaction is repulsive, $U(r) > 0$, the addition of the positive angular energy term only increases the trend, and the scattering scenario is the only one possible.
and hence the rotation period \( T_{\phi} \equiv 2\pi/\omega \) obeys the elementary relation

\[
T_{\phi} = \frac{2\pi r_0}{v}.
\]  \hspace{1cm} (3.54)

Now let the energy be above its minimum value (but still negative). Using Eq. (46) just as in Sec. 3, we see that the distance \( r \) now oscillates with the period

\[
T_r = \left(\frac{2m}{12}\right)^{1/2} \int_{r_{\text{min}}}^{r_{\text{max}}} \frac{dr}{r^2 \left[E - U(r) - \frac{L_z^2}{2mr^2}\right]^{1/2}}.
\]  \hspace{1cm} (3.55)

This period is not necessarily equal to another period, \( T_{\phi} \), that corresponds to the \( 2\pi \)-change of the angle. Indeed, according to Eq. (48), the change of the angle \( \phi \) between two sequential points of the nearest approach,

\[
|\Delta \phi| = 2 \frac{L_z}{(2m)^{1/2}} \int_{r_{\text{min}}}^{r_{\text{max}}} \frac{dr}{r \left[E - U(r) - \frac{L_z^2}{2mr^2}\right]^{1/2}},
\]  \hspace{1cm} (3.56)

is generally different from \( 2\pi \). Hence, the general trajectory of the bound motion has a spiral shape – see, e.g., an illustration in Fig. 6.

The situation is special, however, for a very important particular case, namely that of the Coulomb potential described by Eq. (49). Indeed, plugging this potential into Eq. (48), we get

\[
\varphi = \pm \frac{L_z}{(2m)^{1/2}} \int \frac{dr}{r^2 \left[E + \alpha/r - \frac{L_z^2}{2mr^2}\right]^{1/2}}.
\]  \hspace{1cm} (3.57)

This is a table integral,\(^{17}\) giving

\[
\varphi = \pm \cos^{-1} \left\{ \frac{L_z^2 / m\alpha r - 1}{1 + 2EL_z^2 / m^2 \alpha^2} \right\}^{1/2} + \text{const.}
\]  \hspace{1cm} (3.58)

\(^{17}\) See, e.g., MA Eq. (6.3a).
The reciprocal function, \( r(\varphi) \), is \( 2\pi \)-periodic:

\[
\frac{p}{1 + e \cos(\varphi + \text{const})},
\]

so that at \( E < 0 \), the orbit is a closed line,\(^{18}\) characterized by the following parameters:\(^ {19}\)

\[
p \equiv \frac{L_z}{m \alpha}, \quad e \equiv \left(1 + \frac{2E L_z^2}{m \alpha^2}\right)^{1/2}.
\]

The physical meaning of these parameters is very simple. Indeed, the general Eq. (52), in the Coulomb potential for which \( dU/dr = \alpha/r^2 \), shows that \( p \) is just the circular orbit radius\(^ {20}\) for the given \( L_z \): \( r_0 = L_z^2/(2m\alpha) \equiv p \), so that

\[
\min[U_{\text{eff}}(r)] \equiv U_{\text{eff}}(r_0) = -\frac{\alpha^2 m}{2L_z^2}.
\]

Using this equality together with the second of Eqs. (60), we see that the parameter \( e \) (called the eccentricity) may be represented just as

\[
e = \left[1 - \frac{E}{\min[U_{\text{eff}}(r)]}\right]^{1/2}.
\]

Analytical geometry tells us that Eq. (59), with \( e < 1 \), is one of the canonical representations of an ellipse, with one of its two focuses located at the origin. The fact that planets have such trajectories is known as the 1\(^{st}\) Kepler law. Figure 7 shows the relations between the dimensions of the ellipse and the parameters \( p \) and \( e \).\(^ {21}\)

In particular, the major semi-axis \( a \) and the minor semi-axis \( b \) are simply related to \( p \) and \( e \) and hence, via Eqs. (60), to the motion integrals \( E \) and \( L_z \):

\(^{18}\) It may be proved that for the power-law interaction, \( U \propto r^\nu \), the orbits are closed curves only if \( \nu = -1 \) (our current case of the Coulomb potential) or if \( \nu = +2 \) (the 3D harmonic oscillator) – the so-called Bertrand theorem.

\(^{19}\) Let me hope that the difference between the parameter \( p \) and the particle momentum’s magnitude is absolutely clear from the context, so that using the same (traditional) notation for both notions cannot lead to confusion.

\(^{20}\) Mathematicians prefer a more solemn terminology: the parameter \( 2p \) is called the latus rectum of the ellipse.

\(^{21}\) In this figure, the constant participating in Eqs. (58)-(59) is assumed to be zero. A different choice of the constant corresponds just to a different origin of \( \varphi \), i.e. a constant turn of the ellipse about the origin.
\[ a = \frac{p}{1-e^2} = \frac{\alpha}{2|E|}, \quad b = \frac{p}{(1-e^2)^{1/2}} = \frac{L_z}{(2m|E|)^{1/2}}. \]  

(3.63)

As was mentioned above, at \( E \to \min [U_0(r)] \) the orbit is almost circular, with \( r(\phi) \cong r_0 \approx p \). On the contrary, as \( E \) is increased to approach zero (its maximum value for the closed orbit), then \( e \to 1 \), so that the aphelion point \( r_{\text{max}} = p/(1-e) \) tends to infinity, i.e. the orbit becomes extremely extended – see the red lines in Fig. 8.

![Diagram showing orbits with different eccentricities](image)

Fig. 3.8. (a) Zoom-in and (b) zoom-out on the Coulomb-field trajectories corresponding to the same parameter \( p \) (i.e., the same \( L_z \)), but different values of the eccentricity parameter \( e \), i.e. of the energy \( E \) – see Eq. (60): ellipses \( (e < 1, \) red lines), a parabola \( (e = 1, \) magenta line), and hyperbolas \( (e > 1, \) blue lines). Note that the transition from closed to open trajectories at \( e = 1 \) is dramatic only at very large distances, \( r >> p \).

The above relations enable, in particular, a ready calculation of the rotation period \( \mathcal{T} \equiv \mathcal{T}_r = \mathcal{T}_\phi \) (In the case of a closed trajectory, \( \mathcal{T}_r \) and \( \mathcal{T}_\phi \) coincide.) Indeed, it is well known that the ellipse area \( A = \pi ab \). But according to the 2\textsuperscript{nd} Kepler law (40), \( dA/dt = L_z/2m = \text{const.} \) Hence

\[ \mathcal{T} = \frac{A}{dA/dt} = \frac{\pi ab}{L_z / 2m}. \]  

(3.64a)

Using Eqs. (60) and (63), this important result may be represented in several other forms:

\[ \mathcal{T} = \frac{\pi p^2}{(1-e^2)^{3/2}(L_z / 2m)} = \pi \alpha \left( \frac{m}{2|E|} \right)^{1/2} = 2\pi a^{3/2} \left( \frac{m}{\alpha} \right)^{1/2}. \]  

(3.64b)

Since for the Newtonian gravity (1.15), \( \alpha = Gm_1m_2 = GmM \) at \( m_1 << m_2 \) (i.e. \( m \ll M \)) this constant is proportional to \( m \), and the last form of Eq. (64b) yields the 3\textsuperscript{rd} Kepler law: periods of motion of different planets in the same central field, say that of our Sun, scale as \( T \propto a^{3/2} \). Note that in contrast
to the 2nd Kepler law (which is valid for any central field), the 1st and the 3rd Kepler laws are potential-specific.

Now reviewing the above derivation of Eqs. (59)-(60), we see that they are also valid in the case of \( E \geq 0 \) – see the top horizontal line in Fig. 5 and its discussion above, if we limit the results to the physically meaningful range \( r \geq 0 \). This means that if the energy is exactly zero, Eq. (59) (with \( e = 1 \)) is still valid for all values of \( \varphi \) (except for one special point \( \varphi = \pi \) where \( r \) becomes infinite) and describes a *parabolic* (i.e. open) trajectory – see the magenta lines in Fig. 8.

Moreover, if \( E > 0 \), Eq. (59) is still valid within a certain sector of angles \( \varphi \),

\[
\Delta \varphi = 2 \cos^{-1} \left( \frac{1}{e} \right) \equiv 2 \cos^{-1} \left( 1 + \frac{2EL^2}{m\alpha^2} \right)^{-1/2} < \pi, \quad \text{for } E > 0,
\]

and describes an open, *hyperbolic* trajectory (see the blue lines in Fig. 8). As was mentioned earlier, such trajectories are typical, in particular, for particle scattering.

### 3.5. Elastic scattering

If \( E > 0 \), the motion is unbound for any realistic interaction potential. In this case, the two most important parameters of the particle trajectory are the *impact parameter* \( b \) and the *scattering angle* \( \theta \) (Fig. 9), and the main task for theory is to find the relation between them in the given potential \( U(r) \).

![Fig. 3.9. Main geometric parameters of the scattering problem.](image-url)

For that, it is convenient to note that \( b \) is related to the two conserved quantities, particle’s energy\(^{22} \) \( E \) and its angular momentum \( L_z \), in a simple way. Indeed, at \( r \gg b \), the definition \( L = r \times (mv) \) yields \( L_z = bmv_x \), where \( v_x = (2E/m)^{1/2} \) is the initial (and hence the final) velocity of the particle, so that

\[
L_z = b(2mE)^{1/2}.
\]

Hence the angular contribution to the effective potential (44) may be represented as

\[
\frac{L_z^2}{2mr^2} = E \frac{b^2}{r^2}.
\]

Second, according to Eq. (48), the trajectory sections going from infinity to the nearest approach point \( (r = r_{min}) \) and from that point to infinity, have to be similar, and hence correspond to equal angle

\(^{22}\) The energy conservation law is frequently emphasized by calling such process *elastic scattering*. 

changes $\varphi_0$ — see Fig. 9. Hence we may apply the general Eq. (48) to just one of the sections, say $[r_{\text{min}}, \infty]$, to find the scattering angle:

$$
\theta = \pi - 2\varphi_0 = \pi - \frac{L_z}{(2m)^{1/2}} \int_{r_{\text{min}}}^{\infty} \frac{dr}{r^2 \left[ E - U(r) - \frac{L_z^2}{2mr^2} \right]^{1/2}} = \pi - 2 \int_{r_{\text{min}}}^{\infty} \frac{bdr}{r^2 \left[ 1 - U(r) / E - b^2 / r^2 \right]^{1/2}}. \tag{3.68}
$$

In particular, for the Coulomb potential (49), now with an arbitrary sign of $\alpha$, we can apply the same table integral as in the previous section to get\(^{23}\)

$$
\left| \theta \right| = \left| \pi - 2 \cos^{-1} \left( \frac{\alpha / 2Eb}{1 + (\alpha / 2Eb)^2} \right) \right|. \tag{3.69a}
$$

This result may be more conveniently rewritten as

$$
\tan \left( \frac{\theta}{2} \right) = \frac{\left| \alpha \right|}{2Eb}. \tag{3.69b}
$$

Very clearly, the scattering angle’s magnitude increases with the potential strength $\alpha$, and decreases as either the particle energy or the impact parameter (or both) are increased.

The general result (68) and the Coulomb-specific relations (69) represent a formally complete solution of the scattering problem. However, in a typical experiment on elementary particle scattering, the impact parameter $b$ of a single particle is unknown. In this case, our results may be used to obtain the statistics of the scattering angle $\theta$, in particular, the so-called differential cross-section\(^{24}\)

$$
\frac{d\sigma}{d\Omega} \equiv \frac{1}{n} \frac{dN}{d\Omega}, \tag{3.70}
$$

where $n$ is the average number of the incident particles per unit area, and $dN$ is the average number of the particles scattered into a small solid angle range $d\Omega$. For a uniform beam of initial particles, $d\sigma/d\Omega$ may be calculated by counting the average number of incident particles that have the impact parameters within a small range $db$:

$$
dN = n 2\pi b db. \tag{3.71}
$$

and are scattered by a spherically-symmetric center, which provides an axially-symmetric scattering pattern, into the corresponding small solid angle range $d\Omega = 2\pi |\sin \theta d\theta|$. Plugging these two equalities into Eq. (70), we get the following general geometric relation:

$$
\frac{d\sigma}{d\Omega} = b \left| \frac{db}{\sin \theta d\theta} \right|. \tag{3.72}
$$

In particular, for the Coulomb potential (49), a straightforward differentiation of Eq. (69) yields the so-called Rutherford scattering formula (reportedly derived by Ralph Howard Fowler):

---

\(^{23}\) Alternatively, this result may be recovered directly from the first form of Eq. (65), with the eccentricity $e$ expressed via the same dimensionless parameter $(2Eb/\alpha)$: $e = [1 + (2Eb/\alpha)^2]^{1/2} > 1$.  

\(^{24}\) This terminology stems from the fact that an integral (74) of $d\sigma/d\Omega$ over the full solid angle, called the total cross-section $\sigma$, has the dimension of the area: $\sigma = N/n$, where $N$ is the total number of scattered particles.
This result, which shows a very strong scattering to small angles (so strong that the integral that expresses the total cross-section
\[ \sigma = \int_{4\pi} d\Omega \frac{d\sigma}{d\Omega}, \tag{3.74} \]
is diverging at \( \theta \to 0 \), and very weak backscattering (to angles \( \theta \approx \pi \)) was historically extremely significant: in the early 1910s: its good agreement with \( \alpha \)-particle scattering experiments carried out by Ernest Rutherford’s group gave a strong justification for his introduction of the planetary model of atoms, with electrons moving around very small nuclei – just as planets move around stars.

Note that elementary particle scattering is frequently accompanied by electromagnetic radiation and/or other processes leading to the loss of the initial mechanical energy of the system. Such inelastic scattering may give significantly different results. (In particular, capture of an incoming particle becomes possible even for a Coulomb attracting center.) Also, quantum-mechanical effects may be important at the scattering of light particles with relatively low energies, so that the above results should be used with caution.

### 3.6. Exercise problems

**3.1.** For the system considered in Problem 2.6 (a bead sliding along a string with fixed tension \( \mathcal{F} \), see the figure on the right), analyze small oscillations of the bead near the equilibrium.

**3.2.** For the system considered in Problem 2.7 (a bead sliding along a string of a fixed length \( 2l \), see the figure on the right), analyze small oscillations near the equilibrium.

**3.3.** For a 1D particle of mass \( m \), placed into potential \( U(q) = \alpha q^{2n} \) (where \( \alpha > 0 \), and \( n \) is a positive integer), calculate the functional dependence of the particle oscillation period \( T \) on its energy \( E \). Explore the limit \( n \to \infty \).

**3.4.** Explain why the term \( mr^2 \varphi^2 / 2 \), recast in accordance with Eq. (42), cannot be merged with \( U(r) \) in Eq. (38), to form an effective 1D potential energy \( U(r) - L_z^2 / 2mr^2 \), with the second term’s sign opposite to that given by Eq. (44). We have done an apparently similar thing for our testbed, bead-on-rotating-ring problem at the very end of Sec. 1 – see Eq. (6); why cannot the same trick work for the planetary problem? Besides a formal explanation, discuss the physics behind this difference.

---

25 This divergence, which persists at the quantum-mechanical treatment of the problem (see, e.g., QM Chapter 3), is due to particles with very large values of \( b \), and disappears at an account, for example, of any non-zero concentration of the scattering centers.

26 Their discussion may be found in QM Secs. 3.3 and 3.8.
3.5. A system consisting of two equal masses $m$ on a light rod of length $l$ (frequently called a *dumbbell*) can slide without friction along a vertical ring of radius $R$, rotated about its vertical diameter with constant angular velocity $\omega$ – see the figure on the right. Derive the condition of stability of the lower horizontal position of the dumbbell.

3.6. Analyze the dynamics of the so-called *spherical pendulum* – a point mass hung, in a uniform gravity field $g$, on a light cord of length $l$, with no motion’s confinement to a vertical plane. In particular:

(i) find the integrals of motion and reduce the problem to a 1D one,
(ii) calculate the time period of the possible circular motion around the vertical axis, and
(iii) explore small deviations from the circular motion. (Are the pendulum orbits closed?)

3.7. The orbits of Mars and Earth around the Sun may be well approximated as circles, with a radii ratio of 3/2. Use this fact, and the Earth year duration (which you should know :-), to calculate the time of travel to Mars spending the least energy for spacecraft’s launch. Neglect the planets’ size and the effects of their gravitational fields.

3.8. Derive first-order and second-order differential equations for the reciprocal distance $u \equiv 1/r$ as a function of $\varphi$, describing the trajectory of particle’s motion in a central potential $U(r)$. Spell out the latter equation for the particular case of the Coulomb potential (49) and discuss the result.

3.9. For the motion of a particle in the Coulomb attractive field (with potential $U(r) = -\alpha/r$, with $\alpha > 0$), calculate and sketch the so-called *hodograph* – the trajectory followed by the head of the velocity vector $\mathbf{v}$, provided that its tail is kept at the origin.

3.10. For motion in the following central potential:

$$U(r) = -\frac{\alpha}{r^2} + \frac{\beta}{r^2},$$

(i) find the orbit $r(\varphi)$, for positive $\alpha$ and $\beta$, and all possible ranges of energy $E$;
(ii) prove that in the limit $\beta \to 0$, and for energy $E < 0$, the orbit may be represented as a slowly rotating ellipse;
(iii) express the angular velocity of this slow orbit rotation via the parameters $\alpha$ and $\beta$, the particle’s mass $m$, its energy $E$, and the angular momentum $L_z$.

3.11. A particle is moving in the field of an attractive central force, with potential

$$U(r) = -\frac{\alpha}{r^n}, \quad \text{where } \alpha n > 0.$$
For what values of $n$ is a circular orbit stable?

3.12. Determine the condition for a particle of mass $m$, moving under the effect of a central attractive force

$$F = -\alpha \frac{r}{r^3} \exp\left\{-\frac{r}{R}\right\},$$

where $\alpha$ and $R$ are positive constants, to have a stable circular orbit.

3.13. A particle of mass $m$, with angular momentum $L_z$, moves in the field of an attractive central force with a distance-independent magnitude $F$. If particle's energy $E$ is slightly higher than the value $E_{\text{min}}$ corresponding to the circular orbit of the particle, what is the time period of its radial oscillations? Compare the period with that of the circular orbit at $E = E_{\text{min}}$.

3.14. For particle scattering by a repulsive Coulomb field, calculate the minimum approach distance $r_{\text{min}}$ and the velocity $v_{\text{min}}$ at that point, and analyze their dependence on the impact parameter $b$ (see Fig. 9) and the initial velocity $v_\infty$ of the particle.

3.15. A particle is launched from afar, with impact parameter $b$, toward an attracting center with

$$U(r) = -\frac{\alpha}{r^n}, \quad \text{with} \ n > 2, \ \alpha > 0.$$

(i) Express the minimum distance between the particle and the center via $b$, if the initial kinetic energy $E$ of the particle is barely sufficient for escaping its capture by the attracting center.

(ii) Calculate the capture’s total cross-section; explore the limit $n \to 2$.

3.16. A meteorite with initial velocity $v_\infty$ approaches an atmosphere-free planet of mass $M$ and radius $R$.

(i) Find the condition on the impact parameter $b$ for the meteorite to hit the planet’s surface.

(ii) If the meteorite barely avoids the collision, what is its scattering angle?

3.17. Calculate the differential and total cross-sections of the classical, elastic scattering of small particles by a hard sphere of radius $R$.

3.18. The most famous confirmation of Einstein’s general relativity theory has come from the observation, by A. Eddington and his associates, of star light’s deflection by the Sun, during the May 1919 solar eclipse. Considering light photons as classical particles propagating with the speed of light, $v_0 \to c \approx 3.00 \times 10^8 \text{m/s}$, and the astronomic data for Sun’s mass, $M_S \approx 1.99 \times 10^{30} \text{kg}$, and radius, $R_S \approx 6.96 \times 10^8 \text{m}$, calculate the non-relativistic mechanics’ prediction for the angular deflection of the light rays grazing the Sun’s surface.

It was not the first confirmation, though. The first one came four years earlier from Albert Einstein himself, who showed that his theory may qualitatively explain the difference between the rate of Mercury orbit’s precession, known from earlier observations, and the non-relativistic theory of that effect.
Chapter 4. Rigid Body Motion

This chapter discusses the motion of rigid bodies, with a heavy focus on its most nontrivial part: the rotation. Some byproduct results of this analysis enable a discussion, at the end of the chapter, of the motion of point particles as observed from non-inertial reference frames.

4.1. Translation and rotation

It is natural to start a discussion of many-particle systems from a (relatively :-) simple limit when the changes of distances \( r_{kk'} \equiv |r_k - r_{k'}| \) between the particles are negligibly small. Such an abstraction is called the (absolutely) rigid body, and is a reasonable approximation in many practical problems, including the motion of solids. In other words, this model neglects deformations – which will be the subject of the next chapters. The rigid-body approximation reduces the number of degrees of freedom of the system of \( N \) particles from \( 3N \) to just six – for example, three Cartesian coordinates of one point (say, 0), and three angles of the system’s rotation about three mutually perpendicular axes passing through this point – see Fig. 1.\(^1\)

As it follows from the discussion in Secs. 1.1-3, any purely translational motion of a rigid body, at which the velocity vectors \( v \) of all points are equal, is not more complex than that of a point particle. Indeed, according to Eqs. (1.8) and (1.30), in an inertial reference frame such a body moves, upon the effect of the net external force \( \mathbf{F}^{(ext)} \), exactly as a point particle. However, the rotation is a bit more tricky.

Let us start by showing that an arbitrary elementary displacement of a rigid body may be always considered as a sum of the translational motion discussed above, and what is called a pure rotation. For that, consider a “moving” reference frame, firmly bound to the body, and an arbitrary vector \( \mathbf{A} \) (Fig. 1). The vector may be represented by its Cartesian components \( A_j \) in that moving frame:

\[
\mathbf{A} = \sum_{j=1}^{3} A_j \mathbf{n}_j .
\]  

\(^1\) An alternative way to arrive at the same number six is to consider three points of the body, which uniquely define its position. If movable independently, the points would have nine degrees of freedom, but since three distances \( r_{kk'} \) between them are now fixed, the resulting three constraints reduce the number of degrees of freedom to six.
Let us calculate the time derivative of this vector as observed from a different (“lab”) frame, taking into account that if the body rotates relative to this frame, the directions of the unit vectors \( n_j \), as seen from the lab frame, change in time. Hence, we have to differentiate both operands in each product contributing to the sum (1):

\[
\frac{dA}{dt}_{\text{in}_{\text{lab}}} = \sum_{j=1}^{3} \frac{dA_j}{dt} n_j + \sum_{j=1}^{3} A_j \frac{dn_j}{dt}. \tag{4.2}
\]

On the right-hand side of this equality, the first sum evidently describes the change of vector \( A \) as observed from the moving frame. In the second sum, each of the infinitesimal vectors \( dn_j \) may be represented by its Cartesian components:

\[
dn_j = \sum_{j'=1}^{3} d\varphi_{jj'} n_{j'}. \tag{4.3}
\]

where \( d\varphi_{jj'} \) are some dimensionless scalar coefficients. To find out more about them, let us scalar-multiply each side of Eq. (3) by an arbitrary unit vector \( n_{j''} \), and take into account the evident orthonormality condition:

\[
n_{j'} \cdot n_{j''} = \delta_{jj''}, \tag{4.4}
\]

where \( \delta_{jj''} \) is the Kronecker delta symbol.\(^2\) As a result, we get

\[
dn_j \cdot n_{j''} = d\varphi_{jj'}. \tag{4.5}
\]

Now let us use Eq. (5) to calculate the first differential of Eq. (4):

\[
dn_j \cdot n_{j''} + n_{j'} \cdot dn_{j'} = d\varphi_{jj'} + d\varphi_{jj''} = 0; \quad \text{in particular,} \quad 2dn_j \cdot n_j = 2d\varphi_{jj} = 0. \tag{4.6}
\]

These relations, valid for any choice of indices \( j, j', \) and \( j'' \) of the set \( \{1, 2, 3\} \), show that the matrix of \( d\varphi_{jj'} \) is antisymmetric with respect to the swap of its indices; this means that there are not nine just three non-zero independent coefficients \( d\varphi_{jj'} \), all with \( j \neq j' \). Hence it is natural to renumber them in a simpler way: \( d\varphi_{jj'} = -d\varphi_{j'j} \equiv d\varphi_{j''} \), where the indices \( j, j' \), and \( j'' \) follow in the “correct” order – either \( \{1,2,3\} \), or \( \{2,3,1\} \), or \( \{3,1,2\} \). It is easy to check (either just by a component-by-component comparison or using the Levi-Civita permutation symbol \( \varepsilon_{jj'j} \)) that in this new notation, Eq. (3) may be represented just as a vector product:

\[
dn_j = d\varphi \times n_j, \tag{4.7}
\]

where \( d\varphi \) is the infinitesimal vector defined by its Cartesian components \( d\varphi_j \) in the rotating reference frame \( \{n_1, n_2, n_3\} \) – see Eq. (3).

This relation is the basis of all rotation kinematics. Using it, Eq. (2) may be rewritten as

\[
\frac{dA}{dt}_{\text{in}_{\text{lab}}} = \frac{dA}{dt}_{\text{in}_{\text{mov}}} + \sum_{j=1}^{3} A_j \frac{d\varphi}{dt} \times n_j = \frac{dA}{dt}_{\text{in}_{\text{mov}}} + \omega \times A, \quad \text{where} \quad \omega \equiv \frac{d\varphi}{dt}. \tag{4.8}
\]

To reveal the physical sense of the vector \( \omega \), let us apply Eq. (8) to the particular case when \( A \) is the radius vector \( r \) of a point of the body, and the lab frame is selected in a special way: its origin has the

\(^2\) See, e.g., MA Eq. (13.1).

\(^3\) See, e.g., MA Eq. (13.2). Using this symbol, we may write \( d\varphi_{jj'} = -d\varphi_{j'j} \equiv \varepsilon_{jj'j} d\varphi_{j''} \) for any choice of \( j, j', \) and \( j'' \).
same position and moves with the same velocity as that of the moving frame in the particular instant under consideration. In this case, the first term on the right-hand side of Eq. (8) is zero, and we get

\[
\frac{dr}{dt} \text{ in special lab frame} = \omega \times r, \quad (4.9)
\]

were vector \( \mathbf{r} \) itself is the same in both frames. According to the vector product definition, the particle velocity described by this formula has a direction perpendicular to the vectors \( \mathbf{\omega} \) and \( \mathbf{r} \) (Fig. 2), and magnitude \( \omega r \sin \theta \). As Fig. 2 shows, the last expression may be rewritten as \( \omega \rho \), where \( \rho = r \sin \theta \) is the distance from the line that is parallel to the vector \( \mathbf{\omega} \) and passes through the point 0. This is of course just the pure rotation about that line (called the instantaneous axis of rotation), with the angular velocity \( \omega \). Since according to Eqs. (3) and (8), the angular velocity vector \( \mathbf{\omega} \) is defined by the time evolution of the moving frame alone, it is the same for all points \( \mathbf{r} \), i.e. for the rigid body as a whole. Note that nothing in our calculations forbids not only the magnitude but also the direction of the vector \( \mathbf{\omega} \), and thus of the instantaneous axis of rotation, to change in time (and in many cases it does); hence the name.

![Fig. 4.2. The instantaneous axis and the angular velocity of rotation.](image)

Now let us generalize our result a step further, considering two reference frames that do not rotate versus each other: one (“lab”) frame arbitrary, and another one selected in the special way described above, so that for it Eq. (9) is valid in it. Since their relative motion of these two reference frames is purely translational, we can use the simple velocity addition rule given by Eq. (1.6) to write

\[
\mathbf{v}_0 \big|_{\text{lab}} + \mathbf{v} \big|_{\text{in special lab frame}} = \mathbf{v}_0 \big|_{\text{lab}} + \mathbf{\omega} \times \mathbf{r}, \quad (4.10)
\]

where \( \mathbf{r} \) is the radius vector of a point is measured in the body-bound (“moving”) frame 0.

4.2. Inertia tensor

Since the dynamics of each point of a rigid body is strongly constrained by the conditions \( r_{kk'} = \text{const} \), this is one of the most important fields of application of the Lagrangian formalism discussed in Chapter 2. For using this approach, the first thing we need to calculate is the kinetic energy of the body in an inertial reference frame. Since it is just the sum of the kinetic energies (1.19) of all its points, we can use Eq. (10) to write:\(^4\)

\[
T \equiv \sum \frac{m}{2} \mathbf{v}^2 = \sum \frac{m}{2} (\mathbf{v}_0 + \mathbf{\omega} \times \mathbf{r})^2 = \sum \frac{m}{2} \mathbf{v}_0^2 + \sum m \mathbf{v}_0 \cdot (\mathbf{\omega} \times \mathbf{r}) + \sum \frac{m}{2} (\mathbf{\omega} \times \mathbf{r})^2. \quad (4.11)
\]

\(^4\) Actually, all symbols for particle masses, coordinates, and velocities should carry the particle’s index, over which the summation is carried out. However, in this section, for the notation simplicity, this index is just implied.
Let us apply to the right-hand side of Eq. (11) two general vector analysis formulas listed in the Math Appendix: the so-called operand rotation rule MA Eq. (7.6) to the second term, and MA Eq. (7.7b) to the third term. The result is

\[ T = \sum \frac{m}{2} v_0^2 + \sum m \mathbf{r} \cdot (\mathbf{v}_0 \times \mathbf{\omega}) + \sum \frac{m}{2} \left[ \mathbf{\omega} \cdot \mathbf{r}^2 - (\mathbf{\omega} \cdot \mathbf{r})^2 \right]. \]  

(4.12)

This expression may be further simplified by making a specific choice of the point 0 (from that the radius vectors \( \mathbf{r} \) of all particles are measured), namely by using for this point the center of mass of the body. As was already mentioned in Sec. 3.4 for the 2-point case, the radius vector \( \mathbf{R} \) of this point is defined as

\[ \mathbf{M}\mathbf{R} \equiv \sum m\mathbf{r}, \quad M \equiv \sum m, \]  

(4.13)

where \( M \) is the total mass of the body. In the reference frame centered as this point, \( \mathbf{R} = 0 \), so that the second sum in Eq. (12) vanishes, and the kinetic energy is a sum of just two terms:

\[ T = T_{\text{trans}} + T_{\text{rot}}, \quad T_{\text{trans}} = \frac{M}{2} \mathbf{V}^2, \quad T_{\text{rot}} = \sum \frac{m}{2} \left[ \mathbf{\omega} \cdot \mathbf{r}^2 - (\mathbf{\omega} \cdot \mathbf{r})^2 \right], \]  

(4.14)

where \( \mathbf{V} \equiv d\mathbf{R}/dt \) is the center-of-mass velocity in our inertial reference frame, and all particle positions \( \mathbf{r} \) are measured in the center-of-mass frame. Since the angular velocity vector \( \mathbf{\omega} \) is common for all points of a rigid body, it is more convenient to rewrite the rotational energy in a form in that the summation over the components of this vector is clearly separated from the summation over the points of the body:

\[ T_{\text{rot}} = \frac{1}{2} \sum_{j,j=1}^{3} I_{jj} \omega_j \omega_j, \]  

(4.15)

where the 3×3 matrix with elements

\[ I_{jj} \equiv \sum m(r^2 \delta_{jj} - r_j r_j) \]  

(4.16)

is called the inertia tensor of the body.\(^5\)

Actually, the term “tensor” for this matrix has to be justified, because in physics this term implies a certain reference-frame-independent notion, whose elements have to obey certain rules at the transfer between reference frames. To show that the matrix (16) indeed deserves its title, let us calculate another key quantity, the total angular momentum \( \mathbf{L} \) of the same body.\(^6\) Summing up the angular momenta of each particle, defined by Eq. (1.31), and then using Eq. (10) again, in our inertial reference frame we get

\[ \mathbf{L} \equiv \sum \mathbf{r} \times \mathbf{p} = \sum \mathbf{m} \mathbf{r} \times \mathbf{v} = \sum \mathbf{m} \mathbf{r} \times (\mathbf{v_0} + \mathbf{\omega} \times \mathbf{r}) \equiv \sum \mathbf{m} \mathbf{r} \times \mathbf{v_0} + \sum \mathbf{m} \mathbf{r} \times (\mathbf{\omega} \times \mathbf{r}). \]  

(4.17)

We see that the momentum may be represented as a sum of two terms. The first one,

\(^5\)While the ABCs of the rotational dynamics were developed by Leonhard Euler in 1765, an introduction of the inertia tensor’s formalism had to wait very long – until the invention of the tensor analysis by Tullio Levi-Civita and Gregorio Ricci-Curbastro in 1900 – soon popularized by its use in Einstein’s theory of general relativity.

\(^6\)Hopefully, there is very little chance of confusing the angular momentum \( \mathbf{L} \) (a vector) and its Cartesian components \( L_j \) (scalars with an index) on one hand, and the Lagrangian function \( L \) (a scalar without an index) on the other hand.
describes the possible rotation of the center of mass around the inertial frame’s origin. This term evidently vanishes if the moving reference frame’s origin 0 is positioned at the center of mass (where \( \mathbf{R} = 0 \)). In this case, we are left with only the second term, which describes a pure rotation of the body about its center of mass:

\[
\mathbf{L} = \mathbf{L}_{\text{rot}} = \sum m \mathbf{r} \times (\mathbf{\omega} \times \mathbf{r}).
\] (4.19)

Using one more vector algebra formula, the “bac minis cab” rule,\(^7\) we may rewrite this expression as

\[
\mathbf{L} = \sum m(\mathbf{\omega} \mathbf{r}^2 - \mathbf{r}(\mathbf{r} \cdot \mathbf{\omega})).
\] (4.20)

Let us spell out an arbitrary Cartesian component of this vector:

\[
L_j = \sum m \left[ \mathbf{\omega} \mathbf{r}^2 - r_j \sum \mathbf{r}_j \mathbf{\omega}_j \right] = \sum m \sum \mathbf{r}_j \mathbf{\omega}_j \left( r_j^2 \delta_{jj'} - r_j r_{j'} \right).
\] (4.21)

By changing the summation order and comparing the result with Eq. (16), the angular momentum may be conveniently expressed via the same matrix elements \( I_{jj'} \) as the rotational kinetic energy:

\[
L_j = \sum I_{jj'} \mathbf{\omega}_j. \tag{4.22}
\]

Since \( \mathbf{L} \) and \( \mathbf{\omega} \) are both legitimate vectors (meaning that they describe physical vectors independent of the reference frame choice), their connection, the matrix of elements \( I_{jj'} \), is a legitimate tensor. This fact, and the symmetry of the tensor \( (I_{jj'} = I_{jj'}) \), which is evident from its definition (16), allow the tensor to be further simplified. In particular, mathematics tells us that by a certain choice of the axes’ orientations, any symmetric tensor may be reduced to a diagonal form

\[
I_{jj'} = I_j \delta_{jj'}, \tag{4.23}
\]

where in our case

\[
I_j = \sum m \left( r_j^2 - r^2 \right) = \sum m \left( r_j^2 + r_{j'}^2 \right) \equiv \sum m \rho_j^2,
\] (4.24)

\( \rho_j \) being the distance of the particle from the \( j \)th axis, i.e. the length of the perpendicular dropped from the point to that axis. The axes of such a special coordinate system are called the principal axes, while the diagonal elements \( I_j \) given by Eq. (24), the principal moments of inertia of the body. In such a special reference frame, Eqs. (15) and (22) are reduced to very simple forms:

\[
T_{\text{rot}} = \sum \frac{I_j}{2} \mathbf{\omega}_j^2, \tag{4.25}
\]

\[
L_j = I_j \mathbf{\omega}_j. \tag{4.26}
\]

Both these results remind the corresponding relations for the translational motion, \( T_{\text{tran}} = M \mathbf{V}^2/2 \) and \( \mathbf{P} = M \mathbf{V} \), with the angular velocity \( \mathbf{\omega} \) replacing the linear velocity \( \mathbf{V} \), and the tensor of inertia playing the role of scalar mass \( M \). However, let me emphasize that even in the specially selected reference frame, with

\(^7\) See, e.g., MA Eq. (7.5).
axes pointing in principal directions, the analogy is incomplete, and rotation is generally more complex than translation, because the measures of inertia, $I_j$, are generally different for each principal axis.

Let me illustrate this fact on a simple but instructive system of three similar massive particles fixed in the vertices of an equilateral triangle (Fig. 3).

Let me use this simple case to illustrate the following general axis shift theorem, which may be rather useful – especially for more complex systems. For that, let us relate the inertia tensor components $I_{j'j'}$ and $I'_{j'j'}$, calculated in two reference frames – one with the origin in the center of mass 0, and another one (0') displaced by a certain vector $d$ (Fig. 4a), so that for an arbitrary point, $r' = r + d$. Plugging this relation into Eq. (16), we get

$$I'_{j'j'} = \sum m(\mathbf{r} + \mathbf{d})^2 \delta_{j'j} - \left( r_j + d_j (r_j + d_j) \right)$$

$$= \sum m\left[(r^2 + 2\mathbf{r} \cdot \mathbf{d} + d^2)\delta_{j'j} - (r_j + d_j) r_j + r_j d_j + d_j d_j \right].$$

Since in the center-of-mass frame, all sums $\sum m r_j$ equal zero, we may use Eq. (16) to finally obtain

$$I'_{j'j'} = I_{j'j'} + M(\delta_{j'j} d^2 - d_j d_j).$$

In particular, this equation shows that if the shift vector $d$ is perpendicular to one (say, $j^\text{th}$) of the principal axes (Fig. 4b), i.e. $d_j = 0$, then Eq. (28) is reduced to a very simple formula:

$$I'_{j} = I_j + M d^2.$$
Now returning to the system shown in Fig. 3, let us perform such a shift to the new ("primed") axis passing through the location of one of the particles, still perpendicular to the particles’ plane. Then the contribution of that particular mass to the primed moment of inertia vanishes, and \( I'_3 = 2ma^2 \). Now, returning to the center of mass and applying Eq. (29), we get \( I_3 = I'_3 - M\rho^2 = 2ma^2 - (3m)(a/\sqrt{3})^2 = ma^2 \), i.e. the same result as above.

The symmetry situation inside the triangle’s plane is somewhat less evident, so let us start with calculating the moments of inertia for the axes shown vertical and horizontal in Fig. 3. From Eq. (24) we readily get:

\[
I_1 = 2mh^2 + m\rho^2 = m\left[2\left(\frac{a}{2\sqrt{3}}\right)^2 + \left(\frac{a}{\sqrt{3}}\right)^2\right] = \frac{ma^2}{2}, \quad I_2 = 2m\left(\frac{a}{2}\right)^2 = \frac{ma^2}{2},
\]

where \( h \) is the distance from the center of mass and any side of the triangle: \( h = \rho \sin (\pi/6) = \rho/2 = a/2\sqrt{3} \). We see that \( I_1 = I_2 \), and mathematics tells us that in this case any in-plane axis (passing through the center-of-mass 0) may be considered as principal, and has the same moment of inertia. A rigid body with this property, \( I_1 = I_2 \neq I_3 \), is called the symmetric top. (The last direction is called the main principal axis of the system.)

Despite the symmetric top’s name, the situation may be even more symmetric in the so-called spherical tops, i.e. highly symmetric systems whose principal moments of inertia are all equal,

\[
I_1 = I_2 = I_3 \equiv I,
\]

Mathematics says that in this case, the moment of inertia for rotation about any axis (but still passing through the center of mass) is equal to the same \( I \). Hence Eqs. (25) and (26) are further simplified for any direction of the vector \( \mathbf{\omega} \):

\[
\mathbf{T}_{rot} = \frac{I}{2}\mathbf{\omega}^2, \quad \mathbf{L} = I\mathbf{\omega},
\]

thus making the analogy of rotation and translation complete. (As will be discussed in the next section, this analogy is also complete if the rotation axis is fixed by external constraints.)

Evident examples of a spherical top are a uniform sphere and a uniform spherical shell; a less obvious example is a uniform cube – with masses either concentrated in vertices, or uniformly spread over the faces, or uniformly distributed over the volume. Again, in this case any axis passing through the center of mass is principal and has the same principal moment of inertia. For a sphere, this is natural; for a cube, rather surprising – but may be confirmed by a direct calculation.

4.3. Fixed-axis rotation

Now we are well equipped for a discussion of rigid body’s rotational dynamics. The general equation of this dynamics is given by Eq. (1.38), which is valid for dynamics of any system of particles – either rigidly connected or not:

\[
\dot{\mathbf{L}} = \mathbf{\tau},
\]

where \( \mathbf{\tau} \) is the net torque of external forces. Let us start exploring this equation from the simplest case when the axis of rotation, i.e. the direction of vector \( \mathbf{\omega} \), is fixed by some external constraints. Directing
the z-axis along this vector, we have $\omega_x = \omega_y = 0$. According to Eq. (22), in this case, the z-component of the angular momentum,

$$L_z = I_{zz} \omega_z,$$  \hfill (4.34)

where $I_{zz}$, though not necessarily one of the principal moments of inertia, still may be calculated using Eq. (24):

$$I_{zz} = \sum m \rho_z^2 = \sum m(x^2 + y^2),$$  \hfill (4.35)

with $\rho_z$ being the distance of each particle from the rotation axis z. According to Eq. (15), in this case the rotational kinetic energy is just

$$T_{\text{rot}} = \frac{I_{zz}}{2} \omega_z^2.$$  \hfill (4.36)

Moreover, it is straightforward to show that if the rotation axis is fixed, Eqs. (34)-(36) are valid even if the axis does not pass through the center of mass – provided that the distances $\rho_z$ are now measured from that axis. (The proof is left for the reader’s exercise.)

As a result, we may not care about other components of the vector $\mathbf{L}$, and use just one component of Eq. (33),

$$\dot{L}_z = \tau_z,$$  \hfill (4.37)

because it, when combined with Eq. (34), completely determines the dynamics of rotation:

$$I_{zz} \dot{\omega}_z = \tau_z, \quad \text{i.e., } I_{zz} \dot{\theta}_z = \tau_z,$$  \hfill (4.38)

where $\theta_z$ is the angle of rotation about the axis, so that $\omega_z = \dot{\theta}_z$. The scalar relations (34), (36) and (38), describing rotation about a fixed axis, are completely similar to the corresponding formulas of 1D motion of a single particle, with $\omega_z$ corresponding to the usual (“linear”) velocity, the angular momentum component $L_z$ – to the linear momentum, and $I_z$ – to particle’s mass.

The resulting motion about the axis is also frequently similar to that of a single particle. As a simple example, let us consider what is called the physical pendulum (Fig. 5) – a rigid body free to rotate about a fixed horizontal axis that does not pass through the center of mass $O$, in a uniform gravity field $g$.

Fig. 4.5. Physical pendulum: a body with a fixed (horizontal) rotation axis $O'$ that does not pass through the center of mass $O$. (The plane of drawing is normal to the axis.)

Note that according to Eq. (22), other Cartesian components of the angular momentum, $L_x$ and $L_y$, may be different from zero, and may even evolve in time. The corresponding torques $\tau_x$ and $\tau_y$, which obey Eq. (33), are automatically provided by the external forces that keep the rotation axis fixed.
Let us drop the perpendicular from point 0 to the rotation axis, and call the oppositely directed vector $\mathbf{l}$ – see the dashed arrow in Fig. 5. Then the torque (relative to the rotation axis $0'$) of the forces keeping the axis fixed is zero, and the only contribution to the net torque is due to gravity alone:

$$\tau_{\text{in}0'} = \sum \mathbf{r}_{\text{in}0'} \times \mathbf{F} = \sum (\mathbf{l} + \mathbf{r}_{\text{in}0'}) \times m\mathbf{g} = \sum m(\mathbf{l} \times \mathbf{g}) + \sum m\mathbf{r}_{\text{in}0'} \times \mathbf{g} = M\mathbf{l} \times \mathbf{g}.$$  \hspace{1cm} (4.39)

(The last step used the facts that point 0 is the center of mass, so that the second term in the right-hand side equals zero, and that the vectors $\mathbf{l}$ and $\mathbf{g}$ are the same for all particles of the body.)

This result shows that the torque is directed along the rotation axis, and its (only) component $\tau_z$ is equal to $-Mgl\sin\theta$, where $\theta$ is the angle between the vectors $\mathbf{l}$ and $\mathbf{g}$, i.e. the angular deviation of the pendulum from the position of equilibrium – see Fig. 5 again. As a result, Eq. (38) takes the form,

$$I'\dot{\theta} = -Mgl\sin\theta,$$  \hspace{1cm} (4.40)

where $I'$ is the moment of inertia for rotation about the axis $0'$ rather than about the center of mass. This equation is identical to Eq. (1.18) for the point-mass (sometimes called “mathematical”) pendulum, with the small-oscillation frequency

$$\Omega = \left(\frac{Mgl}{I'}\right)^{1/2}.$$  \hspace{1cm} (4.41)

As a sanity check, in the simplest case when the linear size of the body is much smaller than the suspension length $l$, Eq. (35) yields $I' = Ml^2$, and Eq. (41) reduces to the well-familiar formula $\Omega = (g/l)^{1/2}$ for the point-mass pendulum.

Now let us discuss the situations when a rigid body not only rotates but also moves as a whole. As we already know from our introductory chapter, the total linear momentum of the body,

$$\mathbf{P} = \sum m\mathbf{v} = \sum m\mathbf{\dot{r}} = \frac{d}{dt}\sum m\mathbf{r},$$ \hspace{1cm} (4.42)

satisfies the 2nd Newton law in the form (1.30). Using the definition (13) of the center of mass, the momentum may be represented as

$$\mathbf{P} = M\mathbf{\dot{R}} = M\mathbf{\dot{V}},$$ \hspace{1cm} (4.43)

so Eq. (1.30) may be rewritten as

$$M\mathbf{\dot{V}} = \mathbf{F},$$ \hspace{1cm} (4.44)

where $\mathbf{F}$ is the vector sum of all external forces. This equation shows that the center of mass of the body moves exactly like a point particle of mass $M$, under the effect of the net force $\mathbf{F}$. In many cases, this fact makes the translational dynamics of a rigid body absolutely similar to that of a point particle.

The situation becomes more complex if some of the forces contributing to the vector sum $\mathbf{F}$ depend on the rotation of the same body, i.e. if its rotational and translational motions are coupled. Analysis of such coupled motion is rather straightforward if the direction of the rotation axis does not change in time, and hence Eqs. (35)-(36) are still valid. Possibly the simplest example is a round cylinder (say, a wheel) rolling on a surface without slippage (Fig. 6). Here the no-slippage condition may be represented as the requirement of the net velocity of the particular wheel’s point A that touches the surface to equal zero – in the reference frame connected to the surface. For the simplest case of plane surface (Fig. 6a), this condition may be spelled out using Eq. (10), giving the following relation between the angular velocity $\omega$ of the wheel and the linear velocity $V$ of its center:
Such kinematic relations are essentially holonomic constraints, which reduce the number of degrees of freedom of the system. For example, without the no-slippage condition (45), the wheel on a plane surface has to be considered as a system with two degrees of freedom, making its total kinetic energy (14) a function of two independent generalized velocities, say \( V \) and \( \omega \):

\[
T = T_{\text{trans}} + T_{\text{rot}} = \frac{M}{2}V^2 + \frac{I}{2}\omega^2.
\]  

Using Eq. (45) we may eliminate, for example, the linear velocity and reduce Eq. (46) to

\[
T = \frac{M}{2}(\omega r)^2 + \frac{I}{2}\omega^2 \equiv \frac{I_{\text{ef}}}{2}\omega^2,
\]  

where \( I_{\text{ef}} \equiv I + Mr^2 \).

This result may be interpreted as the kinetic energy of pure rotation of the wheel about the instantaneous rotation axis \( A \), with \( I_{\text{ef}} \) being the moment of inertia about that axis, satisfying Eq. (29).

Kinematic relations are not always as simple as Eq. (45). For example, if a wheel is rolling on a concave surface (Fig. 6b), we need to relate the angular velocities of the wheel’s rotation about its axis \( 0' \) (say, \( \omega \)) and that (say, \( \Omega \)) of its axis’ rotation about the center \( 0 \) of curvature of the surface. A popular error here is to write \( \Omega = -(r/R)\omega \) [WRONG!]. A prudent way to derive the correct relation is to note that Eq. (45) holds for this situation as well, and on the other hand, the same linear velocity of the wheel’s center may be expressed as \( V = (R - r)\Omega \). Combining these formulas, we get the correct relation

\[
\Omega = -\frac{r}{R - r}\omega.
\]  

Another famous example of the relation between the translational and rotational motion is given by the “sliding ladder” problem (Fig. 7). Let us analyze it for the simplest case of negligible friction, and the ladder’s thickness small in comparison with its length \( l \).
To use the Lagrangian formalism, we may write the kinetic energy of the ladder as the sum (14) of its translational and rotational parts:
\[ T = \frac{M}{2}(\dot{X}^2 + \dot{Y}^2) + \frac{I}{2}\dot{\alpha}^2, \]  
(4.49)
where \( X \) and \( Y \) are the Cartesian coordinates of its center of mass in an inertial reference frame, and \( I \) is the moment of inertia for rotation about the \( z \)-axis passing through the center of mass. (For the uniformly distributed mass, an elementary integration of Eq. (3.5) yields \( I = Ml^2/12 \).) In the reference frame with the center in the corner 0, both \( X \) and \( Y \) may be simply expressed via the angle \( \alpha \):
\[ X = \frac{l}{2}\cos\alpha, \quad Y = \frac{l}{2}\sin\alpha. \]  
(4.50)
(The easiest way to obtain these relations is to notice that the dashed line in Fig. 7 has length \( l/2 \), and the same slope \( \alpha \) as the ladder.) Plugging these expressions into Eq. (49), we get:
\[ T = \frac{I_{\text{ef}}}{2}\dot{\alpha}^2, \quad I_{\text{ef}} \equiv I + M\left(\frac{l}{2}\right)^2 = \frac{1}{3}Ml^2. \]  
(4.51)
Since the potential energy of the ladder in the gravity field may be also expressed via the same angle,
\[ U = MgY = Mg\frac{l}{2}\sin\alpha, \]  
(4.52)
\( \alpha \) may be conveniently used as the (only) generalized coordinate of the system. Even without writing the Lagrange equation of motion for that coordinate, we may notice that since the Lagrangian function \( L \equiv T - U \) does not depend on time explicitly, and the kinetic energy (51) is a quadratic-homogeneous function of the generalized velocity \( \dot{\alpha} \), the full mechanical energy,
\[ E \equiv T + U = \frac{I_{\text{ef}}}{2}\dot{\alpha}^2 + Mg\frac{l}{2}\sin\alpha = \frac{Mgl}{2}\left(\frac{l\dot{\alpha}^2}{3g} + \sin\alpha\right), \]  
(4.53)
is conserved, giving us the first integral of motion. Moreover, Eq. (53) shows that the system’s energy (and hence dynamics) is identical to that of a physical pendulum with an unstable fixed point \( \alpha_1 = \pi/2 \), a stable fixed point at \( \alpha_2 = -\pi/2 \), and frequency
\[ \Omega = \sqrt{\frac{3g}{2l}} \]  
(4.54)
of small oscillations near the latter point. (Of course, this fixed point cannot be reached in the simple geometry shown in Fig. 7, where the ladder’s fall on the floor would change its equations of motion. Moreover, even before that, the left end of the ladder may detach from the wall. The analysis of this issue is left for the reader’s exercise.)

4.4. Free rotation

Now let us proceed to the more complex case when the rotation axis is not fixed. A good illustration of the complexity arising in this case comes from the case of a rigid body left alone, i.e. not subjected to external forces and hence with its potential energy \( U \) constant. Since in this case, according
to Eq. (44), the center of mass moves (as measured from any inertial reference frame) with a constant velocity, we can always use a convenient inertial reference frame with the origin at that point. From the point of view of such a frame, the body’s motion is a pure rotation, and \( T_{\text{trans}} = 0 \). Hence, the system’s Lagrangian equals just the rotational energy (15), which is, first, a quadratic-homogeneous function of the components \( \omega_j \) (which may be taken for generalized velocities), and, second, does not depend on time explicitly. As we know from Chapter 2, in this case the mechanical energy, here equal to \( T_{\text{rot}} \) alone, is conserved. According to Eq. (15), for the principal-axes components of the vector \( \omega \), this means

\[
T_{\text{rot}} = \sum_{j=1}^{3} \frac{I_j}{2} \omega_j^2 = \text{const}.
\]

(4.55)

Next, as Eq. (33) shows, in the absence of external forces, the angular momentum \( L \) of the body is conserved as well. However, though we can certainly use Eq. (26) to represent this fact as

\[
L = \sum_{j=1}^{3} I_j \omega_j n_j = \text{const},
\]

(4.56)

where \( n_j \) are the principal axes, this does not mean that all components \( \omega_j \) are constant, because the principal axes are fixed relative to the rigid body, and hence may rotate with it.

Before exploring these complications, let us briefly mention two conceptually trivial, but practically very important, particular cases. The first is a spherical top \( (I_1 = I_2 = I_3 = I) \). In this case, Eqs. (55) and (56) imply that all components of the vector \( \omega = L/I \), i.e. both the magnitude and the direction of the angular velocity are conserved, for any initial spin. In other words, the body conserves its rotation speed and axis direction, as measured in an inertial frame. The most obvious example is a spherical planet. For example, our Mother Earth, rotating about its axis with angular velocity \( \omega = 2\pi/(1 \text{ day}) \approx 7.3 \times 10^{-5} \text{ s}^{-1} \), keeps its axis at a nearly constant angle of 23°27' to the ecliptic pole, i.e. the axis normal to the plane of its motion around the Sun. (In Sec. 6 below, we will discuss some very slow motions of this axis, due to gravity effects.)

Spherical tops are also used in the most accurate gyroscopes, usually with gas-jet or magnetic suspension in vacuum. If done carefully, such systems may have spectacular stability. For example, the gyroscope system of the Gravity Probe B satellite experiment, flown in 2004-5, was based on quartz spheres – round with precision of about 10 nm and covered with superconducting thin films (which enabled their magnetic suspension and monitoring). The whole system was stable enough to measure that the so-called \textit{geodetic effect} in general relativity (essentially, the space curving by Earth’s mass), resulting in the axis’ precession by only 6.6 arc seconds per year, i.e. with a precession frequency of just \(-10^{-11} \text{ s}^{-1} \), agrees with theory with a record \(-0.3\%\) accuracy.9

The second simple case is that of the symmetric top \( (I_1 = I_2 \neq I_3) \), with the initial vector \( L \) aligned with the main principal axis. In this case, \( \omega = L/I_3 = \text{const} \), so that the rotation axis is conserved.10 Such tops, typically in the shape of a \textit{flywheel} (heavy, flat rotor), and supported by a three-ring \textit{gimbal} system

---

9 Still, the main goal of this rather expensive (~$750M) project, an accurate measurement of a more subtle relativistic effect, the so-called \textit{frame-dragging drift} (also called “the Schiff precession”), predicted to be about 0.04 arc seconds per year, has not been achieved.

10 This is also true for an asymmetric top, i.e. an arbitrary body (with, say, \( I_1 < I_2 < I_3 \)), but in this case the alignment of the vector \( L \) with the axis \( n_2 \) corresponding to the intermediate moment of inertia, is unstable.
(which allows for torque-free rotation in all three directions),\textsuperscript{11} are broadly used in more common gyroscopes – core parts of automatic guidance systems, for example, in ships, airplanes, missiles, etc. Even if the ship’s hull wobbles and/or drifts, the suspended gyroscope sustains its direction relative to the Earth – which is a sufficiently inertial reference frame for these applications.\textsuperscript{12}

However, in the general case with no such special initial alignment, the dynamics of symmetric tops is more complicated. In this case, the vector $\mathbf{L}$ is still conserved, including its direction, but the vector $\mathbf{\omega}$ is not. Indeed, let us direct the $\mathbf{n}_2$ axis normally to the common plane of vectors $\mathbf{L}$ and the current instantaneous direction $\mathbf{n}_3$ of the main principal axis (in Fig. 8 below, the plane of the drawing); then, in that particular instant, $L_2 = 0$. Now let us recall that in a symmetric top, the axis $\mathbf{n}_2$ is a principal one. According to Eq. (26) with $j = 2$, the corresponding component $\omega_2$ has to be equal to $L_2/I_2$, so it is equal to zero. This means that the vector $\mathbf{\omega}$ lies in this plane (the common plane of vectors $\mathbf{L}$ and $\mathbf{n}_3$) as well – see Fig. 8a.

![Diagram of a symmetric top showing the rotation and precession](image)

Now consider any point located on the main principal axis $\mathbf{n}_3$, and hence on the plane $[\mathbf{n}_3, \mathbf{L}]$. Since $\mathbf{\omega}$ is the instantaneous axis of rotation, according to Eq. (9), the instantaneous velocity $\mathbf{v} = \mathbf{\omega} \times \mathbf{r}$ of the point is directed normally to that plane. Since this is true for each point of the main axis (besides only one, with $\mathbf{r} = 0$, i.e. the center of mass, which does not move), this axis as a whole has to move perpendicular to the common plane of the vectors $\mathbf{L}$, $\mathbf{\omega}$, and $\mathbf{n}_3$. Since this conclusion is valid for any moment of time, it means that the vectors $\mathbf{\omega}$ and $\mathbf{n}_3$ rotate about the space-fixed vector $\mathbf{L}$ together, with some angular velocity $\omega_{\text{pre}}$, at each moment staying within one plane. This effect is usually called the free precession (or “torque-free”, or “regular”) precession, and has to be clearly distinguished it from the completely different effect of the torque-induced precession, which will be discussed in the next section.

To calculate $\omega_{\text{pre}}$, let us represent the instant vector $\mathbf{\omega}$ as a sum of not its Cartesian components (as in Fig. 8a), but rather of two non-orthogonal vectors directed along $\mathbf{n}_3$ and $\mathbf{L}$ (Fig. 8b):

$$\mathbf{\omega} = \omega_{\text{rot}} \mathbf{n}_3 + \omega_{\text{pre}} \mathbf{n}_L,$$

$$\mathbf{n}_L \equiv \mathbf{L} / L.$$

\textsuperscript{11} See, for example, a very nice animation available online at http://en.wikipedia.org/wiki/Gimbal.

\textsuperscript{12} Much more compact (and much less accurate) gyroscopes used, for example, in smartphones and tablet computers, are based on a more subtle effect of rotation on mechanical oscillator’s frequency, and are implemented as micro-electromechanical systems (MEMS) on silicon chip surfaces – see, e.g., Chapter 22 in V. Kaajakari, Practical MEMS, Small Gear Publishing, 2009. Too bad I have no time/space to cover their theory!
Fig. 8b shows that $\omega_{rot}$ has the meaning of the angular velocity of rotation of the body about its main principal axis, while $\omega_{pre}$ is the angular velocity of rotation of that axis about the constant direction of the vector $L$, i.e. the frequency of precession, i.e. exactly what we are trying to find. Now $\omega_{pre}$ may be readily calculated from the comparison of two panels of Fig. 8, by noticing that the same angle $\theta$ between the vectors $L$ and $n_3$ participates in two relations:

$$\sin \theta = \frac{L_1}{L} = \frac{\omega_1}{\omega_{pre}}. \quad (4.58)$$

Since the $n_1$-axis is a principal one, we may use Eq. (26) for $j = 1$, i.e. $L_1 = I_1 \omega_1$, to eliminate $\omega_1$ from Eq. (58), and get a very simple formula

$$\omega_{pre} = \frac{L}{I_1}. \quad (4.59)$$

This result shows that the precession frequency is constant and independent of the alignment of the vector $L$ with the main principal axis $n_3$, while the amplitude of this motion (characterized by the angle $\theta$) does depend on the alignment, and vanishes if $L$ is parallel to $n_3$. Note also that if all principal moments of inertia are of the same order, $\omega_{pre}$ is of the same order as the total angular speed $\omega \equiv |\omega|$ of rotation.

Now let us briefly discuss the free precession in the general case of an “asymmetric top”, i.e. a body with arbitrary $I_1 \neq I_2 \neq I_3$. In this case, the effect is more complex because here not only the direction but also the magnitude of the instantaneous angular velocity $\omega$ may evolve in time. If we are only interested in the relation between the instantaneous values of $\omega$ and $L_j$, i.e. the “trajectories” of the vectors $\omega$ and $L$ as observed from the reference frame \{n_1, n_2, n_3\} of the principal axes of the body (rather than the explicit law of their time evolution), they may be found directly from the conservation laws. (Let me emphasize again that the vector $L$, being constant in an inertial reference frame, generally evolves in the frame rotating with the body.) Indeed, Eq. (55) may be understood as the equation of an ellipsoid in Cartesian coordinates \{\omega_1, \omega_2, \omega_3\}, so that for a free body, the vector $\omega$ has to stay on the surface of that ellipsoid. On the other hand, since the reference frame rotation preserves the length of any vector, the magnitude (but not the direction!) of the vector $L$ is also an integral of motion in the moving frame, and we can write

$$L^2 \equiv \sum_{j=1}^{3} L_j^2 = \sum_{j=1}^{3} I_j^2 \omega_j^2 = \text{const}. \quad (4.60)$$

Hence the trajectory of the vector $\omega$ follows the closed curve formed by the intersection of two ellipsoids, (55) and (60). It is evident that this trajectory is generally “taco-edge-shaped”, i.e. more complex than a planar circle, but never very complex either.

---

13 For our Earth, the free precession amplitude is so small (corresponding to sub-10-m linear displacements of the Earth surface) that this effect is of the same order as other, more irregular motions of the rotation axis, resulting from the turbulent fluid flow effects in planet’s interior and its atmosphere.

14 It is frequently called the Poinsot’s ellipsoid, named after Louis Poinsot (1777-1859) who has made several important contributions to rigid body mechanics.

15 Curiously, the “wobbling” motion along such trajectories was observed not only for macroscopic rigid bodies, but also for heavy atomic nuclei – see, e.g., N. Sensharma et al., Phys. Rev. Lett. 124, 052501 (2020).
The same argument may be repeated for the vector $\mathbf{L}$, for whom the first form of Eq. (60) describes a sphere, and Eq. (55), another ellipsoid:

$$T_{\text{rot}} = \sum_{j=1}^{3} \frac{1}{2I_j} L_j^2 = \text{const}. \quad (4.61)$$

On the other hand, if we are interested in the trajectory of the vector $\mathbf{\omega}$ as observed from an inertial frame (in which the vector $\mathbf{L}$ stays still), we may note that the general relation (15) for the same rotational energy $T_{\text{rot}}$ may also be rewritten as

$$T_{\text{rot}} = \frac{1}{2} \sum_{j=1}^{3} \omega_j \sum_{j'=1}^{3} I_{jj'} \omega_{j'}. \quad (4.62)$$

But according to the Eq. (22), the second sum on the right-hand side is nothing more than $L_j$, so that

$$T_{\text{rot}} = \frac{1}{2} \sum_{j=1}^{3} \omega_j L_j = \frac{1}{2} \mathbf{\omega} \cdot \mathbf{L}. \quad (4.63)$$

This equation shows that for a free body ($T_{\text{rot}} = \text{const}$, $\mathbf{L} = \text{const}$), even if the vector $\mathbf{\omega}$ changes in time, its endpoint should stay within a plane perpendicular to the angular momentum $\mathbf{L}$. (Earlier, we have seen that for the particular case of the symmetric top – see Fig. 8b, but for an asymmetric top, the trajectory of the endpoint may not be circular.)

If we are interested not only in the trajectory of the vector $\mathbf{\omega}$, but also the law of its evolution in time, it may be calculated using the general Eq. (33) expressed in the principal components $\omega_j$. For that, we have to recall that Eq. (33) is only valid in an inertial reference frame, while the frame $\{\mathbf{n}_1, \mathbf{n}_2, \mathbf{n}_3\}$ may rotate with the body and hence is generally not inertial. We may handle this problem by applying, to the vector $\mathbf{L}$, the general kinematic relation (8):

$$\frac{d\mathbf{L}}{dt} \bigg|_{\text{in lab}} = \frac{d\mathbf{L}}{dt} \bigg|_{\text{in mov}} + \mathbf{\omega} \times \mathbf{L}. \quad (4.64)$$

Combining it with Eq. (33), in the moving frame we get

$$\frac{d\mathbf{L}}{dt} + \mathbf{\omega} \times \mathbf{L} = \mathbf{\tau}, \quad (4.65)$$

where $\mathbf{\tau}$ is the external torque. In particular, for the principal-axis components $L_{jj}$, related to the components $\omega_j$ by Eq. (26), the vector equation (65) is reduced to a set of three scalar Euler equations

$$I_j \omega_j + (I_{jj'} - I_{j'}) \omega_j \omega_{j'} = \tau_{j'}, \quad (4.66)$$

where the set of indices $\{j,j',j''\}$ has to follow the usual “right” order – e.g., $\{1, 2, 3\}$, etc.\(^{16}\)

In order to get a feeling how do the Euler equations work, let us return to the particular case of a free symmetric top ($\tau_1 = \tau_2 = \tau_3 = 0$, $I_1 = I_2 \neq I_3$). In this case, $I_1 - I_2 = 0$, so that Eq. (66) with $j = 3$ yields $\omega_3 = \text{const}$, while the equations for $j = 1$ and $j = 2$ take the following simple form:

\(^{16}\) These equations are of course valid in the simplest case of the fixed rotation axis as well. For example, if $\omega = \mathbf{n}_z \omega_z$, i.e. $\omega_x = \omega_y = 0$, Eq. (66) is reduced to Eq. (38).
\[
\dot{\omega}_1 = -\Omega_{\text{pre}} \omega_2, \quad \dot{\omega}_2 = \Omega_{\text{pre}} \omega_1, \quad (4.67)
\]

where \( \Omega_{\text{pre}} \) is a constant determined by both the system parameters and the initial conditions:

\[
\Omega_{\text{pre}} \equiv \omega_3 \frac{I_3 - I_1}{I_1}. \quad (4.68)
\]

The system of two equations (67) has a sinusoidal solution with frequency \( \Omega_{\text{pre}} \), and describes a uniform rotation of the vector \( \omega \), with that frequency, about the main axis \( n_3 \). This is just another representation of the torque-free precession analyzed above, this time as observed from the rotating body. Evidently, \( \Omega_{\text{pre}} \) is substantially different from the frequency \( \omega_{\text{pre}} \) of the precession as observed from the lab frame; for example, \( \Omega_{\text{pre}} \) vanishes for the spherical top (with \( I_1 = I_2 = I_3 \)), while \( \omega_{\text{pre}} \), in this case, is equal to the rotation frequency.

Unfortunately, for the rotation of an asymmetric top (i.e., an arbitrary rigid body), when no component \( \omega_j \) is conserved, the Euler equations (66) are strongly nonlinear even in the absence of any external torque, and a discussion of their solutions would take more time than I can afford.\(^{17}\)

### 4.5. Torque-induced precession

The dynamics of rotation becomes even more complex in the presence of external forces. Let us consider the most important and counter-intuitive effect of torque-induced precession, for the simplest case of an axially-symmetric body (which is a particular case of the symmetric top, \( I_1 = I_2 \neq I_3 \)), supported at some point \( A \) of its symmetry axis, that does not coincide with the center of mass \( 0 \) – see Fig. 9.

The uniform gravity field \( g \) creates bulk-distributed forces that, as we know from the analysis of the physical pendulum in Sec. 3, are equivalent to a single force \( Mg \) applied in the center of mass – in Fig. 9, point \( 0 \). The torque of this force relative to the support point \( A \) is

\[
\tau = r_0 \bigg|_{\text{in } A} \times Mg = Ml n_3 \times g. \quad (4.69)
\]

\(^{17}\) Such discussion may be found, for example, in Sec. 37 of L. Landau and E. Lifshitz, Mechanics, 3\(^{\text{rd}}\) ed., Butterworth-Heinemann, 1976.
Hence the general equation (33) of the angular momentum evolution (valid in any inertial frame, for example the one with an origin in point A) becomes

\[ \mathbf{\dot{L}} = Ml\mathbf{n}_3 \times \mathbf{g}. \]  \hspace{1cm} (4.70)

Despite the apparent simplicity of this (exact!) equation, its analysis is straightforward only in the limit when the top is launched spinning about its symmetry axis \( \mathbf{n}_3 \) with a very high angular velocity \( \omega_{\text{rot}} \). In this case, we may neglect the contribution to \( \mathbf{L} \) due to a relatively small precession velocity \( \omega_{\text{pre}} \) (still to be calculated), and use Eq. (26) to write

\[ \mathbf{L} = I_3 \omega = I_3 \omega_{\text{rot}} \mathbf{n}_3. \]  \hspace{1cm} (4.71)

Then Eq. (70) shows that the vector \( \mathbf{L} \) is perpendicular to both \( \mathbf{n}_3 \) (and hence \( \mathbf{L} \)) and \( \mathbf{g} \), i.e. lies within the horizontal plane and is perpendicular to the horizontal component \( L_{xy} \) of the vector \( \mathbf{L} \) – see Fig. 9b. Since, according to Eq. (70), the magnitude of this vector is constant, \( |\mathbf{L}| = mgl \sin \theta \), the vector \( \mathbf{L} \) (and hence the body’s main axis) rotates about the vertical axis with the following angular velocity:

\[ \omega_{\text{pre}} = \frac{Mgl\sin \theta}{L_{xy}} = \frac{Mgl}{L} = \frac{Mgl}{I_3 \omega_{\text{rot}}}. \]  \hspace{1cm} (4.72)

Thus, very counter-intuitively, the fast-rotating top does not follow the external, vertical force and, in addition to fast spinning about the symmetry axis \( \mathbf{n}_3 \), performs a revolution, called the torque-induced precession, about the vertical axis. Note that, similarly to the free-precession frequency (59), the torque-induced precession frequency (72) does not depend on the initial (and sustained) angle \( \theta \). However, the torque-induced precession frequency is inversely (rather than directly) proportional to \( \omega_{\text{rot}} \). This fact makes the above simple theory valid in many practical cases. Indeed, Eq. (71) is quantitatively valid if the contribution of the precession into \( \mathbf{L} \) is relatively small: \( I \omega_{\text{pre}} \ll I_3 \omega_{\text{rot}} \), where \( I \) is a certain effective moment of inertia for the precession - to be calculated below. Using Eq. (72), this condition may be rewritten as

\[ \omega_{\text{rot}} >> \left( \frac{Mgl}{I_3} \right)^{1/2}. \]  \hspace{1cm} (4.73)

According to Eq. (16), for a body of not too extreme proportions, i.e. with all linear dimensions of the order of the same length scale \( l \), all inertia moments are of the order of \( Ml^2 \), so that the right-hand side of Eq. (73) is of the order of \( (g/l)^{1/2} \), i.e. comparable with the frequency of small oscillations of the same body as the physical pendulum, i.e. at the absence of its fast rotation.

To develop a qualitative theory that would be valid beyond such approximate treatment, the Euler equations (66) may be used, but are not very convenient. A better approach, suggested by the same L. Euler, is to introduce a set of three independent angles between the principal axes \( \{ \mathbf{n}_1, \mathbf{n}_2, \mathbf{n}_3 \} \) bound to the rigid body, and the axes \( \{ \mathbf{n}_x, \mathbf{n}_y, \mathbf{n}_z \} \) of an inertial reference frame (Fig. 10), and then express the basic equation (33) of rotation, via these angles. There are several possible options for the definition of such angles; Fig. 10 shows the set of Euler angles, most convenient for analyses of fast rotation.\(^{18}\) As one can see, the first Euler angle, \( \theta \), is the usual polar angle measured from the \( \mathbf{n}_z \)-axis to

\(^{18}\) Of the several choices more convenient in the absence of fast rotation, the most common is the set of so-called Tait-Brian angles (called the yaw, pitch, and roll), which are broadly used for aircraft and maritime navigation.
the \(n_3\)-axis. The second one is the azimuthal angle \(\varphi\), measured from the \(n_c\)-axis to the so-called \textit{line of nodes} formed by the intersection of planes \([n_x, n_y]\) and \([n_1, n_2]\). The last Euler angle, \(\psi\), is measured within the plane \([n_1, n_2]\), from the line of nodes to axis \(n_1\)-axis. For example, in the simple picture of slow force-induced precession of a symmetric top, that was discussed above, the angle \(\theta\) is constant, the angle \(\psi\) changes rapidly, with the rotation velocity \(\omega_{\text{rot}}\), while the angle \(\varphi\) evolves with the precession frequency \(\omega_{\text{pre}}\) (72).

![Diagram](image)

Fig. 4.10. Definition of the Euler angles.

Now we can express the principal-axes components of the instantaneous angular velocity vector, \(\omega_1\), \(\omega_2\), and \(\omega_3\), as measured in the lab reference frame, in terms of the Euler angles. This may be readily done by calculating, from Fig. 10, the contributions of the Euler angles’ evolution to the rotation about each principal axis, and then adding them up:

\[
\begin{align*}
\omega_1 &= \dot{\phi}\sin\theta\sin\psi + \dot{\theta}\cos\psi, \\
\omega_2 &= \dot{\phi}\sin\theta\cos\psi - \dot{\theta}\sin\psi, \\
\omega_3 &= \dot{\phi}\cos\theta + \dot{\psi}.
\end{align*}
\]

These relations enable the expression of the kinetic energy of rotation (25) and the angular momentum components (26) via the generalized coordinates \(\theta\), \(\phi\), and \(\psi\) and their time derivatives (i.e. the corresponding generalized velocities), and then using the powerful Lagrangian formalism to derive their equations of motion. This is especially simple to do in the case of symmetric tops (with \(I_1 = I_2\)), because plugging Eqs. (74) into Eq. (25) we get an expression,

\[
T_{\text{rot}} = \frac{I_1}{2} \left( \dot{\phi}^2 + \dot{\phi}^2 \sin^2 \theta \right) + \frac{I_3}{2} \left( \dot{\phi} \cos \theta + \dot{\psi} \right)^2,
\]

which does not include explicitly either \(\varphi\) or \(\psi\). (This reflects the fact that for a symmetric top we can always select the \(n_1\)-axis to coincide with the line of nodes, and hence take \(\psi = 0\) at the considered moment of time. Note that this trick does \textit{not} mean we can take \(\psi = 0\), because the \(n_1\)-axis, as observed from an inertial reference frame, moves!) Now we should not forget that at the torque-induced precession, the center of mass moves as well (see, e.g., Fig. 9), so that according to Eq. (14), the total kinetic energy of the body is the sum of two terms,

\[
T = T_{\text{rot}} + T_{\text{trans}}, \quad T_{\text{trans}} = \frac{M}{2} V^2 = \frac{M}{2} l^2 \left( \dot{\phi}^2 + \dot{\phi}^2 \sin^2 \theta \right),
\]
while its potential energy is just

\[ U = Mgl \cos \theta + \text{const}. \]  

(4.77)

Now we could readily write the Lagrange equations of motion for the Euler angles, but it is simpler to immediately notice that according to Eqs. (75)-(77), the Lagrangian function, \( T - U \), does not depend explicitly on the “cyclic” coordinates \( \varphi \) and \( \psi \), so that the corresponding generalized momenta (2.31) are conserved:

\[
p_{\varphi} \equiv \frac{\partial T}{\partial \dot{\varphi}} = I_{A} \dot{\varphi} \sin^{2} \theta + I_{3} (\dot{\varphi} \cos \theta + \dot{\psi}) \cos \theta = \text{const},
\]

\[
p_{\psi} \equiv \frac{\partial T}{\partial \dot{\psi}} = I_{3} (\dot{\varphi} \cos \theta + \dot{\psi}) = \text{const},
\]

(4.78)

where \( I_{A} \equiv I_{1} + Ml^{2} \). (According to Eq. (29), \( I_{A} \) is just the body’s moment of inertia for rotation about a horizontal axis passing through the support point A.) According to the last of Eqs. (74), \( p_{\psi} \) is just \( L_{3} \), i.e. the angular momentum’s component along the precessing axis \( n_{3} \). On the other hand, by its very definition (78), \( p_{\varphi} \) is \( L_{2} \), i.e. the same vector \( \mathbf{L} \)’s component along the static axis \( z \). (Actually, we could foresee in advance the conservation of both these components of \( \mathbf{L} \) for our system, because the vector (69) of the external torque is perpendicular to both \( n_{3} \) and \( n_{z} \).) Using this notation, and solving the simple system of linear equations (78)-(79) for the angle derivatives, we get

\[
\dot{\varphi} = \frac{L_{z} - L_{3} \cos \theta}{I_{A} \sin^{2} \theta}, \quad \dot{\psi} = \frac{L_{3} - L_{z} \cos \theta}{I_{3}} \sin^{2} \theta \cos \theta .
\]

(4.80)

One more conserved quantity in this problem is the full mechanical energy\(^{19}\)

\[
E \equiv T + U = \frac{I_{A}}{2} \left( \dot{\theta}^{2} + \dot{\varphi}^{2} \sin^{2} \theta \right) + I_{3} (\dot{\varphi} \cos \theta + \dot{\psi})^{2} + Mgl \cos \theta.
\]

(4.81)

Plugging Eqs. (80) into Eq. (81), we get a first-order differential equation for the angle \( \theta \), which may be represented in the following physically transparent form:

\[
\frac{I_{A}}{2} \dot{\theta}^{2} + U_{\text{ef}}(\theta) = E,
\]

\[
U_{\text{ef}}(\theta) \equiv \frac{(L_{z} - L_{3} \cos \theta)^{2}}{2I_{A} \sin^{2} \theta} + \frac{L_{3}^{2}}{2I_{3}} + Mgl \cos \theta + \text{const}.
\]

(4.82)

Thus, similarly to the planetary problems considered in Sec. 3.4, the torque-induced precession of a symmetric top has been reduced (without any approximations!) to a 1D problem of the motion of one of its degrees of freedom, the polar angle \( \theta \), in the effective potential \( U_{\text{ef}}(\theta) \). According to Eq. (82), very similar to Eq. (3.44) for the planetary problem, this potential is the sum of the actual potential energy \( U \) given by Eq. (77), and a contribution from the kinetic energy of motion along two other angles. In the absence of rotation about the axes \( n_{z} \) and \( n_{3} \) (i.e., \( L_{z} = L_{3} = 0 \)), Eq. (82) is reduced to the first integral of the equation (40) of motion of a physical pendulum, with \( I' = I_{A} \). If the rotation is present, then (besides the case of very special initial conditions when \( \theta(0) = 0 \) and \( L_{z} = L_{3} \)\(^{20}\), the first

\(^{19}\) Indeed, since the Lagrangian does not depend on time explicitly, \( H = \text{const} \), and since the full kinetic energy \( T \) (75)-(76) is a quadratic-homogeneous function of the generalized velocities, \( E = H \).

\(^{20}\) In that simple case, the body continues to rotate about the vertical symmetry axis: \( \dot{\varphi}(t) = 0 \). Note, however, that such motion is stable only if the spinning speed is sufficiently high – see Eq. (85) below.
contribution to \( U_{\text{ef}}(\theta) \) diverges at \( \theta \to 0 \) and \( \pi \), so that the effective potential energy has a minimum at some non-zero value \( \theta_0 \) of the polar angle \( \theta \) – see Fig. 11.

If the initial angle \( \theta(0) \) is equal to this value \( \theta_0 \), i.e. if the initial effective energy is equal to its minimum value \( U_{\text{ef}}(\theta_0) \), the polar angle remains constant through the motion: \( \theta(t) = \theta_0 \). This corresponds to the pure torque-induced precession whose angular velocity is given by the first of Eqs. (80):

\[
\omega_{\text{pre}} = \phi = \frac{L_z - L_3 \cos \theta_0}{I_A \sin^2 \theta_0}.
\]  

(4.83)

The condition for finding \( \theta_0 \), \( dU_{\text{ef}}/d\theta = 0 \), is a transcendental algebraic equation that cannot be solved analytically for arbitrary parameters. Indeed, in this limit the \( Mgl \)-proportional contribution to \( U_{\text{ef}} \) is small, and we may analyze its effect by successive approximations. In the 0th approximation, i.e. at \( Mgl = 0 \), the minimum of \( U_{\text{ef}} \) is evidently achieved at \( \cos \theta_0 = L_z/L_3 \), turning the precession frequency (83) to zero. In the next, 1st approximation, we may require that at \( \theta = \theta_0 \), the derivative of the first term of Eq. (82) for \( U_{\text{ef}} \) over \( \cos \theta \), equal to 

\[
-\frac{L_z - L_3 \cos \theta}{I_A \sin^2 \theta} \cos \theta, \quad \theta_0 \approx \cos^{-1} r \approx 0.1011 \pi,
\]

is canceled with that of the gravity-induced term, equal to \( Mgl \). This immediately yields \( \omega_{\text{pre}} = (L_z - L_3 \cos \theta_0)/I_A \sin^2 \theta_0 = Mgl/L_3 \), so that identifying \( \omega_{\text{rot}} \) with \( \omega_3 \equiv L_3/I_3 \) (see Fig. 8), we recover the simple expression (72).

The second important result that may be readily obtained from Eq. (82) is the exact expression for the threshold value of the spinning speed for a vertically rotating top \( (\theta = 0, L_z = L_3) \). Indeed, in the limit \( \theta \to 0 \) this expression may be readily simplified:

\[
U_{\text{ef}}(\theta) \approx \text{const} + \left( \frac{L_3^2 - Mgl}{8I_A} \right) \theta^2.
\]  

(4.84)

This formula shows that if \( \omega_{\text{rot}} \equiv L_3/I_3 \) is higher than the following threshold value,

\[
\omega_{\text{rot}} \approx \frac{L_3}{I_3} \approx \frac{L_3}{I_3} - \frac{Mgl}{I_3}
\]

Furthermore, the derivative of the fraction \( 1/2I_A \sin^2 \theta \), taken at the point \( \cos \theta = L_z/L_3 \), is multiplied by the numerator, \( (L_z - L_3 \cos \theta)^2 \), which turns to zero at this point.

\[21\] Indeed, the derivative of the fraction \( 1/2I_A \sin^2 \theta \), taken at the point \( \cos \theta = L_z/L_3 \), is multiplied by the numerator, \( (L_z - L_3 \cos \theta)^2 \), which turns to zero at this point.
then the coefficient at $\theta^2$ in Eq. (84) is positive, so that $U_{\text{ef}}$ has a stable minimum at $\theta_0 = 0$. On the other hand, if $\omega_3$ is decreased below $\omega_{\text{th}}$, the fixed point becomes unstable, so that the top falls. As the plots in Fig. 11 show, Eq. (85) for the threshold frequency works very well even for non-zero but small values of the precession angle $\theta_0$. Note that if we take $I = I_A$ in the condition (73) of the approximate treatment, it acquires a very simple sense: $\omega_{\text{tot}} \gg \omega_{\text{th}}$.

Finally, Eqs. (82) give a natural description of one more phenomenon. If the initial energy is larger than $U_{\text{ef}}(\theta_0)$, the angle $\theta$ oscillates between two classical turning points on both sides of the fixed point $\theta_0$—see also Fig. 11. The law and frequency of these oscillations may be found exactly as in Sec. 3.3—see Eqs. (3.27) and (3.28). At $\omega_3 \gg \omega_{\text{th}}$, this motion is a fast rotation of the symmetry axis $n_3$ of the body about its average position performing the slow torque-induced precession. Historically, these oscillations are called *nutations*, but their physics is similar to that of the free precession that was analyzed in the previous section, and the order of magnitude of their frequency is given by Eq. (59).

It may be proved that small friction (not taken into account in the above analysis) leads first to decay of these nutations, then to a slower drift of the precession angle $\theta_0$ to zero and, finally, to a gradual decay of the spinning speed $\omega_{\text{tot}}$ until it reaches the threshold (85) and the top falls.

### 4.6. Non-inertial reference frames

To complete this chapter, let us use the results of our analysis of the rotation kinematics in Sec. 1 to complete the discussion of the transfer between two reference frames, started in the introductory Chapter 1. As Fig. 12 (which reproduces Fig. 1.2 in a more convenient notation) shows, even if the “moving” frame $0'$ rotates relative to the “lab” frame $0'$, the radius vectors observed from these two frames are still related, at any moment of time, by the simple Eq. (1.5). In our new notation:

$$r' = r_0 + r.$$  \hspace{1cm} (4.86)

![Fig. 4.12. The general case of transfer between two reference frames.](image)

However, as was mentioned in Sec. 1, for velocities the general addition rule is already more complex. To find it, let us differentiate Eq. (86) over time:

$$\frac{d}{dt} r' = \frac{d}{dt} r_0 + \frac{d}{dt} r.$$  \hspace{1cm} (4.87)

The left-hand side of this relation is evidently the particle’s velocity as measured in the lab frame, and the first term on the right-hand side is the velocity $v_0$ of the point $0$, as measured in the same lab frame.
The last term is more complex: due to the possible mutual rotation of the frames 0 and 0’, that term may not vanish even if the particle does not move relative to the rotating frame 0 – see Fig. 12.

Fortunately, we have already derived the general Eq. (8) to analyze situations exactly like this one. Taking \( \mathbf{A} = \mathbf{r} \) in it, we may apply the result to the last term of Eq. (87), to get

\[
\mathbf{v}_{\text{in lab}} = \mathbf{v}_0 + (\mathbf{v} \times \mathbf{\omega}) + \mathbf{r}, \tag{4.88}
\]

where \( \mathbf{\omega} \) is the instantaneous angular velocity of an imaginary rigid body connected to the moving reference frame (or we may say, of this frame as such), as measured in the lab frame 0’, while \( \mathbf{v} \) is \( \frac{d\mathbf{r}}{dt} \) as measured in the moving frame 0. The relation (88), on one hand, is a natural generalization of Eq. (10) for \( \mathbf{v} \neq 0 \); on the other hand, if \( \mathbf{\omega} = 0 \), it is reduced to simple Eq. (1.8) for the translational motion of the frame 0.

To calculate the particle’s acceleration, we may just repeat the same trick: differentiate Eq. (88) over time, and then use Eq. (8) again, now for the vector \( \mathbf{A} = \mathbf{v} + \mathbf{\omega} \times \mathbf{r} \). The result is

\[
\mathbf{a}_{\text{in lab}} \equiv \mathbf{a}_0 + \frac{d}{dt}(\mathbf{v} \times \mathbf{\omega}) + \mathbf{\omega} \times (\mathbf{v} \times \mathbf{\omega}). \tag{4.89}
\]

Carrying out the differentiation in the second term, we finally get the goal relation,

\[
\mathbf{a}_{\text{in lab}} \equiv \mathbf{a}_0 + \mathbf{a} + \mathbf{\dot{\omega}} \times \mathbf{r} + 2\mathbf{\omega} \times \mathbf{v} + \mathbf{\omega} \times (\mathbf{\omega} \times \mathbf{r}), \tag{4.90}
\]

where \( \mathbf{a} \) is particle’s acceleration, as measured in the moving frame. This result is a natural generalization of the simple Eq. (1.9) to the rotating frame case.

Now let the lab frame 0’ be inertial; then the 2nd Newton law for a particle of mass \( m \) is

\[
ma_{\text{in lab}} = \mathbf{F}, \tag{4.91}
\]

where \( \mathbf{F} \) is the vector sum of all forces exerted on the particle. This is simple and clear; however, in many cases it is much more convenient to work in a non-inertial reference frame; for example, describing most phenomena on Earth’s surface, it is rather inconvenient to use a reference frame resting on the Sun (or in the galactic center, etc.). In order to understand what we should pay for the convenience of using a moving frame, we may combine Eqs. (90) and (91) to write

\[
ma = \mathbf{F} - ma_0 - m\mathbf{\omega} \times (\mathbf{\omega} \times \mathbf{r}) - 2m\mathbf{\omega} \times \mathbf{v} - m\mathbf{\omega} \times \mathbf{\omega} \times \mathbf{r}. \tag{4.92}
\]

This result means that if we want to use a 2nd Newton law’s analog in a non-inertial reference frame, we have to add, to the actual net force \( \mathbf{F} \) exerted on a particle, four pseudo-force terms, called inertial forces, all proportional to particle’s mass. Let us analyze them one by one, always remembering that these are just mathematical terms, not actual forces. (In particular, it would be futile to seek for the 3rd Newton law’s counterpart for any inertial force.)

The first term, \( -ma_0 \), is the only one not related to rotation and is well known from the undergraduate mechanics. (Let me hope the reader remembers all these weight-in-the-moving-elevator problems.) However, despite its simplicity, this term has more subtle consequences. As an example, let us consider, semi-qualitatively, the motion of a planet, such as our Earth, orbiting a star and also rotating about its own axis – see Fig. 13. The bulk-distributed gravity forces, acting on a planet from its star, are
not quite uniform, because they obey the $1/r^2$ gravity law (1.15), and hence are equivalent to a single force applied to a point A slightly offset from the planet’s center of mass $0$, toward the star. For a spherically-symmetric planet, the direction from $0$ to $A$ would be exactly aligned with the direction toward the star. However, real planets are not absolutely rigid, so that, due to the centrifugal “force” (to be discussed imminently), the rotation about their own axis makes them slightly ellipsoidal – see Fig. 13. (For our Earth, this equatorial bulge is about 10 km.) As a result, the net gravity force does create a small torque relative to the center of mass $0$. On the other hand, repeating all the arguments of this section for a body (rather than a point), we may see that, in the reference frame moving with the planet, the inertial force $-Ma_0$ (with the magnitude of the total gravity force, but directed from the star) is applied exactly to the center of mass and hence does not create a torque about it. As a result, this pair of forces creates a torque $\tau$ perpendicular to both the direction toward the star and the vector $0A$. (In Fig. 13, the torque vector is perpendicular to the plane of the drawing). If the angle $\delta$ between the planet’s “polar” axis of rotation and the direction towards the star was fixed, then, as we have seen in the previous section, this torque would induce a slow axis precession about that direction.

However, as a result of the orbital motion, the angle $\delta$ oscillates in time much faster (once a year) between values $(\pi/2 + \varepsilon)$ and $(\pi/2 - \varepsilon)$, where $\varepsilon$ is the axis tilt, i.e. angle between the polar axis (the direction of vectors $L$ and $\omega_{rot}$) and the normal to the ecliptic plane of the planet’s orbit. (For the Earth, $\varepsilon \approx 23.4^\circ$.) A straightforward averaging over these fast oscillations$^{22}$ shows that the torque leads to the polar axis’ precession about the axis perpendicular to the ecliptic plane, keeping the angle $\varepsilon$ constant – see Fig. 13. For the Earth, the period $T_{pre} = 2\pi/0_{pre}$ of this precession of the equinoxes, corrected to a substantial effect of Moon’s gravity, is close to 26,000 years.$^{23}$

Returning to Eq. (92), the direction of the second term of its right-hand side, called the centrifugal force, is always perpendicular to, and directed out of the instantaneous rotation axis – see Fig. 14. Indeed, the vector $\omega \times r$ is perpendicular to both $\omega$ and $r$ (in Fig. 14, normal to the drawing plane and directed from the reader) and has the magnitude $\omega \sin \theta = \omega \rho$, where $\rho$ is the distance of the particle from the rotation axis. Hence the outer vector product, with the account of the minus sign, is normal to the rotation axis $\omega$, directed from this axis, and is equal to $\omega^2 \sin \theta = \omega^2 \rho$. The “centrifugal

$^{22}$ Details of this calculation may be found, e.g., in Sec. 5.8 of the textbook by H. Goldstein et al., Classical Mechanics, 3rd ed., Addison Wesley, 2002.

$^{23}$ This effect is known from antiquity, apparently discovered by Hipparchus of Rhodes (190-120 BC).
force” is of course just the result of the fact that the centripetal acceleration \( \omega^2 \rho \), explicit in the inertial reference frame, disappears in the rotating frame. For a typical location of the Earth (\( \rho \sim R_E \approx 6 \times 10^6 \) m), with its angular velocity \( \omega_E \approx 10^{-4} \) s\(^{-1}\), the acceleration is rather considerable, of the order of 3 cm/s\(^2\), i.e. \( \sim 0.003 \) g, and is responsible, in particular, for the largest part of the equatorial bulge mentioned above.

As an example of using the centrifugal force concept, let us return again to our “testbed” problem on the bead sliding along a rotating ring – see Fig. 2.1. In the non-inertial reference frame attached to the ring, we have to add, to the actual forces \( mg \) and \( N \) acting on the bead, the horizontal centrifugal force\(^{24}\) directed from the rotation axis, with the magnitude \( m\omega^2 \rho \). Its component tangential to the ring equals \( (m\omega^2 \rho)\cos\theta = m\omega^2 R \sin\theta \cos\theta \), and hence the component of Eq. (92) along this direction is \( ma = -mg \sin\theta + m\omega^2 R \sin\theta \cos\theta \). With \( a = R \dot{\theta} \), this gives us an equation of motion equivalent to Eq. (2.25), which had been derived in Sec. 2.2 (in the inertial frame) using the Lagrangian formalism.

The third term on the right-hand side of Eq. (92),

\[
F_C \equiv -2m\omega \times v ,
\]  

(4.94)

is the so-called Coriolis force\(^{25}\), which is different from zero only if the particle moves in the rotating reference frame. Its physical sense may be understood by considering a projectile fired horizontally, say from the North Pole – see Fig. 15.

From the point of view of the Earth-based observer, the projectile will be affected by an additional Coriolis force (94), directed westward, with magnitude \( 2m\omega E v \), where \( v \) is the main, southward component of the velocity. This force would cause the westward acceleration \( a = 2\omega_E v \), and

\[\text{Fig. 4.15. The trajectory of a projectile fired horizontally from the North Pole, from the point of view of an Earth-bound observer looking down. The circles show parallels, while the straight lines mark meridians.}\]

\[\text{Coriolis } \text{"force"}\]

---

\(^{24}\) For this problem, all other inertial “forces”, besides the Coriolis force (see below) vanish, while the latter force is directed perpendicular to the ring and does not affect the bead’s motion along it.

\(^{25}\) Named after G.-G. de Coriolis (already reverently mentioned in Chapter 1) who described its theory and applications in detail in 1835, though the first semi-quantitative analyses of this effect were given by Giovanni Battista Riccioli and Claude François Dechales already in the mid-1600s, and all basic components of the Coriolis theory may be traced to a 1749 work by Leonard Euler.
hence the westward deviation growing with time as $d = \frac{at^2}{2} = \omega_E vt^2$. (This formula is exact only if $d$ is much smaller than the distance $r = vt$ passed by the projectile.) On the other hand, from the point of view of an inertial-frame observer, the projectile’s trajectory in the horizontal plane is a straight line. However, during the flight time $t$, the Earth surface slips eastward from under the trajectory by the distance $d = r\varphi = (vt)(\omega_E t) = \omega_E vt^2$, where $\varphi = \omega_E t$ is the azimuthal angle of the Earth rotation during the flight). Thus, both approaches give the same result – as they should.

Hence, the Coriolis “force” is just a fancy (but frequently very convenient) way of description of a purely geometric effect pertinent to the rotation, from the point of view of the observer participating in it. This force is responsible, in particular, for the higher right banks of rivers in the Northern hemisphere, regardless of the direction of their flow – see Fig. 16. Despite the smallness of the Coriolis force (for a typical velocity of the water in a river, $v \sim 1$ m/s, it is equivalent to acceleration $a_C \sim 10^{-2}$ cm/s$^2 \sim 10^{-5}$ g), its multi-century effects may be rather prominent.\textsuperscript{26}

Finally, the last, fourth term of Eq. (92), $-m\dot{\omega} \times r$, exists only when the rotation frequency changes in time, and may be interpreted as a local-position-specific addition to the first term.

The key relation (92), derived above from the Newton equation (91), may be alternatively obtained from the Lagrangian approach, which gives, as a by-product, some important insights on the momentum, as well as on the relation between $E$ and $H$, at rotation. Let us use Eq. (88) to represent the kinetic energy of the particle in an inertial “lab” frame in terms of $v$ and $r$ measured in a rotating frame:

$$T = \frac{m}{2} \left[ v_0 |_{\text{in lab}} + (v + \omega \times r) \right]^2,$$

and use this expression to calculate the Lagrangian function. For the relatively simple case of a particle’s motion in the field of potential forces, measured from a reference frame that performs a pure rotation (so that $v_0 |_{\text{in lab}} = 0$)\textsuperscript{27} with a constant angular velocity $\omega$, we get

$$L \equiv T - U = \frac{m}{2} v^2 + m v \cdot (\omega \times r) + \frac{m}{2} (\omega \times r)^2 - U \equiv \frac{m}{2} v^2 + m v \cdot (\omega \times r) - U_{\text{ef}},$$

\textsuperscript{26} The same force causes the counter-clockwise circulation in the “Nor’easter” storms on the US East Coast, having an the air velocity component directed toward the cyclone’s center, due to lower pressure in its middle.

\textsuperscript{27} A similar analysis of the cases with $v_0 |_{\text{in lab}} \neq 0$, for example, of a translational relative motion of the reference frames, is left for reader’s exercise.
where the effective potential energy,\(^{28}\)

\[ U_{ef} \equiv U + U_{cf}, \quad \text{with} \quad U_{cf} \equiv -\frac{m}{2}(\omega \times r)^2, \quad (4.96b) \]

is just the sum of the actual potential energy \(U\) of the particle and the so-called *centrifugal potential energy*, associated with the centrifugal force (93):

\[ \mathbf{F}_{cf} = -\nabla U_{cf} = -\nabla \left[ -\frac{m}{2}(\omega \times r)^2 \right] = -m\omega \times (\omega \times r). \quad (4.97) \]

It is straightforward to verify that the Lagrangian equations of motion derived from Eqs. (96), considering the Cartesian components of \(\mathbf{r}\) and \(\mathbf{v}\) as generalized coordinates and velocities, coincide with Eq. (92) (with \(a_{0|\text{lab}} = 0, \ \dot{\phi} = 0,\) and \(\mathbf{F} = -\nabla U\)). Now it is very informative to have a look at a by-product of this calculation, the generalized momentum (2.31) corresponding to the particle’s coordinate \(\mathbf{r}\) as measured in the rotating reference frame,\(^{29}\)

\[
\mathbf{p} \equiv \frac{\partial L}{\partial \dot{\mathbf{v}}} = m(\mathbf{v} + \omega \times \mathbf{r}). \quad (4.98)
\]

According to Eq. (88) with \(v_{0|\text{lab}} = 0\), the expression in the parentheses is just \(v_{|\text{lab}}\). However, from the point of view of the moving frame, i.e. not knowing about the simple physical sense of the vector \(\mathbf{p}\), we would have a reason to speak about two different linear momenta of the same particle, the so-called *kinetic momentum* \(\mathbf{p} = m\mathbf{v}\) and the *canonical momentum* \(\mathbf{p} = \mathbf{p} + m\omega \times \mathbf{r}\).\(^{30}\)

Now let us calculate the Hamiltonian function \(H\), defined by Eq. (2.32), and the energy \(E\) as functions of the same moving-frame variables:

\[
H \equiv \sum_{j=1}^{3} \frac{\partial L}{\partial \dot{v}_j} v_j - L = \mathbf{p} \cdot \mathbf{v} - L = m(\mathbf{v} + \omega \times \mathbf{r}) \cdot \mathbf{v} - \left[ \frac{m}{2} v^2 + m\mathbf{v} \cdot (\omega \times \mathbf{r}) - U_{ef} \right] = \frac{mv^2}{2} + U_{ef}, \quad (4.99)
\]

\[
E \equiv T + U = \frac{m}{2} v^2 + m\mathbf{v} \cdot (\omega \times \mathbf{r}) + \frac{m}{2} (\omega \times r)^2 + U = \frac{m}{2} v^2 + U_{ef} + m\mathbf{v} \cdot (\omega \times \mathbf{r}) + m(\omega \times \mathbf{r})^2. \quad (4.100)
\]

These expressions clearly show that \(E\) and \(H\) are *not* equal.\(^{31}\) In hindsight, this is not surprising, because the kinetic energy (95), expressed in the moving-frame variables, includes a term linear in \(\mathbf{v}\), and hence

---

\(^{28}\) For the attentive reader who has noticed the difference between the negative sign in the expression for \(U_{cf}\), and the positive sign before the similar second term in Eq. (3.44): as was already discussed in Chapter 3, this difference is due to the difference of assumptions. In the planetary problem, the angular momentum \(\mathbf{L}\) (and hence its component \(L_z\)) is fixed, while the corresponding angular velocity \(\dot{\phi}\) is not. On the opposite, in our current discussion, the angular velocity \(\omega\) of the reference frame is assumed to be fixed, i.e. is independent of \(\mathbf{r}\) and \(\mathbf{v}\).

\(^{29}\) Here \(\partial L/\partial \dot{\mathbf{v}}\) is just a shorthand for a vector with Cartesian components \(\partial L/\partial v_j\). In a more formal language, this is the gradient of the scalar function \(L\) in the velocity space.

\(^{30}\) A very similar situation arises at the motion of a particle with electric charge \(q\) in magnetic field \(\mathbf{B}\). In that case, the role of the additional term \(\mathbf{p} = m\omega \times \mathbf{r}\) is played by the product \(q\mathbf{A}\), where \(\mathbf{A}\) is the vector potential of the field \((\mathbf{B} = \nabla \times \mathbf{A})\) – see, e.g., EM Sec. 9.7, and in particular Eqs. (9.183) and (9.192).

\(^{31}\) Please note the last form of Eq. (99), which shows the physical sense of the Hamiltonian function of a particle in the rotating frame very clearly, as the sum of its kinetic energy (as measured in the moving frame), and the effective potential energy (96b), including that of the centrifugal “force”.
is not a quadratic-homogeneous function of this generalized velocity. The difference of these functions
may be represented as
\[
E - H = m\mathbf{v} \cdot (\mathbf{\omega} \times \mathbf{r}) + m(\mathbf{\omega} \times \mathbf{r})^2 = m(\mathbf{v} + \mathbf{\omega} \times \mathbf{r}) \cdot (\mathbf{\omega} \times \mathbf{r}) = m\mathbf{v}_{\text{lab}} \cdot (\mathbf{\omega} \times \mathbf{r}). \tag{4.101}
\]
Now using the operand rotation rule again, we may transform this expression into a simpler form:32
\[
E - H = \mathbf{\omega} \cdot (\mathbf{r} \times m\mathbf{v}_{\text{lab}}) = \mathbf{\omega} \cdot (\mathbf{r} \times \mathbf{L}) = \mathbf{\omega} \cdot \mathbf{L}_{\text{lab}}. \tag{4.102}
\]
As a sanity check, let us apply this general expression to the particular case of our testbed
problem – see Fig. 2.1. In this case, the vector \( \mathbf{\omega} \) is aligned with the \( z \)-axis, so that of all Cartesian
components of the vector \( \mathbf{L} \), only the component \( L_z \) is important for the scalar product in Eq. (102). This
component evidently equals \( \omega L_z = \omega m \rho^2 = \omega m (R \sin \theta)^2 \), so that
\[
E - H = m \omega^2 R^2 \sin^2 \theta, \tag{4.103}
\]
i.e. the same result that follows from the subtraction of Eqs. (2.40) and (2.41).

### 4.7. Exercise problems

#### 4.1. Calculate the principal moments of inertia for the following uniform rigid bodies:

(i) a thin, planar, round hoop, (ii) a flat round disk, (iii) a thin spherical shell, and (iv) a solid sphere.
Compare the results, assuming that all the bodies have the same radius \( R \) and mass \( M \).

#### 4.2. Calculate the principal moments of inertia for the rigid bodies shown in the figure below:

(i) an equilateral triangle made of thin rods with a uniform linear mass density \( \mu \),
(ii) a thin plate in the shape of an equilateral triangle, with a uniform areal mass density \( \sigma \), and

---

32 Note that by the definition (1.36), the angular momenta \( \mathbf{L} \) of particles merely add up. As a result, the final form
of Eq. (102) is valid for an arbitrary system of particles.
(iii) a tetrahedron made of a heavy material with a uniform bulk mass density $\rho$. Assuming that the total mass of the three bodies is the same, compare the results and give an interpretation of their difference.

4.3. Prove that Eqs. (34)-(36) are valid for rotation of a rigid body about a fixed axis $z$, even if it does not pass through its center of mass.

4.4. The end of a uniform, thin rod of length $2l$ and mass $m$, initially at rest, is hit by a bullet of mass $m'$, flying with velocity $v_0$ (see the figure on the right), which gets stuck in the rod. Use two different approaches to calculate the velocity of the opposite end of the rod right after the collision.

4.5. A uniform ball is placed on a horizontal plane, while rotating with an angular velocity $\omega_0$, but having no initial linear velocity. Calculate the angular velocity after the ball’s slippage stops, assuming the Coulomb approximation for the kinetic friction force: $F_f = \mu N$, where $N$ is a pressure between the surfaces, and $\mu$ is a velocity-independent coefficient.

4.6. A body may rotate about a fixed horizontal axis A – see Fig. 5. Find the frequency of its small oscillations, in a uniform gravity field, as a function of the distance $l$ of the axis from the body’s center of mass 0, and analyze the result.

4.7. Calculate the frequency, and sketch the mode of oscillations of a round uniform cylinder of radius $R$ and the mass $M$, that may roll, without slipping, on a horizontal surface of a block of mass $M'$. The block, in turn, may move in the same direction, without friction, on a horizontal surface, being connected to it with an elastic spring – see the figure on the right.

4.8. A thin uniform bar of mass $M$ and length $l$ is hung on a light thread of length $l'$ (like a “chime” bell – see the figure on the right). Derive the equations of motion of the system within the plane of the drawing.

4.9. A solid, uniform, round cylinder of mass $M$ can roll, without slipping, over a concave, round cylindrical surface of a block of mass $M'$, in a uniform gravity field – see the figure on the right. The block can slide without friction on a horizontal surface. Using the Lagrangian formalism,

(i) find the frequency of small oscillations of the system near the equilibrium, and
(ii) sketch the oscillation mode for the particular case $M' = M$, $R' = 2R$.

4.10. A uniform solid hemisphere of radius $R$ is placed on a horizontal plane – see the figure on the right. Find the frequency of its small oscillations within a vertical plane, for two ultimate cases:
(i) there is no friction between the hemisphere and plane surfaces, and
(ii) the static friction is so strong that there is no slippage between these surfaces.

4.11. For the “sliding ladder” problem, started in Sec. 3 (see Fig. 7), find the critical value $\alpha_c$ of
the angle $\alpha$ at that the ladder loses its contact with the vertical wall, assuming that it starts sliding from
the vertical position, with a negligible initial velocity.

4.12. Six similar, uniform rods of length $l$ and mass $m$ are connected by
light joints so that they may rotate, without friction, versus each other, forming
a planar polygon. Initially, the polygon was at rest, and had the correct hexagon
shape – see the figure on the right. Suddenly, an external force $\mathbf{F}$ is applied to
the middle of one rod, in the direction of the hexagon’s symmetry center.
Calculate the accelerations: of the rod to which the force is applied ($a$), and of
the opposite rod ($a'$), immediately after the application of the force.

4.13. A rectangular cuboid (parallelepiped) with sides $a_1$, $a_2$, and $a_3$,
made of a material with a constant mass density $\rho$, is rotated, with a constant
angular velocity $\omega$, about one of its space diagonals – see the figure on the
right. Calculate the torque $\tau$ necessary to sustain such rotation.

4.14. One end of a light shaft of length $l$ is firmly
attached to the center of a thin uniform solid disk of radius $R \ll
l$ and mass $M$, whose plane is perpendicular to the shaft. Another
end of the shaft is attached to a vertical axis (see the figure on
the right) so that the shaft may rotate about the axis without
friction. The disk rolls, without slippage, over a horizontal surface, so that the whole system rotates
about the vertical axis with a constant angular velocity $\omega$. Calculate the (vertical) supporting force $N$
exerted on the disk by the surface.

4.15. An air-filled balloon is placed inside a water-filled container, which moves by inertia in
free space, at negligible gravity. Suddenly, force $\mathbf{F}$ is applied to the container, pointing in a certain
direction. What direction does the balloon move relative to the container?

4.16. Two planets are in a circular orbit around their common center of mass. Calculate the
effective potential energy of a much lighter body (say, a spacecraft) rotating with the same angular
velocity, on the line connecting the planets. Sketch the plot of the radial dependence of $U_{\text{ef}}$ and find out
the number of so-called Lagrange points is which the potential energy has local maxima. Calculate their
position explicitly in the limit when one of the planets is much more massive than the other one.

4.17. A small body is dropped down to the surface of Earth from height $h \ll R_E$, without initial
velocity. Calculate the magnitude and direction of its deviation from the vertical, due to the Earth
rotation. Estimate the effect’s magnitude for a body dropped from the Empire State Building.
4.18. Calculate the height of solar tides on a large ocean, using the following simplifying assumptions: the tide period (½ of Earth's day) is much longer than the period of all ocean waves, the Earth (of mass $M_E$) is a sphere of radius $R_E$, and its distance $r_S$ from the Sun (of mass $M_S$) is constant and much larger than $R_E$.

4.19. A coin of radius $r$ is rolled, with velocity $V$, on a horizontal surface without slippage. What should be the coin's tilt angle $\theta$ (see the figure on the right) for it to roll on a circle of radius $R >> r$? Modeling the coin as a very thin, uniform disk, and assuming that the angle $\theta$ is small, solve this problem in:

(i) an inertial ("lab") reference frame, and
(ii) the non-inertial reference frame moving with the coin's center (but not rotating with it).

4.20. A satellite is on a circular orbit of radius $R$, around the Earth.

(i) Write the equations of motion of a small body as observed from the satellite, and simplify them for the case when the motion is limited to the satellite’s close vicinity.

(ii) Use the equations to prove that the body may be placed on an elliptical trajectory around the satellite’s center of mass, within its plane of rotation about Earth. Calculate the ellipse’s orientation and eccentricity.

4.21. A non-spherical shape of an artificial satellite may ensure its stable angular orientation relative to Earth’s surface, advantageous for many practical goals. Modeling the satellite as a strongly elongated, axially-symmetric body, moving around the Earth on a circular orbit of radius $R$, find its stable orientation.

4.22. A rigid, straight, uniform rod of length $l$, with the lower end on a pivot, falls in a uniform gravity field – see the figure on the right. Neglecting friction, calculate the distribution of the bending torque $\tau$ along its length, and analyze the result.

Hint: The bending torque is the net torque of the force $F$ acting between two parts of the rod, mentally separated by its cross-section, about a certain "neutral axis". As will be discussed in detail in Sec. 7.5, at the proper definition of this axis, the bending torque’s gradient along the rod’s length is equal to $(-F)$, where $F$ is the rod-normal ("shear") component of the force exerted by the top part of the rod on its lower part.

4.23. Let $\mathbf{r}$ be the radius vector of a particle, as measured in a possibly non-inertial but certainly non-rotating reference frame. Taking its Cartesian components for the generalized coordinates, calculate the corresponding generalized momentum $\mathbf{p}$ of the particle, and its Hamiltonian function $H$. Compare $\mathbf{p}$ with $m\mathbf{v}$, and $H$ with the particle’s energy $E$. Derive the Lagrangian equation of motion in this approach, and compare it with Eq. (92).

---

33 Inadequate definitions of this torque are the main reason for numerous wrong solutions of this problem, posted online – readers beware!
Chapter 5. Oscillations

In this course, oscillations and waves are discussed in detail, because of their importance for fundamental and applied physics. This chapter starts with a discussion of the so-called “linear” (or “harmonic”) oscillator, whose differential equation of motion is linear and hence allows the full analytical solution, and then proceed to “nonlinear” and parametric systems whose dynamics may be only explored by either approximate analytical or numerical methods.

5.1. Free and forced oscillations

In Sec. 3.2 we briefly discussed oscillations in a keystone Hamiltonian system – a 1D harmonic oscillator described by a very simple Lagrangian

\[ L = T(q) - U(q) = \frac{m}{2} \dot{q}^2 - \frac{k}{2} q^2 , \]

whose Lagrange equation of motion,\(^2\)

\[ m \ddot{q} + k q = 0, \quad \text{i.e. } \ddot{q} + \omega_0^2 q = 0, \quad \text{with } \omega_0^2 \equiv \frac{k}{m} \geq 0 , \]

is a linear homogeneous differential equation. Its general solution is given by (3.16), which is frequently recast into another, amplitude-phase form:

\[ q(t) = u \cos \omega_0 t + v \sin \omega_0 t = A \cos (\omega_0 t - \varphi) , \]  

where \( A \) is the amplitude and \( \varphi \) the phase of the oscillations, which are determined by the initial conditions. Mathematically, it is frequently easier to work with sinusoidal functions as complex exponents, by rewriting the last form of Eq. (3a) in one more form:\(^3\)

\[ q(t) = \text{Re} \left[ A e^{-i(\omega_0 t - \varphi)} \right] = \text{Re} \left[ a e^{-i\omega_0 t} \right] , \]

where \( a \) is the complex amplitude of the oscillations:

\[ a \equiv A e^{i\varphi} , \quad |a| = A , \quad \text{Re} a = A \cos \varphi = u , \quad \text{Im} a = A \sin \varphi = v . \]

For an autonomous, Hamiltonian oscillator, Eq. (3) gives the full classical description of its dynamics. However, it is important to understand that this free-oscillation solution, with a constant amplitude \( A \), is

---

1 For the notation brevity, in this chapter I will drop indices “ef” in the energy components \( T \) and \( U \), and parameters like \( m, k \), etc. However, the reader should still remember that \( T \) and \( U \) do not necessarily coincide with the actual kinetic and potential energies (even if those energies may be uniquely identified) – see Sec. 3.1.

2 \( \omega_0 \) is usually called the own frequency of the oscillator. In quantum mechanics, the Germanized version of the same term, eigenfrequency, is used more. In this series, I will use either of the terms, depending on the context.

3 Note that this is the so-called physics convention. Most engineering texts use the opposite sign in the imaginary exponent, \( \exp \{-i\omega t\} \to \exp \{i\omega t\} \), with the corresponding sign implications for intermediate formulas, but (of course) similar final results for real variables.
due to the conservation of the energy \( E \equiv T + U = \kappa A^2/2 \) of the oscillator. If its energy changes for any reason, the description needs to be generalized.

First of all, if the energy leaks out of the oscillator to its environment (the effect usually called the energy dissipation), the free oscillations decay with time. The simplest model of this effect is represented by an additional linear drag (or “kinematic friction”) force, proportional to the generalized velocity and directed opposite to it:

\[
F_v = -\eta \dot{q},
\]

where constant \( \eta \) is called the drag coefficient.\(^4\) The inclusion of this force modifies the equation of motion (2) to become

\[
m \ddot{q} + \eta \dot{q} + \kappa q = 0. \tag{5.6a}
\]

This equation is frequently rewritten in the form

\[
\ddot{q} + 2\delta \dot{q} + \omega_0^2 q = 0, \quad \text{with} \quad \delta = \frac{\eta}{2m},
\]

where the parameter \( \delta \) is called the damping coefficient (or just “damping”). Note that Eq. (6) is still a linear homogeneous second-order differential equation, and its general solution still has the form of the sum (3.13) of two exponents of the type \( \exp\{\lambda t\} \), with arbitrary pre-exponential coefficients. Plugging such an exponent into Eq. (6), we get the following algebraic characteristic equation for \( \lambda \):

\[
\lambda^2 + 2\delta \lambda + \omega_0^2 = 0.
\]

Solving this quadratic equation, we get

\[
\lambda_{\pm} = -\delta \pm i \omega_0', \quad \text{where} \quad \omega_0' \equiv \left(\omega_0^2 - \delta^2\right)^{1/2}, \tag{5.8}
\]

so that for not very high damping (\( \delta < \omega_0 \))\(^5\) we get the following generalization of Eq. (3):

\[
q_{\text{free}}(t) = c_+ e^{\lambda_++t} + c_- e^{\lambda_--t} = \left(u_0 \cos \omega_0' t + v_0 \sin \omega_0' t\right) e^{-\delta t} = A_0 e^{-\delta t} \cos(\omega_0' t - \varphi_0). \tag{5.9}
\]

The result shows that, besides a certain correction to the free oscillation frequency (which is very small in the most interesting low damping limit, \( \delta \ll \omega_0 \)), the energy dissipation leads to an exponential decay of oscillation amplitude with the time constant \( \tau = 1/\delta \):

---

\(^4\) Here Eq. (5) is treated as a phenomenological model, but in statistical mechanics, such dissipative term may be derived as an average force exerted upon a system by its environment, at very general assumptions. As discussed in detail elsewhere in this series (SM Chapter 5 and QM Chapter 7), due to the numerous degrees of freedom of a typical environment (think about the molecules of air surrounding the usual mechanical pendulum), its force also has a random component; as a result, the dissipation is fundamentally related to fluctuations. The latter effects may be neglected (as they are in this course) only if \( E \) is much higher than the energy scale of the random fluctuations of the oscillator – in the thermal equilibrium at temperature \( T \), the larger of \( k_B T \) and \( \hbar \omega_0/2 \).

\(^5\) Systems with high damping (\( \delta > \omega_0 \)) can hardly be called oscillators, and though they are used in engineering and physics experiment (e.g., for the shock, vibration, and sound isolation), for their detailed discussion I have to refer the interested reader to special literature – see, e.g., C. Harris and A. Piersol, Shock and Vibration Handbook, 5th ed., McGraw Hill, 2002. Let me only note that dynamics of systems with very high damping (\( \delta >> \omega_0 \)) has two very different time scales: a relatively short “momentum relaxation time” \( 1/\lambda_+ \approx 1/2\delta = m/\eta \), and a much longer “coordinate relaxation time” \( 1/\lambda_- \approx 2\delta/\omega_0^2 = \eta/\kappa \).
A very popular dimensionless measure of damping is the so-called quality factor Q (or just the Q-factor) that is defined as $\omega_0/2\delta$, and may be rewritten in several other useful forms:

$$Q \equiv \frac{\omega_0}{2\delta} = \frac{m\omega_0}{\eta} = \frac{(m\kappa)^{1/2}}{\eta} = \frac{\pi}{\tau} = \frac{\omega_0\tau}{2},$$

(5.11)

where $\tau = 2\pi/\omega_0$ is the oscillation period in the absence of damping – see Eq. (3.29). Since the oscillation energy $E$ is proportional to $A^2$, i.e. decays as $\exp\{-2t/\tau\}$, with the time constant $\tau/2$, the last form of Eq. (11) may be used to rewrite the Q-factor in one more form:

$$Q = \omega_0 \frac{E}{(-\dot{E})} = \omega_0 \frac{E}{P},$$

(5.12)

where $P$ is the dissipation power. (Two other practical ways to measure $Q$ will be discussed below.) The range of $Q$-factors of important oscillators is very broad, all the way from $Q \sim 10$ for a human leg (with relaxed muscles), to $Q \sim 10^4$ of the quartz crystals used in electronic clocks and watches, all the way up to $Q \sim 10^{12}$ for carefully designed microwave cavities with superconducting walls.

In contrast to the decaying free oscillations, the forced oscillations, induced by an external force $F(t)$, may maintain their amplitude (and hence energy) infinitely, even at non-zero damping. This process may be described using a still linear but now inhomogeneous differential equation

$$m\ddot{q} + \eta \dot{q} + \kappa q = F(t),$$

(5.13a)

or, more conveniently for analysis, the following generalization of Eq. (6b):

$$\ddot{q} + 2\delta\dot{q} + \omega_0^2 q = f(t), \quad \text{where } f(t) \equiv F(t)/m.$$

(5.13b)

For a mechanical linear, dissipative 1D oscillator (6), under the effect of an additional external force $F(t)$, Eq. (13a) is just an expression of the 2nd Newton law. However, according to Eq. (1.41), Eq. (13) is valid for any dissipative, linear 1D system whose Gibbs potential energy (1.39) has the form $U_G(q, t) = \kappa q^2/2 - F(t)q$.

The forced-oscillation solutions may be analyzed by two mathematically equivalent methods whose relative convenience depends on the character of function $f(t)$.

(i) Frequency domain. Representing the function $f(t)$ as a Fourier sum of sinusoidal harmonics:

$$f(t) = \sum_{\omega} f_{\omega} e^{-i\omega t},$$

(5.14)

and using the linearity of Eq. (13), we may represent its general solution as a sum of the decaying free oscillations (9) with the frequency $\omega_0\delta$, independent of the function $f(t)$, and forced oscillations due to each of the Fourier components of the force:

\begin{itemize}
  \item [6] This is a very unfortunate, but common jargon, meaning “the system described by linear equations of motion”.
  \item [7] Here, in contrast to Eq. (3b), we may drop the operator Re, assuming that $f_{\omega} = f_{\omega}^*$, so that the imaginary components of the sum compensate each other.
\end{itemize}
Plugging Eq. (15) into Eq. (13), and requiring the factors before each \(e^{-i\omega t}\) on both sides to be equal, we get

\[ a_\omega = f_\omega \chi(\omega), \tag{5.16} \]

where the complex function \(\chi(\omega)\), in our particular case equal to

\[ \chi(\omega) = \frac{1}{(\omega_0^2 - \omega^2 - 2i\omega\delta)}, \tag{5.17} \]

is called either the response function or (especially for non-mechanical oscillators) the generalized susceptibility. From here, and Eq. (4), the amplitude of the oscillations under the effect of a sinusoidal force is

\[ A_\omega \equiv |a_\omega| = |f_\omega| |\chi(\omega)|, \quad \text{with} \quad |\chi(\omega)| = \frac{1}{\sqrt{(\omega_0^2 - \omega^2 + 2i\omega\delta)^2 + (2\omega\delta)^2}}. \tag{5.18} \]

This formula describes, in particular, an increase of the oscillation amplitude \(A_\omega\) at \(\omega \to \omega_0\) – see the left panel in Fig. 1. In particular, at the exact equality of these two frequencies,

\[ |\chi(\omega)|_{\omega=\omega_0} = \frac{1}{2\omega_0\delta}, \tag{5.19} \]

so that, according to Eq. (11), the ratio of the response magnitudes at \(\omega = \omega_0\) and \(\omega = 0\) (\(|\chi(\omega)|_{\omega=0} = 1/\omega_0^2\)) is exactly equal to the \(Q\)-factor of the oscillator. Thus, the response increase is especially strong in the low damping limit \((\delta << \omega_0, \text{i.e.} Q >> 1)\); moreover at \(Q \to \infty\) and \(\omega \to \omega_0\) the response diverges. (This fact is very useful for the methods to be discussed later in this section.) This is the classical description of the famous phenomenon of resonance, so ubiquitous in physics.

---

\[8\] In physics, this mathematical property of linear equations is frequently called the linear superposition principle.
Due to the increase of the resonance peak height, its width is inversely proportional to $Q$. Quantitatively, in the most interesting low-damping limit, i.e. at $Q \gg 1$, the reciprocal $Q$-factor gives the normalized value of the so-called full-width at half-maximum (FWHM) of the resonance curve:

$$\frac{\Delta \omega}{\omega_0} = \frac{1}{Q}. \quad (5.20)$$

Indeed, this $\Delta \omega$ is defined as the difference ($\omega_+ - \omega_-$) between the two values of $\omega$ at that the square of the oscillator response function, $|\chi(\omega)|^2$ (which is proportional to the oscillation energy), equals a half of its resonance value (19). In the low damping limit, both these points are very close to $\omega_0$, so that in the linear approximation in $|\omega - \omega_0| \ll \omega_0$, we may write $(\omega_+^2 - \omega_-^2) \approx -(\omega + \omega_0)(\omega - \omega_0) \approx -2\omega\xi \approx -2\omega_0\xi$, where

$$\xi \equiv \omega - \omega_0 \quad (5.21)$$

is a very convenient parameter called detuning, which will be repeatedly used later in this chapter. In this approximation, the second of Eqs. (18) is reduced to

$$\left|\chi(\omega)\right|^2 = \frac{1}{4\omega_0^2 (\delta^2 + \xi^2)}. \quad (5.22)$$

As a result, the points $\omega_\pm$ correspond to $\xi^2 = \delta^2$, i.e. $\omega_\pm = \omega_0 \pm \delta = \omega_0 (1 \pm 1/2Q)$, so that $\Delta \omega = \omega_+ - \omega_- = \omega_0/Q$, thus proving Eq. (20).

(ii) Time domain. Returning to arbitrary external force $f(t)$, one may argue that Eqs. (9), (15)-(17) provide a full solution of the forced oscillation problem even in this general case. This is formally correct, but this solution may be very inconvenient if the external force is far from a sinusoidal function of time, especially if it is not periodic at all. In this case, we should first calculate the complex amplitudes $f_\omega$ participating in the Fourier sum (14). In the general case of a non-periodic $f(t)$, this is actually the Fourier integral,

$$f(t) = \int_{-\infty}^{+\infty} f_\omega e^{-i\omega t} \, dt, \quad (5.23)$$

so that $f_\omega$ should be calculated using the reciprocal Fourier transform,

$$f_\omega = \frac{1}{2\pi} \int_{-\infty}^{+\infty} f(t') e^{i\omega t'} \, dt'. \quad (5.24)$$

Now we may use Eq. (16) for each Fourier component of the resulting forced oscillations, and rewrite the last of Eqs. (15) as

---

9 Note that the phase shift $\phi = \arg[\chi(\omega)]$ between the oscillations and the external force (see the right panel in Fig. 1) makes its steepest change, by $\pi/2$, within the same frequency interval $\Delta \omega$.

10 Let me hope that the reader knows that Eq. (23) may be used for periodic functions as well; in such a case, $f_\omega$ is a set of equidistant delta-functions. (A reminder of the basic properties of the Dirac $\delta$-function may be found, for example, in MA Sec. 14.)
\[ q_{\text{forced}}(t) = \int_{-\infty}^{+\infty} a_\omega e^{-i\omega t} d\omega = \int_{-\infty}^{+\infty} \chi(\omega) f_\omega e^{-i\omega t} d\omega = \int_{-\infty}^{+\infty} d\omega \chi(\omega) \frac{1}{2\pi} \int_{-\infty}^{+\infty} dt' f(t') e^{i\omega(t'-t)} \]

\[ = \int_{-\infty}^{+\infty} dt' f(t') \left[ \frac{1}{2\pi} \int_{-\infty}^{+\infty} d\omega \chi(\omega) e^{i\omega(t'-t)} \right] , \]

(5.25)

with the response function \( \chi(\omega) \) given, in our case, by Eq. (17). Besides requiring two integrations, Eq. (25) is conceptually uncomforting: it seems to indicate that the oscillator’s coordinate at time \( t \) depends not only on the external force exerted at earlier times \( t' < t \), but also at future times. This would contradict one of the most fundamental principles of physics (and indeed, science as a whole), the \textit{causality}: no effect may precede its cause.

Fortunately, a straightforward calculation (left for the reader’s exercise) shows that the response function (17) satisfies the following rule: 11

\[ \int_{-\infty}^{+\infty} \chi(\omega)e^{-i\omega\tau} d\omega = 0, \quad \text{for } \tau < 0. \]

(5.26)

This fact allows the last form of Eq. (25) to be rewritten in either of the following equivalent forms:

\[ q_{\text{forced}}(t) = \int_{-\infty}^{t} f(t') G(t-t') dt' \equiv \int_{0}^{\infty} f(t-\tau) G(\tau) d\tau , \]

(5.27)

where \( G(\tau) \), defined as the Fourier transform of the response function,

\[ G(\tau) = \frac{1}{2\pi} \int_{-\infty}^{+\infty} \chi(\omega)e^{-i\omega\tau} d\omega , \]

(5.28)

is called the \textit{(temporal) Green’s function} of the system. According to Eq. (26), \( G(\tau) = 0 \) for all \( \tau < 0 \).

While the second form of Eq. (27) is frequently more convenient for calculations, its first form is more suitable for physical interpretation of the Green’s function. Indeed, let us consider the particular case when the force is a delta-function

\[ f(t) = \delta(t - t'), \quad \text{with } t' < t, \quad \text{i.e. } \tau \equiv t - t' > 0 , \]

(5.29)

representing an ultimately short pulse at the moment \( t' \), with unit “area” \( \int f(t') dt' \). Substituting Eq. (29a) into Eq. (27), 12 we get

\[ q(t) = G(t - t'). \]

(5.30)

Thus the Green’s function \( G(t - t') \) is just the oscillator’s response, as measured at time \( t \), to a short force pulse of unit “area”, exerted at time \( t' \). Hence Eq. (27) expresses the linear superposition principle in the time domain: the full effect of the force \( f(t) \) on a linear system is a sum of effects of short pulses of duration \( dt' \) and magnitude \( f(t') \), each with its own “weight” \( G(t - t') \) – see Fig. 2.

---

11 Eq. (26) remains true for any linear physical systems in which \( f(t) \) represents a cause, and \( q(t) \) its effect. Following tradition, I discuss the frequency-domain expression of this causality relation (called the \textit{Kramers-Kronig relations}) in the \textit{Classical Electrodynamics} part of this lecture series – see EM Sec. 7.2.

12 Technically, for this integration, \( t' \) in Eq. (27) should be temporarily replaced with another letter, say \( t'' \).
Fig. 5.2. A schematic, finite-interval representation of a force \( f(t) \) as a sum of short pulses at all times \( t' < t \), and their contributions to the linear system’s response \( q(t) \), as given by Eq. (27).

This picture may be used for the calculation of Green’s function for our particular system. Indeed, Eqs. (29)-(30) mean that \( G(\tau) \) is just the solution of the differential equation of motion of the system, in our case, Eq. (13), with the replacement \( t \to \tau \), and a \( \delta \)-functional right-hand side:

\[
\frac{d^2G(\tau)}{d\tau^2} + 2\delta \frac{dG(\tau)}{d\tau} + \omega_0^2 G(\tau) = \delta(\tau).
\]  

(5.31)

Since Eqs. (27) describes only the second term in Eq. (15), i.e. only the forced, rather than free oscillations, we have to exclude the latter by solving Eq. (31) with zero initial conditions:

\[
G(-0) = \frac{dG}{d\tau}(-0) = 0,
\]  

(5.32)

where \( \tau = -0 \) means the instant immediately preceding \( \tau = 0 \).

This calculation may be simplified even further. Let us integrate both sides of Eq. (31) over an infinitesimal interval including the origin, e.g. \([-d\tau/2, +d\tau/2]\), and then follow the limit \( d\tau \to 0 \). Since the Green’s function has to be continuous because of its physical sense as the (generalized) coordinate, all terms on the left-hand side but the first one vanish, while the first term yields \( dG/d\tau\big|_{-0} - dG/d\tau\big|_{+0} \). Due to the second of Eqs. (32), the last of these two derivatives equals zero, while the right-hand side of Eq. (31) yields 1 upon the integration. Thus, the function \( G(\tau) \) may be calculated for \( \tau > 0 \) (i.e. for all times when it is different from zero) by solving the homogeneous version of the system’s equation of motion for \( \tau > 0 \), with the following special initial conditions:

\[
G(0) = 0, \quad \frac{dG}{d\tau}(0) = 1.
\]  

(5.33)

This approach gives us a convenient way for the calculation of Green’s functions of linear systems. In particular for the oscillator with not very high damping \( (\delta < \omega_0, \text{ i.e. } Q > \frac{1}{2}) \), imposing the boundary conditions (33) on the homogeneous equation’s solution (9), we immediately get

\[
G(\tau) = \frac{1}{\omega_0'} e^{-\delta\tau} \sin \omega_0' \tau.
\]  

(5.34)

(The same result may be obtained directly from Eq. (28) with the response function \( \chi(\omega) \) given by Eq. (19). This way is, however, a little bit more cumbersome, and is left for the reader’s exercise.)

Relations (27) and (34) provide a very convenient recipe for solving many forced oscillations problems. As a very simple example, let us calculate the transient process in an oscillator under the effect of a constant force being turned on at \( t = 0 \), i.e. proportional to the theta-function of time:
provided that at \( t < 0 \) the oscillator was at rest, so that in Eq. (15), \( q_{\text{free}}(t) \equiv 0 \). Then the second form of Eq. (27), and Eq. (34), yield

\[
q(t) = f_0 \int_0^\infty f(t - \tau) G(\tau) d\tau = f_0 \int_0^\infty \frac{1}{\omega_0'} e^{-\delta \tau} \sin \omega_0' \tau \, d\tau.
\] (5.36)

The simplest way to work out such integrals is to represent the sine function under it as the imaginary part of \( \exp\{i\omega_0' \tau\} \), and merge the two exponents, getting

\[
q(t) = f_0 \frac{1}{\omega_0'} \text{Im} \left[ \frac{1}{-\delta + i\omega_0'} e^{-\delta \tau + i\omega_0' \tau} \right]_0^t = \frac{F_0}{k} \left[ 1 - e^{-\delta t} \left( \cos \omega_0' t + \frac{\delta}{\omega_0'} \sin \omega_0' t \right) \right].
\] (5.37)

This result, plotted in Fig. 3, is rather natural: it describes nothing more than the transient from the initial position \( q = 0 \) to the new equilibrium position \( q_0 = f_0/\omega_0^2 = F_0/k \), accompanied by decaying oscillations. For this particular simple function \( f(t) \), the same result might be also obtained by introducing a new variable \( \tilde{q}(t) \equiv q(t) - q_0 \) and solving the resulting homogeneous equation for \( \tilde{q} \) (with appropriate initial condition \( \tilde{q}(0) = -q_0 \)). However, for more complicated functions \( f(t) \) the Green’s function approach is irreplaceable.

![Fig. 5.3. The transient process in a linear oscillator, induced by a step-like force \( f(t) \), for the particular case \( \delta/\omega_0 = 0.1 \) (i.e., \( Q = 5 \)).](image)

Note that for any particular linear system, its Green’s function should be calculated only once, and then may be repeatedly used in Eq. (27) to calculate the system response to various external forces – either analytically or numerically. This property makes the Green’s function approach very popular in many other fields of physics – with the corresponding generalization or re-definition of the function.13

### 5.2. Weakly nonlinear oscillations

In comparison with systems discussed in the last section, which are described by linear differential equations with constant coefficients and thus allow a complete and exact analytical solution, oscillations in nonlinear systems (very unfortunately but commonly called nonlinear oscillations) present a complex and, generally, analytically intractable problem. However, much insight on possible

---

13 See, e.g., EM Sec. 2.7, and QM Sec. 2.2.
processes in such systems may be gained from a discussion of an important case of weakly nonlinear systems, which may be explored analytically. An important example of such systems is given by an anharmonic oscillator – a 1D system whose higher terms in the potential expansion (3.10) cannot be neglected, but are small and may be accounted for approximately. If, in addition, damping is low (or negligible), and the external harmonic force exerted on the system is not too large, the equation of motion is a slightly modified version of Eq. (13):

$$\ddot{q} + \omega^2 q = f(t, q, \dot{q}, \ldots) \tag{5.38}$$

where $\omega \approx \omega_0$ is the anticipated frequency of oscillations (whose choice is to a certain extent arbitrary – see below), and the right-hand side $f$ is small (say, scales as some small dimensionless parameter $\varepsilon \ll 1$), and may be considered as a small perturbation.

Since at $\varepsilon = 0$ this equation has the sinusoidal solution given by Eq. (3), one might naïvely think that at a nonzero but small $\varepsilon$, the approximate solution to Eq. (38) should be sought in the form

$$q(t) = q^{(0)} + q^{(1)} + q^{(2)} + \ldots, \text{ where } q^{(n)} \propto \varepsilon^n \tag{5.39}$$

with $q^{(0)} = A \cos(\omega_0 t - \varphi) \propto \varepsilon^0$. This is a good example of apparently impeccable mathematical reasoning that would lead to a very inefficient procedure. Indeed, let us apply it to the problem we already know the exact solution for, namely the free oscillations in a linear but damped oscillator, for this occasion assuming the damping to be very low, $\delta \omega_0 \sim \varepsilon << 1$. The corresponding equation of motion, Eq. (6), may be represented in form (38) if we take $\omega = \omega_0$ and

$$f = -2\delta \dot{q}, \quad \text{with } \delta \propto \varepsilon. \tag{5.40}$$

The naïve approach described above would allow us to find small corrections, of the order of $\delta$, to the free, non-decaying oscillations $A \cos(\omega_0 t - \varphi)$. However, we already know from Eq. (9) that the main effect of damping is a gradual decrease of the free oscillation amplitude to zero, i.e. a very large change of the amplitude, though at low damping, $\delta << \omega_0$, this decay takes large time $t \sim \tau >> 1/\omega_0$. Hence, if we want our approximate method to be productive (i.e. to work at all time scales, in particular for forced oscillations with stationary amplitude and phase), we need to account for the fact that the small right-hand side of Eq. (38) may eventually lead to essential changes of oscillation’s amplitude $A$ (and sometimes, as we will see below, also of oscillation’s phase $\varphi$) at large times, because of the slowly accumulating effects of the small perturbation.\(^{14}\)

This goal may be achieved\(^{15}\) by the account of these slow changes already in the “0th approximation”, i.e. the basic part of the solution in the expansion (39):

\(^{14}\)The same flexible approach is necessary to approximations used in quantum mechanics. The method discussed here is much closer in spirit (though not completely identical) to the WKB approximation (see, e.g., QM Sec. 2.4) rather than most perturbative approaches (QM Ch. 6).

\(^{15}\)The basic idea of this approach was reportedly suggested in 1920 by Balthasar van der Pol, and its first approximation (on which I will focus) is frequently called the van der Pol method. However, in optics and quantum mechanics, it is most commonly called the Rotating Wave Approximation (RWA). In math-oriented texts, this approach, especially its extensions to higher approximations, is usually called either the small parameter method or the asymptotic method. The list of other scientists credited for the development of this method, its variations, and extensions includes, most notably, N. Krylov, N. Bogolyubov, and Yu. Mitropolsky.
\[ q^{(0)} = A(t) \cos(\omega t - \varphi(t)), \quad \text{with } \dot{A}, \dot{\varphi} \to 0 \quad \text{at } \varepsilon \to 0. \]  

(5.41)

(It is evident that Eq. (9) is a particular case of this form.) Let me discuss this approach using a simple but representative example of a dissipative (but high-\(Q\)) pendulum driven by a weak sinusoidal external force with a nearly-resonant frequency:

\[ \ddot{q} + 2\delta \dot{q} + \omega_0^2 \sin q = f_0 \cos \omega t, \]  

(5.42)

with \( |\omega - \omega_0|, \delta \ll \omega_0 \), and the force amplitude \( f_0 \) so small that \( |q| \ll 1 \) at all times. From what we know about the forced oscillations from Sec. 1, in this case it is natural to identify \( \omega \) on the left-hand side of Eq. (38) with the force’s frequency. Expanding \( \sin q \) into the Taylor series in small \( q \), keeping only the first two terms of this expansion, and moving all small terms to the right-hand side, we can rewrite Eq. (42) in the following popular form (38):

\[ \ddot{q} + \omega^2 q = -2\delta \dot{q} + 2\xi \omega \dot{q} + \alpha q^3 + f_0 \cos \omega t \equiv f(t, q, \dot{q}). \]  

(5.43)

Here \( \alpha = \omega_0^2/6 \) in the case of the pendulum (though the calculations below will be valid for any \( \alpha \)), and the second term on the right-hand side was obtained using the approximation already employed in Sec. 1: \( (\omega^2 - \omega_0^2)q \approx 2\alpha(\omega - \omega_0)q = 2\omega \xi q \), where \( \xi \equiv \omega - \omega_0 \) is the detuning parameter that was already used earlier – see Eq. (21).

Now, following the general recipe expressed by Eqs. (39) and (41), in the 1\textsuperscript{st} approximation in \( f \propto \varepsilon \) we may look for the solution to Eq. (43) in the following form:

\[ q(t) = A \cos \Psi + q^{(1)}(t), \quad \text{where } \Psi \equiv \omega t - \varphi, \quad q^{(1)} \sim \varepsilon. \]  

(5.44)

Let us plug this solution into both parts of Eq. (43), keeping only the terms of the first order in \( \varepsilon \). Thanks to our (smart :-) choice of \( \omega \) on the left-hand side of that equation, the two zero-order terms in that part cancel each other. Moreover, since each term on the right-hand side of Eq. (43) is already of the order of \( \varepsilon \), we may drop \( q^{(1)} \propto \varepsilon \) from the substitution into that part at all, because this would give us only terms \( O(\varepsilon^2) \) or higher. As a result, we get the following approximate equation:

\[ \ddot{q}^{(1)} + \omega^2 q^{(1)} = f^{(0)} \equiv -2\delta \frac{d}{dt}(A \cos \Psi) + 2\xi \omega (A \cos \Psi) + \alpha (A \cos \Psi)^3 + f_0 \cos \omega t. \]  

(5.45)

According to Eq. (41), generally, \( A \) and \( \varphi \) should be considered (slow) functions of time. However, let us leave the analyses of the transient process and system’s stability until the next section, and use Eq. (45) to find stationary oscillations in the system, that are established after an initial transient. For that limited task, we may take \( A = \text{const}, \varphi = \text{const} \), so that \( q^{(0)} \) represents sinusoidal

---

\[ \textit{This equation is frequently called the Duffing equation (or the equation of the Duffing oscillator), after Georg Duffing who carried out its first (rather incomplete) analysis in 1918.} \]

\[ \textit{For a mathematically rigorous treatment of higher approximations, see, e.g., Yu. Mitropolsky and N. Dao,} \]

\textit{Applied Asymptotic Methods in Nonlinear Oscillations,} \textit{Springer, 2004. A more laymen (and, by today’s standards, somewhat verbose) discussion of various oscillatory phenomena may be found in the classical text A. Andronov, A. Vitt, and S. Khaikin, Theory of Oscillators,} \textit{Dover, 2011.} \]
oscillations of frequency $\omega$. Sorting the terms on the right-hand side according to their time dependence, we see that it has terms with frequencies $\omega$ and $3\omega$:

$$f^{(0)} = \left(2\xi \omega A + \frac{3}{4} \alpha A^3 + f_0 \cos \varphi\right) \cos \Psi + (2\delta \omega A - f_0 \sin \varphi) \sin \Psi + \frac{1}{4} \alpha A^3 \cos 3\Psi. \quad (5.46)$$

Now comes the main punch of the van der Pol approach: mathematically, Eq. (45) may be viewed as the equation of oscillations in a linear, dissipation-free harmonic oscillator of frequency $\omega$ (not $\omega_0$!) under the action of an external force $f(t)$ represented by the right-hand side of the equation. In our particular case, it has three terms: two “quadrature” components at that very frequency $\omega$, and the third one at frequency $3\omega$. As we know from our analysis of this problem in Sec. 1, if any of the first two components is not equal to zero, $q^{(1)}$ grows to infinity – see Eq. (19) with $\delta = 0$. At the same time, by the very structure of the van der Pol approximation, $q^{(1)}$ has to be finite – moreover, small! The only way out of this contradiction is to require that the amplitudes of both quadrature components of $f^{(0)}$ with frequency $\omega$ are equal to zero:

$$2\xi \omega A + \frac{3}{4} \alpha A^3 + f_0 \cos \varphi = 0, \quad 2\delta \omega A - f_0 \sin \varphi = 0. \quad (5.47)$$

These two harmonic balance equations enable us to find both parameters of the forced oscillations: their amplitude $A$ and phase $\varphi$. The phase may be readily eliminated from this system (most easily, by expressing $\sin \varphi$ and $\cos \varphi$ from Eqs. (47), and then requiring the sum $\sin^2 \varphi + \cos^2 \varphi$ to equal 1), and the solution for $A$ recast in the following implicit but convenient form:

$$A^2 = \frac{f_0^2}{4\omega^2} \frac{1}{\xi^2(A) + \delta^2}, \quad \text{where} \quad \xi(A) \equiv \xi + \frac{3}{8} \frac{\alpha A^2}{\omega} = \omega - \left(\omega_0 - \frac{3}{8} \frac{\alpha A^2}{\omega}\right). \quad (5.48)$$

This expression differs from Eq. (22) for the linear resonance in the low-damping limit only by the replacement of the detuning $\xi$ with its effective amplitude-dependent value $\xi(A)$ – or, equivalently, the replacement of the frequency $\omega_0$ of the oscillator with its effective, amplitude-dependent value

$$\omega_0(A) = \omega_0 - \frac{3}{8} \frac{\alpha A^2}{\omega}. \quad (5.49)$$

The physical meaning of $\omega_0(A)$ is simple: this is just the frequency of free oscillations of amplitude $A$ in a similar nonlinear system, but with zero damping. Indeed, for $\delta = 0$ and $f_0 = 0$ we could repeat our calculations, assuming that $\omega$ is an amplitude-dependent eigenfrequency $\omega_0(A)$. Then the second of Eqs. (47) is trivially satisfied, while the second of them gives Eq. (49). The implicit relation (48) enables us to draw the curves of this nonlinear resonance just by bending the linear resonance plots (Fig. 1) according to the so-called skeleton curve expressed by Eq. (49). Figure 4 shows the result of this procedure. Note that at small amplitude, $\omega_0(A) \to \omega_0$, i.e. we return to the usual, “linear” resonance (22).

---

18 Using the second of Eqs. (44), $\cos \omega t$ may be rewritten as $\cos (\Psi + \varphi) = \cos \Psi \cos \varphi - \sin \Psi \sin \varphi$. Then using the identity given, for example, by MA Eq. (3.4): $\cos^3 \Psi = (3/4) \cos \Psi + (1/4) \cos 3\Psi$, we get Eq. (46).

19 The effect of pendulum’s frequency dependence on its oscillation amplitude was observed as early as 1673 by Christiaan Huygens – who by the way had invented the pendulum clock, increasing the timekeeping accuracy by about three orders of magnitude (and also discovered the largest of Saturn’s moons, Titan).
To bring our solution to its logical completion, we should still find the first perturbation $q^{(1)}(t)$ from what is left of Eq. (45). Since the structure of this equation is similar to Eq. (13) with the force of frequency $3\omega$ and zero damping, we may use Eqs. (16)-(17) to obtain

$$q^{(1)}(t) = -\frac{1}{32\omega^2} \alpha A^3 \cos 3(\omega t - \varphi).$$

Adding this perturbation (note the negative sign!) to the sinusoidal oscillation (41), we see that as the amplitude $A$ of oscillations in a system with $\alpha > 0$ (e.g., a pendulum) grows, their waveform becomes a bit more “blunt” near the largest deviations from the equilibrium.

The same Eq. (50) also enables an estimate of the range of validity of our first approximation: since it has been based on the assumption $|q^{(1)}| \ll |q^{(0)}| \leq A$, for this particular problem we have to require $\alpha A^2/32\omega^2 \ll 1$. For a pendulum (i.e. for $\alpha = \omega_0^2/6$), this condition becomes $A^2 \ll 192$. Though numerical coefficients in such strong inequalities should be taken with a grain of salt, the large magnitude of this particular coefficient gives a good hint that the method may give very accurate results even for relatively large oscillations with $A \sim 1$. In Sec. 7 below, we will see that this is indeed the case.

From the mathematical viewpoint, the next step would be to write the next approximation as

$$q(t) = A \cos \Psi + q^{(1)}(t) + q^{(2)}(t), \quad q^{(2)} \sim \varepsilon^2,$$

and plug it into the Duffing equation (43), which (thanks to our special choice of $q^{(0)}$ and $q^{(1)}$) would retain only the sum $\ddot{q}^{(2)} + \omega^2 q^{(2)}$ on its left-hand side. Again, requiring the amplitudes of two quadrature components of the frequency $\omega$ on the right-hand side to vanish, we may get second-order corrections to $A$ and $\varphi$. Then we may use the remaining part of the equation to calculate $q^{(2)}$, and then go after the third-order terms, etc. However, for most purposes, the sum $q^{(0)} + q^{(1)}$, and sometimes even just the crudest approximation $q^{(0)}$ alone, are completely sufficient. For example, according to Eq. (50), for a simple pendulum swinging as much as between the opposite horizontal positions ($A = \pi/2$), the $1^{\text{st}}$ order correction $q^{(1)}$ is of the order of 0.5%. (Soon beyond this value, completely new dynamic phenomena start – see Sec. 7 below – but they cannot be described by these successive approximations at all.) Due to such reasons, higher approximations are rarely pursued for particular systems.

Fig. 5.4. The nonlinear resonance in the Duffing oscillator, as described by Eq. (48), for the particular case $\alpha = \omega_0^2/6$, $\delta \omega = 0.01$ (i.e. $Q = 50$), and several values of the parameter $f_0/\omega_0^2$, increased by equal steps of 0.005 from 0 to 0.03.
5.3. Reduced equations

A much more important issue is the stability of the solutions described by Eq. (48). Indeed, Fig. 4 shows that within a certain range of parameters, these equations give three different values for the oscillation amplitude (and phase), and it is important to understand which of these solutions are stable. Since these solutions are not the fixed points in the sense discussed in Sec. 3.2 (each point in Fig. 4 represents a nearly-sinusoidal oscillation), their stability analysis needs a more general approach that would be valid for oscillations with amplitude and phase slowly evolving in time. This approach will also enable the analysis of non-stationary (especially the initial transient) processes, which are of importance for some dynamic systems.

First of all, let us formalize the way the harmonic balance equations, such as Eqs. (47), are obtained for the general case (38) – rather than for the particular Eq. (43) considered in the last section. After plugging in the 0th approximation (41) into the right-hand side of equation (38) we have to require the amplitudes of both quadrature components of frequency $\omega$ to vanish. From the standard Fourier analysis, we know that these requirements may be represented as

$$
\bar{f}^{(0)} \sin \Psi = 0, \quad f^{(0)} \cos \Psi = 0,
$$

(5.52)

where the top bar means the time averaging – in our current case, over the period $2\pi/\omega$ of the right-hand side of Eq. (52), with the arguments calculated in the 0th approximation:

$$
f^{(0)} \equiv f(t, q^{(0)}, \dot{q}^{(0)}, \ldots) \equiv f(t, A \cos \Psi, -A \omega \sin \Psi, \ldots), \quad \text{with } \Psi = \omega t - \varphi. \quad (5.53)
$$

Now, for a transient process the contribution of $q^{(0)}$ to the left-hand side of Eq. (38) is not zero any longer, because its amplitude and phase may be both slow functions of time – see Eq. (41). Let us calculate this contribution. The exact result would be

$$
\ddot{q}^{(0)} + \omega^2 q^{(0)} \equiv \left( \frac{d^2}{dt^2} + \omega^2 \right) A \cos(\omega t - \varphi) = \left( \dot{A} + 2\varphi \omega A - \varphi^2 A \right) \cos(\omega t - \varphi) - 2A(\omega - \dot{\varphi}) \sin(\omega t - \varphi).
$$

(5.54)

However, in the first approximation in $\varepsilon$, we may neglect the second derivative of $A$, and also the squares and products of the first derivatives of $A$ and $\varphi$ (which are all of the second order in $\varepsilon$), so that Eq. (54) is reduced to

$$
\ddot{q}^{(0)} + \omega^2 q^{(0)} \approx 2A \varphi \omega \cos(\omega t - \varphi) - 2A \omega \sin(\omega t - \varphi).
$$

(5.55)

On the right-hand side of Eq. (53), we can neglect the time derivatives of the amplitude and phase at all, because this part is already proportional to the small parameter. Hence, in the first order in $\varepsilon$, Eq. (38) becomes

$$
\ddot{q}^{(1)} + \omega^2 q^{(1)} = f^{(1)}_{ef} \equiv f^{(0)} - \left( 2A \varphi \omega \cos \Psi - 2A \omega \sin \Psi \right).
$$

(5.56)

Now, applying Eqs. (52) to the function $f_{ef}^{(0)}$, and taking into account that the time averages of $\sin^2 \Psi$ and $\cos^2 \Psi$ are both equal to $1/2$, while the time average of the product $\sin \Psi \cos \Psi$ vanishes, we get a pair of so-called reduced equations (alternatively called “truncated”, or “RWA”, or “van der Pol” equations) for the time evolution of the amplitude and phase:
Extending the definition (4) of the complex amplitude of oscillations to their slow evolution in time, \( a(t) \equiv A(t)\exp\{i\varphi(t)\} \), and differentiating this relation, the two equations (57a) may be also rewritten in the form of either one equation for \( a(t) \):

\[
\dot{a} = -\frac{i}{\omega} f^{(0)} e^{i(\Psi + \varphi)} = -\frac{i}{\omega} f^{(0)} e^{i\omega t},
\]

or two equations for the real and imaginary parts of \( a(t) = u(t) + iv(t) \):

\[
\dot{u} = -\frac{1}{\omega} f^{(0)} \sin \omega t, \quad \dot{v} = \frac{1}{\omega} f^{(0)} \cos \omega t.
\]

The first-order harmonic balance equations (52) are evidently just the particular case of the reduced equations (57) for stationary oscillations \( \dot{A} = \dot{\varphi} = 0 \).

Superficially, the system (57a) of two coupled, first-order differential equations may look more complex than the initial, second-order differential equation (38), but actually, it is usually much simpler. For example, let us spell them out for the easy case of free oscillations a linear oscillator with damping. For that, we may reuse the ready Eq. (46) by taking \( \alpha = f_0 = 0 \), and thus turning Eqs. (57a) into

\[
\dot{A} = -\frac{1}{\omega} f^{(0)} \sin \Psi \equiv -\frac{1}{\omega} (2\xi A \cos \Psi + 2\delta \omega A \sin \Psi) \sin \Psi \equiv -\delta A, \quad (5.58a)
\]

\[
\dot{\varphi} = \frac{1}{\omega A} f^{(0)} \cos \Psi \equiv \frac{1}{\omega A} (2\xi A \cos \Psi + 2\delta \omega A \sin \Psi) \cos \Psi \equiv \xi . \quad (5.58b)
\]

The solution of Eq. (58a) gives us the same “envelope” law \( A(t) = A(0)e^{-\delta t} \) as the exact solution (10) of the initial differential equation, while the elementary integration of Eq. (58b) yields \( \varphi(t) = \xi t + \varphi(0) \equiv \omega t - \omega t + \varphi(0) \). This means that our approximate solution,

\[
q^{(0)}(t) = A(t)\cos[\omega t - \varphi(t)] = A(0)e^{-\delta t} \cos[\omega t - \varphi(0)] \quad (5.59)
\]

agrees with the exact Eq. (9), and misses only the correction (8) of the oscillation frequency. (This correction is of the second order in \( \delta \), i.e. of the order of \( \epsilon^2 \), and hence is beyond the accuracy of our first approximation.) It is remarkable how nicely do the reduced equations recover the proper frequency of free oscillations in this autonomous system – in which the very notion of \( \omega \) is ambiguous.

The result is different at forced oscillations. For example, for the (generally, nonlinear) Duffing oscillator described by Eq. (43) with \( f_0 \neq 0 \), Eqs. (57a) yield the reduced equations,

\[
\dot{A} = -\delta A + \frac{f_0}{2\omega} \sin \varphi, \quad A\dot{\varphi} = \xi(A) A + \frac{f_0}{2\omega} \cos \varphi , \quad (5.60)
\]
which are valid for an arbitrary function $\xi(A)$, provided that this nonlinear detuning remains much smaller than the oscillation frequency. Here (after a transient), the amplitude and phase tend to the stationary states described by Eqs. (47). This means that $\varphi$ becomes a constant, so that $q^{(0)} \rightarrow A\cos(\omega t - \text{const})$, i.e. the reduced equations again automatically recover the correct frequency of the solution, in this case equal to the external force frequency.

Note that each stationary oscillation regime, with certain amplitude and phase, corresponds to a fixed point of the reduced equations, so that the stability of those fixed points determines that of the oscillations. In the next three sections, we will carry out such an analysis for several simple systems of key importance for physics and engineering.

5.4. Self-oscillations and phase locking

The motivation for B. van der Pol to develop his method was the analysis of one more type of oscillatory motion: self-oscillations. Several systems, e.g., electronic rf amplifiers with positive feedback, and optical media with quantum level population inversion, provide convenient means for the compensation, and even over-compensation of the intrinsic energy losses in oscillators. Phenomenologically, this effect may be described as the change of sign of the damping coefficient $\delta$ from positive to negative. Since for small oscillations the equation of motion is still linear, we may use Eq. (9) to describe its general solution. This equation shows that at $\delta < 0$, even infinitesimal deviations from equilibrium (say, due to unavoidable fluctuations) lead to oscillations with exponentially growing amplitude. Of course, in any real system such growth cannot persist infinitely, and shall be limited by this or that effect – e.g., in the above examples, respectively, by amplifier’s saturation and quantum level population’s exhaustion.

In many cases, the amplitude limitation may be described reasonably well by making the following replacement:

$$2\delta q \rightarrow 2\delta q + \beta q^3,$$

with $\beta > 0$. Let us analyze the effects of such nonlinear damping, applying the van der Pol’s approach to the corresponding homogeneous differential equation (which is also known under his name):

$$\ddot{q} + 2\delta q + \beta q^3 + \omega_0^2 q = 0.$$  \hspace{1cm} (5.62)

Carrying out the dissipative and detuning terms to the right-hand side, and taking them for $f$ in the canonical Eq. (38), we can easily calculate the right-hand sides of the reduced equations (57a), getting\textsuperscript{21}\n
$$A = -\delta(A) A, \quad \text{where } \delta(A) \equiv \delta + \frac{3}{8} \beta \omega^2 A^2,$$

$$A\dot{\varphi} = \xi A.$$  \hspace{1cm} (5.63b)

The last of these equations has exactly the same form as Eq. (58b) for the case of decaying oscillations and hence shows that the self-oscillations (if they happen, i.e. if $A \neq 0$) have the own frequency $\omega_0$ of the oscillator – cf. Eq. (59). However, Eq. (63a) is more substantive. If the initial damping $\delta$ is positive, it has only the trivial fixed point, $A_0 = 0$ (that describes the oscillator at rest), but if $\delta$ is negative, there is also another fixed point,\textsuperscript{21} For that, one needs to use the trigonometric identity $\sin^3 \Psi = (3/4) \sin \Psi - (1/4) \sin^3 \Psi$ – see, e.g., MA Eq. (3.4).
\[
A_1 = \left( \frac{8|\delta|}{3\beta\omega^2} \right)^{1/2}, \quad \text{for } \delta < 0, \tag{5.64}
\]

which describes steady self-oscillations with a non-zero amplitude \(A_1\).

Let us apply the general approach discussed in Sec. 3.2, the linearization of equations of motion, to this reduced equation. For the trivial fixed point \(A_0 = 0\), the linearization of Eq. (63a) is reduced to discarding the nonlinear term in the definition of the amplitude-dependent damping \(\delta(A)\). The resulting linear equation evidently shows that the system’s equilibrium point, \(A = A_0 = 0\), is stable at \(\delta > 0\) and unstable at \(\delta < 0\). (We have already discussed this self-excitation condition above.) On the other hand, the linearization of near the non-trivial fixed point \(A_1\) requires a bit more math: in the first order in \(\theta \equiv A - A_1 \rightarrow 0\), we get

\[
\dot{\theta} = -\delta(A_1 + \theta) - \frac{3}{8} \beta \omega^2 (A_1 + \theta)^3 \approx -\delta \theta - \frac{3}{8} \beta \omega^2 3A_1^2 \theta = (-\delta + 3\delta)A = 2\delta \theta, \tag{5.65}
\]

where Eq. (64) has been used to eliminate \(A_1\). We see that the fixed point \(A_1\) (and hence the whole process) is stable as soon as it exists (\(\delta < 0\)) – similarly to the situation in our “testbed problem” (Fig. 2.1), besides that in our current, dissipative system, the stability is “actual” rather than “orbital” – see Sec. 6 for more on this issue.

Now let us consider another important problem: the effect of an external sinusoidal force on a self-excited oscillator. If the force is sufficiently small, its effects on the self-excitation condition and the oscillation amplitude are negligible. However, if the frequency \(\omega\) of such a weak force is close to the own frequency \(\omega_0\) of the oscillator, it may lead to a very important effect of phase locking\(^\text{22}\) – also called the “synchronization”, though the latter term also has a much broader meaning. At this effect, the oscillation frequency deviates from \(\omega_0\), and becomes exactly equal to the external force’s frequency \(\omega\), within a certain range

\[
-\Delta \leq \omega - \omega_0 < +\Delta. \tag{5.66}
\]

To prove this fact, and also to calculate the phase-locking range width \(2\Delta\), we may repeat the calculation of the right-hand sides of the reduced equations (57a), adding the term \(f_0 \cos \omega t\) to the right-hand side of Eq. (62) – cf. Eqs. (42)-(43). This addition modifies Eqs. (63) as follows:\(^\text{23}\)

\[
\dot{A} = -\delta(A)A + \frac{f_0}{2\omega} \sin \varphi, \tag{5.67a}
\]

\[
A \dot{\varphi} = \frac{\xi}{2\omega} A + \frac{f_0}{2\omega} \cos \varphi. \tag{5.67b}
\]

If the system is self-excited, and the external force is weak, its effect on the oscillation amplitude is small, and in the first approximation in \(f_0\) we can take \(A\) to be constant and equal to the value \(A_1\) given by Eq. (64). Plugging this approximation into Eq. (67b), we get a very simple equation\(^\text{24}\)

\(^{22}\) Apparently, the mutual phase locking of two pendulum clocks was first noticed by the same C. Huygens.

\(^{23}\) Actually, this result should be evident, even without calculations, from the comparison of Eqs. (60) and (63).

\(^{24}\) This equation is ubiquitous in phase-locking systems, including even some digital electronic circuits used for that purpose – at the proper re-definition of the phase difference \(\varphi\).
\[ \dot{\varphi} = \xi + \Delta \cos \varphi , \]  
(5.68)

where in our current case

\[ \Delta \equiv \frac{f_0}{2 \omega A_1} . \]  
(5.69)

Within the range \(-|\Delta| < \xi < +|\Delta|\), Eq. (68) has two fixed points on each \(2\pi\)-segment of the variable \(\varphi\):

\[ \varphi_{\pm} = \pm \cos^{-1}\left( -\frac{\xi}{\Delta} \right) + 2\pi n . \]  
(5.70)

It is easy to linearize Eq. (68) near each point to analyze their stability in our usual way; however, let me use this case to demonstrate another convenient way to do this in 1D systems, using the so-called phase plane – the plot of the right-hand side of Eq. (68) as a function of \(\varphi\) – see Fig. 5.

![Fig. 5.5. The phase plane of a phase-locked oscillator, for the particular case \(\xi = \Delta/2, f_0 > 0\).](image)

Since according to Eq. (68), positive values of this function correspond to the growth of \(\varphi\) in time and vice versa, we may draw the arrows showing the direction of phase evolution. From this graphics, it is clear that one of these fixed points (for \(f_0 > 0, \varphi_+\)) is stable, while its counterpart (in this case, \(\varphi_-\)) is unstable. Hence the magnitude of \(\Delta\) given by Eq. (69) is indeed the phase-locking range (or rather it half) that we wanted to find. Note that the range is proportional to the amplitude of the phase-locking signal – perhaps the most important feature of this effect.

To complete our simple analysis, based on the assumption of fixed oscillation amplitude, we need to find the condition of its validity. For that, we may linearize Eq. (67a), for the stationary case, near the value \(A_1\), just as we have done in Eq. (65) for the transient process. The stationary result,

\[ \tilde{A} \equiv A - A_1 = \frac{1}{2|\delta|} \frac{f_0}{2\omega} \sin \varphi_{\pm} \approx A_1 \left| \frac{\Delta}{2|\delta|} \right| \sin \varphi_{\pm} , \]  
(5.71)

shows that our assumption, \(|\tilde{A}| \ll A_1\), and hence the final result (69), are valid if the calculated phase-locking range \(2\Delta\) is much smaller than \(4|\delta|\).

### 5.5. Parametric excitation

In both problems solved in the last section, the stability analysis was easy because it could be carried out for just one slow variable, either amplitude or phase. More generally, such an analysis of the
reduced equations involves both these variables. A classical example of such a situation is provided by one important physical phenomenon – the *parametric excitation* of oscillations. A simple example of such excitation is given by a pendulum with a variable parameter, for example, the suspension length \( l(t) \) – see Fig. 6. Experiments (including those with playground swings :-) and numerical simulations show that if the length is changed (modulated) periodically, with some frequency \( 2\omega \) that is close to \( 2\omega_0 \), and a sufficiently large swing \( \Delta l \), the equilibrium position of the pendulum becomes unstable, and it starts oscillating with frequency \( \omega \) equal *exactly* to the half of the modulation frequency (and hence only *approximately* equal to the average frequency \( \omega_0 \) of the oscillator).

For an elementary analysis of this effect, we may consider the simplest case when the oscillations are small. At the lowest point (\( \theta = 0 \)), where the pendulum moves with the highest velocity \( v_{\text{max}} \), the suspension string’s tension \( T \) is *higher* than \( mg \) by the centripetal force: \( T_{\text{max}} = mg + mv_{\text{max}}^2/l \). On the contrary, at the maximum deviation of the pendulum from the equilibrium, the force is *lower* than \( mg \), because of the string’s tilt: \( T_{\text{min}} = mg\cos\theta_{\text{max}} \). Using the energy conservation, \( E = mv_{\text{max}}^2/2 = mgl(1 - \cos\theta_{\text{max}}) \), we may express these values as \( T_{\text{max}} = mg + 2E/l \) and \( T_{\text{min}} = mg - E/l \). Now, if during each oscillation period the string is pulled up slightly by \( \Delta l \) (with \( |\Delta l| \ll l \)) at each of its two passages through the lowest point, and is let to go down by the same amount at each of two points of the maximum deviation, the net work of the external force per period is positive:

\[
\mathcal{W} \approx 2(T_{\text{max}} - T_{\text{min}})\Delta l \approx 6\frac{\Delta l}{l}E,
\]

and hence increases the oscillator’s energy. If the parameter swing \( \Delta l \) is sufficient, this increase may overcompensate the energy drained out by damping during the same period. Quantitatively, Eq. (10) shows that low damping (\( \delta \ll \omega_0 \)) leads to the following energy decrease,

\[
\Delta E \approx -4\pi\frac{\delta}{\omega_0}E,
\]

per oscillation period. Comparing Eqs. (72) and (73), we see that the net energy flow into the oscillations is positive, \( \mathcal{W} + \Delta E > 0 \), i.e. oscillation amplitude has to grow\(^{25}\)

\[
\frac{\Delta l}{l} > \frac{2\pi\delta}{3\omega_0} \equiv \frac{\pi}{3Q}.
\]

\(^{25}\) A modulation of the pendulum’s mass (say, by periodic pumping water in and out of a suspended bottle) gives a qualitatively similar result. Note, however, that parametric oscillations cannot be excited by modulating *any* oscillator’s parameter – for example, oscillator’s damping coefficient (at least if it stays positive at all times), because its does not change the system’s energy, just the energy drain rate.
Since this result is independent of the oscillation energy $E$, the growth of energy and amplitude is exponential (until $E$ becomes so large that some of our assumptions fail), so that Eq. (74) is the condition of parametric excitation – in this simple model.

However, this result does not account for a possible difference between the oscillation frequency $\omega$ and the eigenfrequency $\omega_0$, and also does not clarify whether the best phase shift between the oscillations and parameter modulation, assumed in the above calculation, may be sustained automatically. To address these issues, we may apply the van der Pol approach to a simple but reasonable model:

$$\ddot{q} + 2\delta \dot{q} + \omega_0^2 (1 + \mu \cos 2\omega t) q = 0,$$  
(5.75)

describing the parametric excitation in a linear oscillator with a sinusoidal modulation of the parameter $\omega_0^2(t)$. Rewriting this equation in the canonical form (38),

$$\ddot{q} + \omega^2 q = f(t, q, \dot{q}) \equiv -2\delta \dot{q} + 2\xi \omega q - \mu \omega_0^2 q \cos 2\omega t,$$  
(5.76)

and assuming that the dimensionless ratios $\delta/\omega$ and $|\xi|/\omega$, and the modulation depth $\mu$ are all much less than 1, we may use general Eqs. (57a) to get the following reduced equations:

$$\dot{A} = -\delta A - \frac{\mu \omega_0}{4} A \sin 2\varphi,$$  
(5.77)

$$A \dot{\varphi} = A \xi - \frac{\mu \omega_0}{4} A \cos 2\varphi.$$

These equations evidently have a fixed point, with $A_0 = 0$, but its stability analysis (though possible) is not absolutely straightforward, because the phase $\varphi$ of oscillations is undetermined at that point. In order to avoid this (technical rather than conceptual) difficulty, we may use, instead of the real amplitude and phase of oscillations, either their complex amplitude $a = A \exp\{i\varphi\}$, or its Cartesian components $u$ and $v$ – see Eqs. (4). Indeed, for our function $f$, Eq. (57b) gives

$$\dot{a} = (-\delta + i\xi) a - i \frac{\mu \omega_0}{4} a^*,$$  
(5.78)

while Eqs. (57c) yield

$$\dot{u} = -\delta u - \xi v - \frac{\mu \omega_0}{4} v,$$

$$\dot{v} = -\delta v + \xi u - \frac{\mu \omega_0}{4} u.$$  
(5.79)

We see that in contrast to Eqs. (77), in the Cartesian coordinates $\{u, v\}$ the trivial fixed point $a_0 = 0$ (i.e. $u_0 = v_0 = 0$) is absolutely regular. Moreover, equations (78)-(79) are already linear, so they do not require any additional linearization. Thus we may use the same approach as was already used in Secs. 3.2 and 5.1, i.e. look for the solution of Eqs. (79) in the exponential form $\exp\{\lambda t\}$. However, now we are dealing with two variables and should allow them to have, for each value of $\lambda$, a certain ratio $u/v$. For that, we may take the partial solution in the form

$$u = c_u e^{\lambda t}, \quad v = c_v e^{\lambda t}.$$  
(5.80)
where the constants \( c_u \) and \( c_v \) are frequently called the distribution coefficients. Plugging this solution into Eqs. (79), we get from them the following system of two linear algebraic equations:

\[
\begin{aligned}
(-\delta - \lambda) c_u + \left( -\xi - \frac{\mu \omega}{4} \right) c_v &= 0, \\
\left( +\xi - \frac{\mu \omega}{4} \right) c_u + (-\delta - \lambda) c_v &= 0.
\end{aligned}
\]  

(5.81)

The characteristic equation of this system, i.e. the condition of compatibility of Eqs. (81),

\[
\begin{vmatrix}
-\delta - \lambda & -\xi - \frac{\mu \omega}{4} \\
\xi - \frac{\mu \omega}{4} & -\delta - \lambda
\end{vmatrix} = \lambda^2 + 2\delta \lambda + \delta^2 + \xi^2 - \left( \frac{\mu \omega}{4} \right)^2 = 0,
\]  

(5.82)

has two roots:

\[
\lambda_+ = -\delta \pm \left[ \left( \frac{\mu \omega}{4} \right)^2 - \xi^2 \right]^{1/2}.
\]  

(5.83)

Requiring the fixed point to be unstable, \( \text{Re} \lambda_+ > 0 \), we get the parametric excitation condition

\[
\frac{\mu \omega}{4} > (\delta^2 + \xi^2)^{1/2}.
\]  

(5.84)

Thus the parametric excitation may indeed happen without any external phase control: the arising oscillations self-adjust their phase to pick up energy from the external source responsible for the periodic parameter variation.

Our key result (84) may be compared with two other calculations. First, in the case of negligible damping \( (\delta = 0) \), Eq. (84) turns into the condition \( \mu \omega^2 > |\xi| \). This result may be compared with the well-developed theory of the so-called Mathieu equation, whose canonical form is

\[
\frac{d^2 y}{d\nu^2} + (a - 2b \cos 2\nu)y = 0.
\]  

(5.85)

With the substitutions \( y \rightarrow q, \nu \rightarrow \omega \nu, a \rightarrow (\omega \nu / \omega)^2, \) and \( b \rightarrow -\mu / 2, \) this equation is just a particular case of Eq. (75) for \( \delta = 0 \). In terms of Eq. (85), our result (84) may be re-written just as \( b > |a - 1| \), and is supposed to be valid for \( b << 1 \). The boundaries given by this condition are shown with dashed lines in Fig. 7 together with the numerically calculated\(^{26} \) stability boundaries for the Mathieu equation.

One can see that the van der Pol approximation works just fine within its applicability limit (and a bit beyond :-), though it fails to predict some other important features of the Mathieu equation, such as the existence of higher, more narrow regions of parametric excitation \( (a \approx n^2, \) i.e. \( \omega \nu \approx \omega \nu n, \) for all integer \( n \)), and some spill-over of the stability region into the lower half-plane \( a < 0 \).\(^{27} \) The reason for these failures is the fact that, as can be seen in Fig. 7, these phenomena do not appear in the first

\(^{26} \) Such calculations are substantially simplified by the use of the so-called Floquet theorem, which is also the mathematical basis for the discussion of wave propagation in periodic media – see the next chapter.

\(^{27} \) This region describes, in particular, the counter-intuitive stability of an inverted pendulum with periodically modulated length, within a limited range of the modulation depth \( \mu \).
approximation in the parameter modulation amplitude \( \mu \propto \varepsilon \), which is the realm of applicability of the reduced equations (79).

\[
\mu \gg \frac{2}{Q}. 
\]

This condition may be compared with Eq. (74) by taking \( \Delta l/l = 2\mu \). The comparison shows that while the structure of these conditions is similar, the numerical coefficients are different by a factor close to 2. The first reason for this difference is that the instant parameter change at optimal moments of time is more efficient than the smooth, sinusoidal variation described by (75). Even more significantly, the change of pendulum’s length modulates not only its frequency \( \omega \equiv (g/l)^{1/2} \) as Eq. (75) implies but also its mechanical impedance \( Z \equiv (gl)^{1/2} \) – the notion to be discussed in detail in the next chapter. (The analysis of the general case of the simultaneous modulation of \( \omega \) and \( Z \) is left for the reader’s exercise.)

Before moving on, let me summarize the most important differences between the parametric and forced oscillations:

(i) Parametric oscillations completely disappear outside of their excitation range, while the forced oscillations have a non-zero amplitude for any frequency and amplitude of the external force – see Eq. (18).

(ii) Parametric excitation may be described by a linear homogeneous equation – e.g., Eq. (75) – which cannot predict any finite oscillation amplitude within the excitation range, even at finite damping. In order to describe stationary parametric oscillations, some nonlinear effect has to be taken into account. (I am leaving analyses of such effects for the reader’s exercise – see Problems 13 and 14.)

One more important feature of the parametric oscillations will be discussed at the end of the next section.
5.6. Fixed point classification

The reduced equations (79) give us a good pretext for a brief discussion of an important general topic of dynamics: fixed points of a system described by two time-independent, first-order differential equations with time-independent coefficients. After their linearization near a fixed point, the equations for deviations can always be expressed in the form similar to Eq. (79):

\[ \begin{align*}
\dot{\tilde{q}}_1 &= M_{11}\tilde{q}_1 + M_{12}\tilde{q}_2, \\
\dot{\tilde{q}}_2 &= M_{21}\tilde{q}_1 + M_{22}\tilde{q}_2,
\end{align*} \tag{5.87} \]

where \(M_{jj'}\) (with \(j, j' = 1, 2\)) are some real scalars, which may be viewed as the elements of a 2×2 matrix \(M\). Looking for an exponential solution of the type (80),

\[ \tilde{q}_1 = c_1 e^{\lambda t}, \quad \tilde{q}_2 = c_2 e^{\lambda t}, \tag{5.88} \]

we get a general system of two linear equations for the distribution coefficients \(c_{1,2}\):

\[ \begin{align*}
(M_{11} - \lambda) c_1 + M_{12} c_2 &= 0, \\
M_{21} c_1 + (M_{22} - \lambda) c_2 &= 0.
\end{align*} \tag{5.89} \]

These equations are consistent if

\[ \begin{vmatrix} M_{11} - \lambda & M_{12} \\
M_{21} & M_{22} - \lambda \end{vmatrix} = 0, \tag{5.90} \]

giving us a quadratic characteristic equation:

\[ \lambda^2 - \lambda (M_{11} + M_{22}) + (M_{11}M_{22} - M_{12}M_{21}) = 0. \tag{5.91} \]

Its solution,

\[ \lambda_{\pm} = \frac{1}{2} (M_{11} + M_{22}) \pm \frac{1}{2} \left[ (M_{11} - M_{22})^2 + 4M_{12}M_{21} \right]^{1/2}, \tag{5.92} \]

shows that the following situations are possible:

A. The expression under the square root, \((M_{11} - M_{22})^2 + 4M_{12}M_{21}\), is positive. In this case, both characteristic exponents \(\lambda_{\pm}\) are real, and we can distinguish three sub-cases:

(i) Both \(\lambda_+\) and \(\lambda_-\) are negative. As Eqs. (88) show, in this case the deviations \(\tilde{q}\) tend to zero at \(t \to \infty\), i.e., fixed point is stable. Because of generally different magnitudes of the exponents \(\lambda_{\pm}\), the process represented on the phase plane \([\tilde{q}_1, \tilde{q}_2]\) (see Fig. 8a, with the solid arrows, for an example) may be seen as consisting of two stages: first, a faster (with the rate \(|\lambda_-| > |\lambda_+|\)) relaxation to a linear

---

28 Autonomous systems described by a single, second-order homogeneous differential equation, say \(F(q, \dot{q}, \ddot{q}) = 0\), also belong to this class, because we may always treat the generalized velocity \(\dot{q} \equiv v\) as a new variable, and use this definition as one first-order differential equation, while the initial equation, in the form \(F(q, v, \ddot{v}) = 0\), as the second first-order equation.

29 In the language of linear algebra, \(\lambda_{\pm}\) are the eigenvalues, and the corresponding sets of the distribution coefficients \([c_1, c_2]_{\pm}\) are the eigenvectors of the matrix \(M\) with elements \(M_{jj'}\).
asymptote, and then a slower decline, with the rate $|\lambda_-|$, along this line, i.e. at a virtually fixed ratio of the variables. Such a fixed point is called the stable node.

(ii) Both $\lambda_+$ and $\lambda_-$ are positive. This case of an unstable node differs from the previous one only by the direction of motion along the phase plane trajectories – see the dashed arrows in Fig. 8a. Here the variable ratio is also approaching a constant soon, now the one corresponding to $\lambda_+ > \lambda_-$. 

---

30 The asymptote direction may be found by plugging the value $\lambda_+$ back into Eq. (89) and finding the corresponding ratio $c_1/c_2$. Note that the separation of the system’s evolution into the two stages is conditional, being most vivid in the case of a large difference between the exponents $\lambda_+$ and $\lambda_-$. 

---
(iii) Finally, in the case of a saddle ($\lambda_+ > 0$, $\lambda_- < 0$), the system’s dynamics is different (Fig. 8b): after the rate-$|\lambda|$ relaxation to an asymptote, the perturbation starts to grow, with the rate $\lambda_+$, along one of two opposite directions. (The direction is determined on which side of another straight line, called the separatrix, the system has been initially.) So the saddle is an unstable fixed point.

B. The expression under the square root in Eq. (92), $(M_{11}-M_{22})^2 + 4M_{12}M_{21}$, is negative. In this case, the square root is imaginary, making the real parts of both roots equal, $\text{Re}\lambda_\pm = (M_{11} + M_{22})/2$, and their imaginary parts equal but opposite. As a result, here there can be just two types of fixed points:

(i) Stable focus, at $(M_{11} + M_{22}) < 0$. The phase plane trajectories are spirals going to the origin (i.e. toward the fixed point) – see Fig. 8c with the solid arrow.

(ii) Unstable focus, taking place at $(M_{11} + M_{22}) > 0$, differs from the stable one only by the direction of motion along the phase trajectories – see the dashed arrow in the same Fig. 8c.

C. Frequently, the border case, $M_{11} + M_{22} = 0$, corresponding to the orbital (“indifferent”) stability already discussed in Sec. 3.2, is also distinguished, and the corresponding fixed point is referred to as the center (Fig. 8d). Considering centers as a separate category makes sense because such fixed points are typical for Hamiltonian systems, whose first integral of motion may be frequently represented as the distance of the phase point from a fixed point. For example, introducing new variables $\tilde{q}_1 \equiv \tilde{q}$, $\tilde{q}_2 \equiv m\tilde{q}_1$, we may rewrite Eq. (3.12) of a harmonic oscillator without dissipation (again, with indices “ef” dropped for brevity), as a system of two first-order differential equations:

$$\dot{\tilde{q}}_1 = \frac{1}{m}\tilde{q}_2, \quad \dot{\tilde{q}}_2 = -\kappa\tilde{q}_1,$$

i.e. as a particular case of Eq. (87), with $M_{11} = M_{22} = 0$, and $M_{12}M_{21} = -\kappa/m \equiv -\omega_0^2 < 0$, and hence $(M_{11}-M_{22})^2 + 4M_{12}M_{21} = -4\omega_0^2 < 0$, and $M_{11} + M_{22} = 0$. On the symmetrized phase plane $[\tilde{q}_1, \tilde{q}_2/Z]$, where the parameter $Z \equiv (\kappa m)^{1/2} \equiv m\omega_0$ is the oscillator’s impedance, the sinusoidal oscillations of amplitude $A$ are represented by a circle of radius $A$ about the center-type fixed point $A = 0$. In the case when $\tilde{q}_1 = \tilde{q}$ is the linear coordinate $q$ of an actual mechanical oscillator, so that $\tilde{q}_2 \equiv m\tilde{q}_1$ is its linear momentum $p \equiv m\dot{q}$, such a circular trajectory corresponds to the conservation of the oscillator’s energy

$$E \equiv T + U \equiv \frac{p^2}{2m} + \frac{\kappa q^2}{2} \equiv \frac{\kappa}{2} \left[ \tilde{q}_1^2 + \left( \frac{\tilde{q}_2}{Z} \right)^2 \right] = \frac{\kappa A^2}{2} = \text{const}. \quad (5.94)$$

This is a convenient moment for a brief discussion of the so-called Poincaré (or “slow-variable”, or “stroboscopic”) plane. From the point of view of the basic Eq. (41), the sinusoidal oscillations $q(t) = \cos(\omega t - \phi)$, described by a circular trajectory on the actual (symmetrized) phase plane, correspond to a fixed point $\{A, \phi\}$, which may be conveniently represented by a stationary geometric point on the plane with these polar coordinates – see Fig. 9a. (As follows from Eq. (4), the Cartesian coordinates of the point on that plane are just the variables $u \equiv A\cos\phi$ and $v \equiv A\cos\phi$ that were used, in particular, in the

31 The term “saddle” is due to the fact that in this case, the system’s dynamics is qualitatively similar to that of a heavily damped motion in a 2D potential $U(\tilde{q}_1, \tilde{q}_2)$ having the shape of a horse saddle (or a mountain pass).

32 Named after Jules Henri Poincaré (1854-1912), who is credited, among many other achievements in physics and mathematics, for his contributions to special relativity (see, e.g., EM Chapter 9), and the basic idea of unstable trajectories responsible for the deterministic chaos – to be discussed in Chapter 9 of this course.
last section.) The quasi-sinusoidal process (41), with slowly changing $A$ and $\varphi$, may be represented by a slow motion of that point on this Poincaré plane.

\[
\begin{align*}
\text{Fig. 5.9. (a) Representation of a} & \text{ sinusoidal oscillation (point) and a slow transient process (line) on the} \\
& \text{Poincaré plane, and (b) the relation between the “fast” phase plane and the} \\
& \text{“slow” (Poincaré) plane.}
\end{align*}
\]

Figure 9b shows a convenient way to visualize the relation between the actual phase plane of an oscillator, with the “fast” symmetrized coordinates $q$ and $p/m\omega$, and the Poincaré plane with the “slow” coordinates $u$ and $v$: the latter plane rotates relative to the former one, about the origin, clockwise, with the angular velocity $\omega$. Another, “stroboscopic” way to generate the Poincaré plane pattern is to have a fast glance at the “real” phase plane just once during the oscillation period $T = 2\pi/\omega$.

In many cases, the representation on the Poincaré plane is more convenient than that on the “real” phase plane. In particular, we have already seen that the reduced equations for such important phenomena as the phase locking and the parametric oscillations, whose original differential equations include time explicitly, are time-independent – cf., e.g., (75) and (79) describing the latter effect. This simplification brings the equations into the category considered earlier in this section, and enables an easy classification of their fixed points, which may shed additional light on their dynamic properties.

In particular, Fig. 10 shows the classification of the only (trivial) fixed point $A_1 = 0$ on the Poincaré plane of the parametric oscillator, which follows from Eq. (83). As the parameter modulation depth $\mu$ is increased, the type of this fixed point changes from a stable focus (pertinent to a simple oscillator with damping) to a stable node and then to a saddle describing the parametric excitation. In the last case, the two directions of the perturbation growth, so prominently featured in Fig. 8b, correspond to the two possible values of the oscillation phase $\varphi$, with the phase choice determined by initial conditions.

\[
\begin{align*}
\frac{\mu \omega}{4} &= |\xi| \\
\text{saddles} &\quad \text{stable} \\
\frac{\mu \omega}{4} &= \left(\delta^2 + \xi^2\right)^{1/2} \\
\text{stable} &\quad \text{focuses} \\
\text{stable} &\quad \text{focuses}
\end{align*}
\]

\[\text{Fig. 5.10. Types of the trivial fixed point of a parametric oscillator.}\]

---

33 This notion of phase plane rotation is the origin of the term “Rotating Wave Approximation”, mentioned above. (The word “wave” is an artifact of this method’s wide application in classical and quantum optics.)
This double degeneracy of the parametric oscillation’s phase could already be noticed from Eqs. (77), because they are evidently invariant with respect to the replacement $\varphi \to \varphi + \pi$. Moreover, the degeneracy is not an artifact of the van der Pol approximation, because the initial equation (75) is already invariant with respect to the corresponding replacement $q(t) \to q(t - \pi/\omega)$. This invariance means that all other characteristics (including the amplitude) of the parametric oscillations excited with either of the two phases are exactly similar. At the dawn of the computer age (in the late 1950s and early 1960s), there were substantial attempts, especially in Japan, to use this property for storage and processing digital information coded in the phase-binary form. Though these attempts have not survived the competition with simpler approaches based on voltage-binary coding, some current trends in the development of prospective reversible and quantum computers may be traced back to that idea.

5.7. Numerical approaches

If the amplitude of oscillations, for whatever reason, becomes so large that nonlinear terms in the equation describing an oscillator become comparable with its linear terms, numerical methods are virtually the only avenue available for their theoretical studies. In Hamiltonian 1D systems, such methods may be applied directly to Eq. (3.26), but dissipative and/or parametric systems typically lack such first integrals of motion, so that the initial differential equation has to be solved.

Let us discuss the general idea of such methods on the example of what mathematicians call the Cauchy problem (finding the solution for all moments of time, starting from the known initial conditions) for the first-order differential equation

$$\dot{q} = f(t, q).$$

(The generalization to a system of several such equations is straightforward.) Breaking the time axis into small, equal steps $h$ (Fig. 11) we can reduce the equation integration problem to finding the function’s value at the next time point, $q_{n+1} \equiv q(t_{n+1}) \equiv q(t_n + h)$ from the previously found value $q_n = q(t_n)$ – and, if necessary, the values of $q$ at other previous time steps.

In the simplest approach (called the Euler method), $q_{n+1}$ is found using the following formula:

$$q_{n+1} = q_n + k,$$

$$k = hf(t_n, q_n).$$

This approximation is equivalent to the replacement of the genuine function $q(t)$, on the segment $[t_n, t_{n+1}]$, with the two first terms of its Taylor expansion in point $t_n$:

$$q(t_n + h) \approx q(t_n) + \dot{q}(t_n)h = q(t_n) + hf(t_n, q_n).$$
This approximation has an error proportional to $h^2$. One could argue that making the step $h$ sufficiently small, the Euler method’s error might be made arbitrarily small, but even with all the number-crunching power of modern computer platforms, the CPU time necessary to reach sufficient accuracy may be too large for large problems.\textsuperscript{34} Besides that, the increase of the number of time steps, which is necessary at $h \to 0$ at a fixed total time interval, increases the total rounding errors and eventually may cause an increase, rather than the reduction of the overall error of the computed result.

A more efficient way is to modify Eq. (96) to include the terms of the second order in $h$. There are several ways to do this, for example using the \textit{2nd-order} Runge-Kutta method:

$$q_{n+1} = q_n + k_2,$$

$$k_2 \equiv h f(t_n + \frac{h}{2}, q_n + \frac{k_1}{2}), \quad k_1 \equiv h f(t_n, q_n).$$

One can readily check that this method gives the exact result if the function $q(t)$ is a quadratic polynomial, and hence in the general case its errors are of the order of $h^3$. We see that the main idea here is to first break the segment $[t_n, t_{n+1}]$ in half (see Fig. 11), evaluate the right-hand side of the differential equation (95) at the point intermediate (in both $t$ and $q$) between the points number $n$ and $(n + 1)$, and then use this information to predict $q_{n+1}$.

The advantage of the Runge-Kutta approach over other second-order methods is that it may be readily extended to the \textit{4th} order, without an additional breakup of the interval $[t_n, t_{n+1}]$:

$$q_{n+1} = q_n + \frac{1}{6} (k_1 + 2k_2 + 2k_3 + k_4),$$

$$k_4 \equiv h f(t_n + h, q_n + k_3), \quad k_3 \equiv h f(t_n + \frac{h}{2}, q_n + \frac{k_2}{2}), \quad k_2 \equiv h f(t_n + \frac{h}{2}, q_n + \frac{k_1}{2}), \quad k_1 \equiv h f(t_n, q_n).$$

This method has a much lower error, $O(h^5)$, without being not too cumbersome. These features have made the \textit{4th}-order Runge-Kutta the default method in most numerical libraries. Its extension to higher orders is possible, but requires more complex formulas, and is justified only for some special cases, e.g., very abrupt functions $q(t)$.\textsuperscript{35} The most frequent enhancement of the method is an automatic adjustment of the step $h$ to reach the pre-specified accuracy, but not make more calculations than necessary.

Figure 12 shows a typical example of an application of that method to the very simple problem of a damped linear oscillator, for two values of fixed time step $h$ (expressed in terms of the number $N$ of such steps per oscillation period). The black straight lines connect the adjacent points obtained by the \textit{4th}-order Runge-Kutta method, while the points connected with the green straight lines represent the exact analytical solution (22). The plots show that a-few-percent errors start to appear only at as few as $\sim 10$ time steps per period, so that the method is indeed very efficient.

\textsuperscript{34} In addition, the Euler method is not time-reversible – the handicap that may be essential for the integration of Hamiltonian systems described by systems of second-order differential equations. However, this drawback may be partly overcome by the so-called \textit{leapfrogging} – the overlap of time steps $h$ for a generalized coordinate and the corresponding generalized velocity.

\textsuperscript{35} The most popular approaches in such cases are the \textit{Richardson extrapolation}, the \textit{Bulirsch-Stoer algorithm}, and a set of so-called \textit{prediction-correction techniques}, e.g. the \textit{Adams-Bashforth-Moulton method} – see the literature recommended in MA Sec. 16(iii).
Let me hope that the discussion in the next section will make the conveniences and the handicaps of the numerical approach to problems of nonlinear dynamics very clear.

5.8. Higher harmonic and subharmonic oscillations

Figure 13 shows the numerically calculated transient process and stationary oscillations in a linear oscillator and a very representative nonlinear system, the pendulum described by Eq. (42), both with the same $\omega_0$. Both systems are driven by a sinusoidal external force of the same amplitude and frequency – in this illustration, equal to the small-oscillation own frequency $\omega_0$ of both systems. The plots show that despite a very substantial amplitude of the pendulum oscillations (the angle amplitude of about one radian), their waveform remains almost exactly sinusoidal. On the other hand, the nonlinearity affects the oscillation amplitude very substantially. These results imply that the corresponding reduced equations (60), which are based on the assumption (41), may work very well far beyond its formal restriction $|q| << 1$.

Still, the waveform of oscillations in a nonlinear system always differs from that of the applied force – in our case, from the sine function of frequency $\omega$. This fact is frequently formulated as the generation, by the system, of higher harmonics. Indeed, the Fourier theorem tells us that any non-sinusoidal periodic function of time may be represented as a sum of its basic harmonic of frequency $\omega$ and higher harmonics with frequencies $n\omega$, with integer $n > 1$.

Note that an effective generation of higher harmonics is only possible with adequate nonlinearity of the system. For example, consider the nonlinear term $\alpha q^3$ used in the equations explored in Secs. 2 and 3. If the waveform $q(t)$ is sinusoidal, such term will have only the basic (1st) and the 3rd harmonics – see, e.g., Eq. (50). As another example, the “pendulum nonlinearity” $\sin q$ cannot produce, without a time-independent component (“bias”) in $q(t)$, any even harmonic, including the 2nd one. The most

---

36 All numerical results shown in this section have been obtained by the 4th-order Runge-Kutta method with the automatic step adjustment that guarantees the relative error of the order of $10^{-4}$ – much smaller than the pixel size in the shown plots.

37 In this particular case, the higher harmonic content is about 0.5%, dominated by the 3rd harmonic, whose amplitude and phase are in a very good agreement with Eq. (50).
efficient generation of harmonics may be achieved using systems with the sharpest nonlinearities – e.g., semiconductor diodes whose current may follow an exponential dependence on the applied voltage through several orders of magnitude.\(^{38}\)

\[
q(t) = \begin{cases} 
0 & \text{for } t < 0 \\
1 & \text{for } 0 \leq t < 5 \\
2 & \text{for } 5 \leq t < 10 \\
0 & \text{for } 10 \leq t < 15 \\
-1 & \text{for } 15 \leq t < 20 \\
-2 & \text{for } 20 \leq t < 25 \\
0 & \text{for } 25 \leq t < 30 
\end{cases}
\]

\[
\omega_0 t / 2\pi = \begin{cases} 
0 & \text{for } t < 0 \\
5 & \text{for } 0 \leq t < 5 \\
10 & \text{for } 5 \leq t < 10 \\
15 & \text{for } 10 \leq t < 15 \\
20 & \text{for } 15 \leq t < 20 \\
25 & \text{for } 20 \leq t < 25 \\
30 & \text{for } 25 \leq t < 30 
\end{cases}
\]

Fig. 5.13. The oscillations induced by a similar sinusoidal external force (turned on at \(t = 0\)) in two systems with the same small-oscillation frequency \(\omega_0\) and low damping: a linear oscillator (two top panels) and a pendulum (two bottom panels). In all cases, \(\delta/\omega_0 = 0.03\), \(f_0 = 0.1\), and \(\omega = \omega_0\).

Another way to increase the contents of an \(n^{th}\) higher harmonic in a nonlinear oscillator is to reduce the excitation frequency \(\omega\) to \(\sim \omega_0/n\), so that the oscillator resonated at the frequency \(n\omega \approx \omega_0\) of the desired harmonic. For example, Fig. 14a shows the oscillations in a pendulum described by the same Eq. (42), but driven at frequency \(\omega = \omega_0/3\). One can see that the \(3^{rd}\) harmonic amplitude may be comparable with that of the basic harmonic, especially if the external frequency is additionally lowered (Fig. 14b) to accommodate for the deviation of the effective frequency \(\omega_0(A)\) of own oscillations from its small-oscillation value \(\omega_0\) – see Eq. (49), Fig. 4, and their discussion in Sec. 2 above.

However, numerical modeling of nonlinear oscillators, as well as experiments with their physical implementations, bring more surprises. For example, the bottom panel of Fig. 15 shows oscillations in a pendulum under the effect of a strong sinusoidal force with a frequency \(\omega\) close to \(3\omega_0\). One can see that at some parameter values and initial conditions, the system’s oscillation spectrum is heavily contributed (almost dominated) by the \(3^{rd}\) subharmonic, i.e. the Fourier component of frequency \(\omega/3 \approx \omega_0\).

This counter-intuitive phenomenon of such subharmonic generation may be explained as follows. Let us assume that subharmonic oscillations of frequency \(\omega/3 \approx \omega_0\) have somehow appeared, and coexist with the forced oscillations of frequency \(3\omega\).

\(^{38}\) This method is used in practice, for example, for the generation of electromagnetic waves with frequencies in the terahertz range \((10^{12}-10^{13} \text{ Hz})\), which still lacks efficient electronic self-oscillators that could be used as practical generators.
\[ q(t) \approx A\cos\Psi + A_{\text{sub}}\cos\Psi_{\text{sub}}, \quad \text{where } \Psi \equiv \omega t - \varphi, \quad \Psi_{\text{sub}} \equiv \frac{\omega t}{3} - \varphi_{\text{sub}}. \] (5.100)

Then the leading nonlinear term, \( \alpha q^3 \), of the Taylor expansion of the pendulum’s nonlinearity \( \sin q \), is proportional to

\[ q^3 = (A\cos\Psi + A_{\text{sub}}\cos\Psi_{\text{sub}})^3 \equiv A^3\cos^3\Psi + 3A^2A_{\text{sub}}\cos^2\Psi\cos\Psi_{\text{sub}} + 3AA_{\text{sub}}^2\cos\Psi\cos^2\Psi_{\text{sub}} + A_{\text{sub}}^3\cos^3\Psi_{\text{sub}}. \] (5.101)

Fig. 5.14. The oscillations induced in a pendulum, with damping \( \delta/\omega_0 = 0.03 \), by a sinusoidal external force of amplitude \( f_0 = 0.75 \), and frequencies \( \omega_0/3 \) (top panel) and \( 0.8\times\omega_0/3 \) (bottom panel).

Fig. 5.15. The oscillations of a pendulum with \( \delta/\omega_0 = 0.03 \), driven by a sinusoidal external force of amplitude \( f_0 = 3 \) and frequency \( 0.8\times3\omega_0 \), at initial conditions \( q(0) = 0 \) (the top row) and \( q(0) = 1 \) (the bottom row), with \( dq/dt \ (0) = 0 \) in both cases.
While the first and the last terms of the last expression depend only of the amplitudes of the individual components of oscillations, the two middle terms are more interesting, because they produce so-called \textit{combinational frequencies} of the two components. For our case, the third term,
\[3A A_{\text{sub}}^2 \cos \Psi \cos^2 \Psi_{\text{sub}} = \frac{3}{4} A A_{\text{sub}}^2 \cos(\Psi - 2\Psi_{\text{sub}}) + \ldots, \tag{5.102}\]
is of special importance, because it produces, besides other combinational frequencies, the subharmonic component with the total phase
\[\Psi - 2\Psi_{\text{sub}} = \frac{\omega t}{3} - \varphi + 2\varphi_{\text{sub}}, \tag{5.103}\]
Thus, within a certain range of the mutual phase shift between the Fourier components, this nonlinear contribution is synchronous with the subharmonic oscillations, and describes the interaction that can deliver to it the energy from the external force, so that the oscillations may be sustained. Note, however, that the amplitude of the term describing this energy exchange is proportional to the square of \(A_{\text{sub}}\), and vanishes at the linearization of the equations of motion near the trivial fixed point. This means that the point is always stable, i.e., the 3\textsuperscript{rd} subharmonic cannot be self-excited and always needs an initial “kick-off” – compare the two panels of Fig. 15. The same is true for higher-order subharmonics.

Only the second subharmonic is a special case. Indeed, let us make a calculation similar to Eq. (102), by replacing Eq. (101) with
\[q(t) \approx A \cos \Psi + A_{\text{sub}} \cos \Psi_{\text{sub}}, \quad \text{where} \quad \Psi \equiv \omega t - \varphi, \quad \Psi_{\text{sub}} \equiv \frac{\omega t}{2} - \varphi_{\text{sub}}, \tag{5.104}\]
for a nonlinear term proportional to \(q^2\):
\[q^2 = (A \cos \Psi + A_{\text{sub}} \cos \Psi_{\text{sub}})^2 = A^2 \cos^2 \Psi + 2AA_{\text{sub}} \cos \Psi \cos \Psi_{\text{sub}} + A_{\text{sub}}^2 \cos^2 \Psi_{\text{sub}}. \tag{5.105}\]
Here the combinational-frequency term capable of supporting the 2\textsuperscript{nd} subharmonic,
\[2AA_{\text{sub}} \cos \Psi \cos \Psi_{\text{sub}} = AA_{\text{sub}} \cos(\Psi - \Psi_{\text{sub}}) = AA_{\text{sub}} \cos(\omega t - \varphi + \varphi_{\text{sub}}) + \ldots, \tag{5.106}\]
is \textit{linear} in the subharmonic’s amplitude, i.e. survives the linearization near the trivial fixed point. This means that the second subharmonic may arise spontaneously, from infinitesimal fluctuations.

Moreover, such excitation of the second subharmonic is very similar to the parametric excitation that was discussed in detail in Sec. 5, and this similarity is not coincidental. Indeed, let us redo the expansion (106) making a somewhat different assumption – that the oscillations are a sum of the forced oscillations at the external force’s frequency \(\omega\) and an \textit{arbitrary but weak} perturbation:
\[q(t) = A \cos(\omega t - \varphi) + \tilde{q}(t), \quad \text{with} \quad |\tilde{q}| \ll A. \tag{5.107}\]
Then, neglecting the small term proportional to \(\tilde{q}^2\), we get
\[q^2 \approx A^2 \cos^2(\omega t - \varphi) + 2\tilde{q}(t) A \cos(\omega t - \varphi). \tag{5.108}\]
Besides the inconsequential phase \(\varphi\), the second term in the last formula is \textit{exactly} similar to the term describing the parametric effects in Eq. (75). This fact means that for a weak perturbation, a system with a quadratic nonlinearity in the presence of a strong “pumping” signal of frequency \(\omega\) is equivalent to a
system with parameters changing in time with frequency \( \omega \). This fact is broadly used for the parametric excitation at high (e.g., optical) frequencies, where the mechanical means of parameter modulation (see, e.g., Fig. 5) are not practicable. The necessary quadratic nonlinearity at optical frequencies may be provided by a non-centrosymmetric nonlinear crystal, e.g., the \( \beta \)-phase barium borate (\( \text{BaB}_2\text{O}_4 \)).

Before finishing this chapter, let me elaborate a bit on a general topic: the relation between the numerical and analytical approaches to problems of dynamics – and physics as a whole. We have just seen that sometimes numerical solutions, like those shown in Fig. 15b, may give vital clues for previously unanticipated phenomena such as the excitation of subharmonics. (The phenomenon of deterministic chaos, which will be discussed in Chapter 9 below, presents another example of such “numerical discoveries”.) One might also argue that in the absence of exact analytical solutions, numerical simulations may be the main theoretical tool for the study of such phenomena. These hopes are, however, muted by the general problem that is frequently called the curse of dimensionality,\(^{39}\) in which the last word refers to the number of parameters of the problem to be solved.\(^{40}\)

Indeed, let us have another look at Fig. 15. OK, we have been lucky to find a new phenomenon, the 3rd subharmonic generation, for a particular set of parameters – in that case, five of them: \( \delta \omega_0 = 0.03, \omega_1 \omega_0 = 2.4, f_0 = 3, q(0) = 1, \) and \( dq/dt(0) = 0 \). Could we tell anything about how common this effect is? Are subharmonics with different \( n \) possible in this system? The only way to address these questions computationally is to carry out similar numerical simulations in many points of the \( d \)-dimensional (in this case, \( d = 5 \)) space of parameters. Say, we have decided that breaking the reasonable range of each parameter to \( N = 100 \) points is sufficient. (For many problems, even more points are necessary – see, e.g., Sec. 9.1.) Then the total number of numerical experiments to carry out is \( N^d = (10^2)^5 = 10^{10} \) – not a simple task even for the powerful modern computing facilities. (Besides the pure number of required CPU cycles, consider the storage and analysis of the results.) For many important problems of nonlinear dynamics, e.g., turbulence, the parameter dimensionality \( d \) is substantially larger, and the computer resources necessary even for one numerical experiment, are much greater.

In the view of the curse of dimensionality, approximate analytical considerations, like those outlined above for the subharmonic excitation, are invaluable. More generally, physics used to stand on two legs: experiment and analytical theory. The enormous progress of computer performance during a few last decades has provided it with one more point of support (a tail? :-) – numerical simulation. This does not mean we can afford to discard any of the legs we are standing on.

5.9. Exercise problems

5.1. For a system with the response function given by Eq. (17), prove Eq. (26) and use an approach different from the one used in Sec. 1, to derive Eq. (34).

Hint: You may like to use the Cauchy integral theorem and the Cauchy integral formula for analytical functions of a complex variable.\(^{41}\)

---

\(^{39}\) This term had been coined in 1957 by Richard Bellman in the context of the optimal control theory (where the dimensionality means the number of parameters affecting the system under control), but gradually has spread all over quantitative sciences using numerical methods.

\(^{40}\) In EM Sec. 1.2, I discuss implications of the curse implications for a different case, when both analytical and numerical solutions to the same problem are possible.

\(^{41}\) See, e.g., MA Eq. (15.1).
5.2. A square-wave pulse of force (see the figure on the right) is exerted on a linear oscillator with eigenfrequency $\omega_0$ (with no damping), initially at rest. Calculate the law of motion $q(t)$, sketch it, and interpret the result.

5.3. At $t = 0$, a sinusoidal external force $F(t) = F_0 \cos \omega t$, is exerted on a linear oscillator with eigenfrequency $\omega_0$ and damping $\delta$, which was at rest at $t \leq 0$.

   (i) Derive the general expression for the time evolution of the oscillator’s coordinate, and interpret the result.
   (ii) Spell out the result for the exact resonance ($\omega = \omega_0$) in a system with low damping ($\delta \ll \omega_0$), and, in particular, explore the limit $\delta \to 0$.

5.4. A pulse of external force $F(t)$, with a finite duration $T$, is exerted on a linear oscillator, initially at rest in its equilibrium position. Neglecting dissipation, calculate the change of oscillator’s energy, using two different approaches, and compare the results.

5.5. For a system with the following Lagrangian function:

$$L = \frac{m}{2} \dot{q}^2 - \frac{\kappa}{2} q^2 + \frac{\varepsilon}{2} \dot{q}^4,$$

calculate the frequency of free oscillations as a function of their amplitude $A$, at $A \to 0$, using two different approaches.

5.6. For a system with the Lagrangian function

$$L = \frac{m}{2} \dot{q}^2 - \frac{\kappa}{2} q^2 + \varepsilon \dot{q}^4,$$

with small parameter $\varepsilon$, use the van der Pol method to find the frequency of free oscillations as a function of their amplitude.

5.7. On the plane $[a_1, a_2]$ of two real, time-independent parameters $a_1$ and $a_2$, find the regions in which the fixed point of the following system of equations,

$$\dot{q}_1 = a_1 (q_2 - q_1),$$
$$\dot{q}_2 = a_2 q_1 - q_2,$$

is unstable, and sketch the regions of each fixed point type – stable and unstable nodes, focuses, etc.

5.8. Solve Problem 3(ii) using the reduced equations (57), and compare the result with the exact solution.

5.9. Use the reduced equations to analyze forced oscillations in an oscillator with weak nonlinear damping, described by the following equation:

$$\ddot{q} + 2 \delta \dot{q} + \omega_0^2 q + \beta \dot{q}^3 = f_0 \cos \omega t,$$
with $\omega \approx \omega_0$; $\beta$, $\delta > 0$; and $\beta \omega A^2 << 1$. In particular, find the stationary amplitude of the forced oscillations and analyze their stability. Discuss the effect(s) of the nonlinear term on the resonance.

5.10. Within the approach discussed in Sec. 4, calculate the average frequency of a self-oscillator outside of the range of its phase-locking by an external sinusoidal force.

5.11. Use the reduced equations to analyze the stability of the forced nonlinear oscillations described by the Duffing equation (43). Relate the result to the slope of resonance curves (Fig. 4).

5.12. Use the van der Pol method to find the condition of parametric excitation of the oscillator described by the following equation:

$$\ddot{q} + 2\delta \dot{q} + \omega_0^2 q(t)q = 0,$$

where $\omega_0^2(t)$ is the square-wave function shown in the figure on the right, with $\omega \approx \omega_0$.

5.13. Use the van der Pol method to analyze parametric excitation of an oscillator with weak nonlinear damping, described by the following equation:

$$\ddot{q} + 2\delta \dot{q} + \omega_0^2 (1 + \mu \cos 2\omega t)q = 0,$$

with $\omega \approx \omega_0$; $\beta$, $\delta > 0$; and $\mu$, $\beta \omega A^2 << 1$. In particular, find the amplitude of stationary oscillations and analyze their stability.

5.14. Adding nonlinear term $\alpha q^3$ to the left-hand side of Eq. (75),

(i) find the corresponding addition to the reduced equations,
(ii) calculate the stationary amplitude $A$ of the parametric oscillations,
(iii) find the type and stability of each fixed point of the reduced equations,
(iv) sketch the Poincaré phase planes of the system in major parameter regions.

5.15. Use the van der Pol method to find the condition of parametric excitation of an oscillator with weak modulation of both the effective mass $m(t) = m_0(1 + \mu \cos 2\omega t)$ and the effective spring constant $\kappa(t) = \kappa_0[1 + \mu \cos(2\omega t - \psi)]$, with the same frequency $2\omega \approx 2\omega_0$, at arbitrary modulation depths ratio $\mu_m/\mu_0$ and phase shift $\psi$. Interpret the result in terms of modulation of the instantaneous frequency $\omega(t) \equiv [\kappa(t)/m(t)]^{1/2}$ and the mechanical impedance $Z(t) \equiv [\kappa(t)m(t)]^{1/2}$ of the oscillator.

5.16. Find the condition of parametric excitation of a nonlinear oscillator described by the following equation:

$$\ddot{q} + 2\delta \dot{q} + \omega_0^2 q + \gamma q^2 = f_0 \cos 2\omega t,$$

with sufficiently small $\delta$, $\gamma$, $f_0$, and $\xi \equiv \omega - \omega_0$. 
Chapter 6. From Oscillations to Waves

In this chapter, the discussion of oscillations is extended to systems with two and more degrees of freedom. This extension naturally leads to another key notion of physics – the waves, in particular those in uniform 1D systems. (A more general discussion of elastic waves in continua is deferred until the next chapter.) However, even the limited scope of the models analyzed in this chapter will still enable us to discuss such important general aspects of waves as their dispersion, phase and group velocities, impedance, reflection, and attenuation.

6.1. Two coupled oscillators

Let us discuss oscillations in systems with several degrees of freedom, starting from the simplest case of two linear (harmonic), dissipation-free, 1D oscillators. If the oscillators are independent of each other, the Lagrangian function of their system may be represented as a sum of two independent terms of the type (5.1):

\[ L = L_1 + L_2, \quad L_{i,2} = T_{i,2} - U_{i,2} = \frac{m_{i,2}}{2} q_{i,2}^2 - \frac{k_{i,2}}{2} q_{i,2}^2. \]  

(6.1)

Correspondingly, Eqs. (2.19) for \( q_j = q_{1,2} \) yields two independent equations of motion of the oscillators, each one being similar to Eq. (5.2):

\[ m_{i,2} \ddot{q}_{i,2} + m_{i,2} \Omega_{i,2}^2 q_{i,2} = 0, \quad \text{where} \quad \Omega_{i,2}^2 = \frac{k_{i,2}}{m_{i,2}}. \]  

(6.2)

(In the context of what follows, \( \Omega_{i,2} \) are sometimes called the partial frequencies.) This means that in this simplest case, an arbitrary motion of the system is just a sum of independent sinusoidal oscillations at two frequencies equal to the partial frequencies (2).

However, as soon as the oscillators are coupled (i.e. interact), the full Lagrangian \( L \) contains an additional mixed term \( L_{\text{int}} \) depending on both generalized coordinates \( q_1 \) and \( q_2 \) and/or generalized velocities. As a simple example, consider the system shown in Fig. 1, there two small masses \( m_{1,2} \) are constrained to move in only one direction (shown horizontal), and are kept between two stiff walls with three springs.

In this case, the kinetic energy is still separable, \( T = T_1 + T_2 \), but the total potential energy, consisting of the elastic energies of three springs, is not:

\[ U = \frac{k_L}{2} q_1^2 + \frac{k_M}{2} (q_1 - q_2)^2 + \frac{k_R}{2} q_2^2, \]  

(6.3a)
where \( q_{1,2} \) are the horizontal displacements of the particles from their equilibrium positions. It is convenient to rewrite this expression as

\[
U = \frac{\kappa_1}{2} q_1^2 + \frac{\kappa_2}{2} q_2^2 - \kappa q_1 q_2, \quad \text{where } \kappa_1 \equiv \kappa_1 + \kappa_M, \quad \kappa_2 \equiv \kappa_R + \kappa_M, \quad \kappa \equiv \kappa_M, \quad (6.3b)
\]

showing that the Lagrangian function \( L = T - U \) of this system contains, besides the partial terms (1), a bilinear interaction term:

\[
L = L_i + L_{2} + L_{\text{int}}, \quad L_{\text{int}} = \kappa q_1 q_2. \quad (6.4)
\]

The resulting Lagrange equations of motion are

\[
\begin{align*}
m_1 \ddot{q}_1 + m_1 \Omega_1^2 q_1 &= \kappa q_2, \\
m_2 \ddot{q}_2 + m_2 \Omega_2^2 q_2 &= \kappa q_1.
\end{align*} \quad (6.5)
\]

Thus the interaction leads to an effective generalized force \( \kappa q_2 \) exerted on subsystem 1 by subsystem 2, and the reciprocal effective force \( \kappa q_1 \).

Please note two important aspects of this (otherwise rather simple) system of equations. First, in contrast to the actual physical interaction forces (such as \( F_{12} = -F_{21} = \kappa_M (q_2 - q_1) \) for our system\(^1\)) the effective forces on the right-hand sides of Eqs. (5) do not obey the 3rd Newton law. Second, the forces are proportional to the same coefficient \( \kappa \); this feature is a result of the general bilinear structure (4) of the interaction energy, rather than of any special symmetry.

From our prior discussions, we already know how to solve Eqs. (5), because it is still a system of linear and homogeneous differential equations, so that its general solution is a sum of particular solutions of the form similar to Eqs. (5.88),

\[
q_1 = c_1 e^{\lambda t}, \quad q_2 = c_2 e^{\lambda t}, \quad (6.6)
\]

with all possible values of \( \lambda \). These values may be found by plugging Eq. (6) into Eqs. (5), and requiring the resulting system of two linear, homogeneous algebraic equations for the distribution coefficients \( c_{1,2} \),

\[
\begin{align*}
m_1 \lambda^2 c_1 + m_1 \Omega_1^2 c_1 &= \kappa c_2, \\
m_2 \lambda^2 c_2 + m_2 \Omega_2^2 c_2 &= \kappa c_1,
\end{align*} \quad (6.7)
\]

to be self-consistent. In our particular case, we get a characteristic equation,

\[
\begin{vmatrix}
m_1 (\lambda^2 + \Omega_1^2) & -\kappa \\
-\kappa & m_2 (\lambda^2 + \Omega_2^2)
\end{vmatrix} = 0, \quad (6.8)
\]

that is quadratic in \( \lambda^2 \), and thus allows a simple analytical solution:

\[
\left( \lambda^2 \right)_\pm = -\frac{1}{2} \left( \Omega_1^2 + \Omega_2^2 \right) \pm \left[ \frac{1}{4} \left( \Omega_1^2 + \Omega_2^2 \right)^2 - \Omega_1^2 \Omega_2^2 + \frac{\kappa^2}{m_1 m_2} \right]^{1/2}
\]

\(^1\) Using these expressions, Eqs. (5) may be readily obtained from the Newton laws, but the Lagrangian approach used above will make their generalization, in the next section, more straightforward.
\[ \Omega_1 \Omega_2 = (\kappa_L + \kappa_R)(\kappa_L + \kappa_M)/(m_1m_2)^{1/2} \] is always larger than \( \kappa/(m_1m_2)^{1/2} = \kappa_0/(m_1m_2)^{1/2} \), so that the square root in Eq. (9) is always smaller than \((\Omega_1^2 + \Omega_2^2)/2\). As a result, both values of \( \lambda^2 \) are negative, i.e. the general solution to Eq. (5) is a sum of four terms, each proportional to \( \exp\{\pm i \omega \pm t\} \), where both own frequencies (“eigenfrequencies”) \( \omega_\pm \equiv i \lambda_\pm \) are real:

\[ \omega_\pm^2 \equiv -\lambda_\pm^2 = \frac{1}{2} \left( \Omega_1^2 + \Omega_2^2 \right) \pm \frac{1}{4} \left( \Omega_1^2 - \Omega_2^2 \right)^2 + \frac{\kappa^2}{m_1m_2} \right]^{1/2}. \] (6.10)

A plot of these eigenfrequencies as a function of one of the partial frequencies (say, \( \Omega_1 \)), with the other partial frequency fixed, gives us the famous anticrossing (also called the “avoided crossing” or “non-crossing”) diagram – see Fig. 2. One can see that at weak coupling, frequencies \( \omega_\pm \) are close to the partial frequencies \( \Omega_{1,2} \) everywhere besides a narrow range near the anticrossing point \( \Omega_1 = \Omega_2 \). Most remarkably, at passing through this region, \( \omega_\pm \) smoothly “switches” from following \( \Omega_2 \) to following \( \Omega_1 \) and vice versa.

The reason for this counterintuitive behavior may be found by examining the distribution coefficients \( c_{1,2} \) corresponding to each branch of the diagram, which may be obtained by plugging the corresponding value of \( \lambda_\pm = -i \omega_\pm \) back into Eqs. (7). For example, at the anticrossing point \( \Omega_1 = \Omega_2 = \Omega \), Eq. (10) is reduced to

\[ \omega_\pm^2 = \Omega^2 \pm \frac{\kappa}{(m_1m_2)^{1/2}} = \Omega^2 \left( 1 \pm \frac{\kappa}{(\kappa_1, \kappa_2)^{1/2}} \right), \] (6.11)

Plugging this expression back into any of Eqs. (7), we see that for the two branches of the anticrossing diagram, the distribution coefficient ratio is the same by magnitude but opposite by sign:

\[ \left( \frac{c_1}{c_2} \right)_\pm = \mp \left( \frac{m_2}{m_1} \right)^{1/2}, \quad \text{at} \quad \Omega_1 = \Omega_2. \] (6.12)
In particular, if the system is symmetric \((m_1 = m_2, \kappa_L = \kappa_R)\), then at the upper branch, corresponding to \(\omega_+ > \omega_\pm\), we get \(c_1 = -c_2\). This means that in this so-called hard mode,\(^2\) \(2\) masses oscillate in anti-phase: \(q_1(t) \equiv -q_2(t)\). The resulting substantial extension/compression of the middle spring (see Fig. 1 again) yields additional returning force which increases the oscillation frequency. On the contrary, at the lower branch, corresponding to \(\omega_-\), the particle oscillations are in phase: \(c_1 = c_2\), i.e. \(q_1(t) \equiv q_2(t)\), so that the middle spring is neither stretched nor compressed at all. As a result, in this soft mode, the oscillation frequency \(\omega_-\) is lower than \(\omega_\pm\), and does not depend on \(\kappa_M\):

\[
\omega_-^2 = \Omega^2 - \frac{\kappa}{m} \frac{\kappa_L}{m} = \frac{\kappa_R}{m}.
\]  

(6.13)

Note that for both modes, the oscillations equally engage both particles.

Far from the anticrossing point, the situation is completely different. Indeed, a similar calculation of \(c_{1,2}\) shows that on each branch of the diagram, the magnitude of one of the distribution coefficients is much larger than that of its counterpart. Hence, in this limit, any particular mode of oscillations involves virtually only one particle. A slow change of system parameters, bringing it through the anticrossing, results, first, in a maximal delocalization of each mode at \(\Omega_1 = \Omega_2\), and then in the restoration of the localization, but in a different partial degree of freedom.

We could readily carry out similar calculations for the case when the systems are coupled via their velocities, \(L_{\text{int}} = m \dot{q}_1 \dot{q}_2\), where \(m\) is a coupling coefficient – not necessarily a certain physical mass.\(^3\) The results are generally similar to those discussed above, again with the maximum level splitting at \(\Omega_1 = \Omega_2 \equiv \Omega\):

\[
\omega_z^2 = \frac{\Omega^2}{1 \mp |m|/(m_1m_2)^{1/2}} \approx \Omega^2 \left[1 \pm \frac{|m|}{(m_1m_2)^{1/2}}\right],
\]  

(6.14)

the last relation being valid for weak coupling. The generalization to the case of both coordinate and velocity coupling is also straightforward – see the next section.

Note that the anticrossing diagram, shown in Fig. 2, is even more ubiquitous in quantum mechanics, because, due to the time-oscillatory character of the Schrödinger equation solutions, a weak coupling of any two quantum states leads to qualitatively similar behavior of the eigenfrequencies \(\omega_z\) of the system, and hence of its eigenenergies (“energy levels”) \(E_z = \hbar \omega_z\) of the system.

One more property of weakly coupled oscillators, a periodic slow transfer of energy from one oscillator to the other and back, especially well pronounced at or near the anticrossing point \(\Omega_1 = \Omega_2\), is also more important for quantum than for classical mechanics. This is why I refer the reader to the QM part of this series for a detailed discussion of this phenomenon.

\(^2\) In physics, the term “mode” is typically used to describe the distribution of a variable in space, at its oscillations with a single frequency. In our current case, when the notion of space is reduced to two oscillator numbers, the “mode” means just a set of two distribution coefficients \(c_{1,2}\) for a particular eigenfrequency.

\(^3\) In mechanics, with \(q_{1,2}\) standing for the actual linear displacements of particles, such coupling is not very natural, but there are many dynamic systems of non-mechanical nature in which such coupling is the most natural one. The simplest example is the system of two \(LC\) (“tank”) circuits, with either capacitive or inductive coupling. Indeed, as was discussed in Sec. 2.2, for such a system, the very notions of the potential and kinetic energies are conditional and interchangeable.
6.2. $N$ coupled oscillators

The calculations of the previous section may be readily generalized to the case of an arbitrary number (say, $N$) coupled harmonic oscillators, with an arbitrary type of coupling. It is evident that in this case Eq. (4) should be replaced with

$$L = \sum_{j=1}^{N} L_j + \sum_{j,j'=1}^{N} L_{jj'}.$$  \hfill (6.15)

Moreover, we can generalize the above expression for the mixed terms $L_{jj'}$, taking into account their possible dependence not only on the generalized coordinates but also on the generalized velocities, in a bilinear form similar to Eq. (4). The resulting Lagrangian may be represented in a compact form,

$$L = \sum_{j,j'=1}^{N} \left( \frac{m_{jj'}}{2} \ddot{q}_j \dot{q}_{j'} - \frac{\kappa_{jj'}}{2} q_j q_{j'} \right),$$ \hfill (6.16)

where the off-diagonal terms are index-symmetric: $m_{jj'} = m_{j'j}$, $\kappa_{jj'} = \kappa_{j'j}$, and the factors $\frac{1}{2}$ compensate the double counting of each term with $j \neq j'$, taking place at the summation over two independently running indices. One may argue that Eq. (16) is quite general if we still want to keep the equations of motion linear – as they always are if the oscillations are small enough.

Plugging Eq. (16) into the general form (2.19) of the Lagrange equation, we get $N$ equations of motion of the system, one for each value of the index $j' = 1, 2, \ldots, N$:

$$\sum_{j=1}^{N} \left( m_{jj'} \ddot{q}_j + \kappa_{jj'} q_j \right) = 0.$$ \hfill (6.17)

Just as in the previous section, let us look for a particular solution to this system in the form

$$q_j = c_j e^{\lambda t}.$$ \hfill (6.18)

As a result, we are getting a system of $N$ linear, homogeneous algebraic equations,

$$\sum_{j=1}^{N} \left( m_{jj'} \lambda^2 + \kappa_{jj'} \right) c_j = 0,$$ \hfill (6.19)

for the set of $N$ distribution coefficients $c_j$. The condition that this system is self-consistent is that the determinant of its matrix equals zero:

$$\text{Det} \left( m_{jj'} \lambda^2 + \kappa_{jj'} \right) = 0.$$ \hfill (6.20)

This characteristic equation is an algebraic equation of degree $N$ for $\lambda^2$, and so has $N$ roots ($\lambda^2$)$_n$. For any Hamiltonian system with stable equilibrium, the matrices $m_{jj'}$ and $\kappa_{jj'}$ ensure that all these roots are real and negative. As a result, the general solution to Eq. (17) is the sum of $2N$ terms proportional to exp \{±i$\omega_n$t\}, $n = 1, 2, \ldots, N$, where all $N$ eigenfrequencies $\omega_n$ are real.

Plugging each of these $2N$ values of $\lambda = \pm i\omega_n$ back into a particular set of linear equations (17), one can find the corresponding set of distribution coefficients $c_{j'\pm}$. Generally, the coefficients are complex, but to keep $q_j(t)$ real, the coefficients $c_{j'}$ corresponding to $\lambda = +i\omega_n$, and $c_{j}$ corresponding to $\lambda = -i\omega_n$ have to be complex-conjugate of each other. Since the sets of the distribution coefficients may be
different for each $\lambda_n$, they should be marked with two indices, $j$ and $n$. Thus, at general initial conditions, the time evolution of the $j$th coordinate may be represented as

$$ q_j = \frac{1}{2} \sum_{n=1}^{N} (c_{jn} \exp\{i\omega_n t\} + c_{jn}^* \exp\{-i\omega_n t\}) \equiv \text{Re} \sum_{n=1}^{N} c_{jn} \exp\{i\omega_n t\}. \quad (6.21) $$

This formula shows very clearly again the physical sense of the distribution coefficients $c_{jn}$: a set of these coefficients, with different values of index $j$ but the same $n$, gives the complex amplitudes of oscillations of the coordinates for the special initial conditions that ensure purely sinusoidal motion of all the system, with frequency $\omega_n$.

The calculation of the eigenfrequencies and distribution coefficients of a particular coupled system with many degrees of freedom from Eqs. (19)–(20) is a task that frequently may be only done numerically.\textsuperscript{4} Let us discuss just two particular but very important cases. First, let all the coupling coefficients be small in the following sense: $|m_{jj'}| << m_j \equiv m_{jj}$ and $|\kappa_{jj'}| << \kappa_j \equiv \kappa_{jj}$, for all $j \neq j'$, and all partial frequencies $\Omega_j \equiv (\kappa_j/m_j)^{1/2}$ be not too close to each other:

$$ \frac{\Omega_j^2 - \Omega_{j'}^2}{\Omega_j^2} \gg \frac{|\kappa_{jj'}|}{\kappa_j}, \quad \frac{|m_{jj'}|}{m_j}, \quad \text{for all } j \neq j'. \quad (6.22) $$

(Such situation frequently happens if parameters of the system are “random” in the sense that they do not follow any special, simple rule – for example, resulting from some simple symmetry of the system.) Results of the previous section imply that in this case, the coupling does not produce a noticeable change of oscillation frequencies: $\{\omega_n\} \approx \{\Omega_j\}$. In this situation, oscillations at each eigenfrequency are heavily concentrated in one degree of freedom, i.e. in each set of the distribution coefficients $c_{jn}$ (for a given $n$), one coefficient’s magnitude is much larger than all others.

Now let the conditions (22) be valid for all but one pair of partial frequencies, say $\Omega_1$ and $\Omega_2$, while these two frequencies are so close that coupling of the corresponding partial oscillators becomes essential. In this case, the approximation $\{\omega_n\} \approx \{\Omega_j\}$ is still valid for all other degrees of freedom, and the corresponding terms may be neglected in Eqs. (19) for $j = 1$ and 2. As a result, we return to Eqs. (7) (perhaps generalized for velocity coupling) and hence to the anticrossing diagram (Fig. 2) discussed in the previous section. As a result, an extended change of only one partial frequency (say, $\Omega_1$) of a weakly coupled system produces a sequence of eigenfrequency anticrossings – see Fig. 3.

\[\text{Fig. 6.3. The level anticrossing in a system of } N \text{ weakly coupled oscillators – schematically.}\]

\textsuperscript{4} Fortunately, very effective algorithms have been developed for this matrix diagonalization task – see, e.g., references in MA Sec. 16(iii)-(iv). For example, the popular MATLAB software package was initially created exactly for this purpose. (‘‘MAT” in its name stands for “matrix” rather than “mathematics”.)
6.3. 1D waves

The second case when the general results of the last section may be simplified are coupled systems with a considerable degree of symmetry. Perhaps the most important of them are uniform systems that may sustain traveling and standing waves. Figure 4a shows a simple example of such a system – a long uniform chain of particles, of mass $m$, connected with light, elastic springs, pre-stretched with the tension force $T$ to have equal lengths $d$. (To some extent, this is a generalization of the two-particle system considered in Sec. 1 – cf. Fig. 1.)

![Diagram](Image)

The spring’s pre-stretch does not affect small longitudinal oscillations $q_j$ of the particles about their equilibrium positions $z_j = jd$ (where the integer $j$ numbers the particles sequentially) – see Fig. 4b.\(^5\) Indeed, in the 2\(^{nd}\) Newton law for such a longitudinal motion of the $j^{th}$ particle, the forces $\mathcal{F}$ and $-\mathcal{F}$ exerted by the springs on the right and the left of it, cancel. However, elastic additions, $\kappa \Delta q$, to these forces are generally different:

$$m\ddot{q}_j = \kappa(q_{j+1} - q_j) - \kappa(q_j - q_{j-1}).$$  \hfill (6.23)

On the contrary, for transverse oscillations within one plane (Fig. 4c), the net transverse component of the pre-stretch force exerted on the $j^{th}$ particle, $\mathcal{F}_t = \mathcal{F}(\sin \varphi_- - \sin \varphi_+)$, where $\varphi_\pm$ are the force direction angles, does not vanish. As a result, direct contributions into this force from small

\(^5\) Note the need a clear distinction between the equilibrium position $z_j$ of the $j^{th}$ point and its deviation from it, $q_j$. Such distinction has to be sustained in the continuous limit (see below), where it is frequently called the Eulerian description – named after L. Euler, even though it was introduced to mechanics by J. d’Alembert. In this course, the distinction is emphasized by using different letters – respectively, $z$ and $q$. (In the 3D case, $r$ and $\mathbf{q}$.)
transverse oscillations, with \( |q_j| \ll d \), \( \mathcal{T} \kappa \) are negligible. Also, due to the first of these strong conditions, the angles \( \varphi_k \) are small, and hence may be approximated, respectively, as \( \varphi_k \approx (q_{j+1} - q_j)/d \) and \( \varphi_k \approx (q_j - q_{j-1})/d \). Plugging these expressions into a similar approximation, \( \mathcal{T}_k \approx \mathcal{T}(\varphi_k - \varphi) \) for the transverse force, we see that it may be expressed as \( \mathcal{T}(q_{j+1} - q_j)/d - \mathcal{T}(q_j - q_{j-1})/d \), i.e. is absolutely similar to that in the longitudinal case, just with the replacement \( \kappa \to \mathcal{T}/d \). As a result, we may write the equation of motion of the \( j \)th particle for these two cases in the same form:

\[
m \ddot{q}_j = \kappa_{ef} (q_{j+1} - q_j) - \kappa_{ef} (q_j - q_{j-1}), \quad (6.24)
\]

where \( \kappa_{ef} \) is the “effective spring constant”, equal to \( \kappa \) for the longitudinal oscillations, and to \( \mathcal{T}/d \) for the transverse oscillations.\(^6\)

Apart from the (formally) infinite size of the system, Eq. (24) is just a particular case of Eq. (17), and thus its particular solution may be looked for in the form (18), where in the light of our previous experience, we may immediately take \( \lambda^2 \equiv -\omega^2 \). With this substitution, Eq. (24) gives the following simple form of the general system of equations (17) for the distribution coefficients \( c_j \):

\[
\left(-m\omega^2 + 2\kappa_{ef}\right)c_j - \kappa_{ef}c_{j+1} - \kappa_{ef}c_{j-1} = 0.
\]  

Now comes the most important conceptual step toward the wave theory. The translational symmetry of Eq. (25), i.e. its invariance to the replacement \( j \to j + 1 \), allows it to have particular solutions of the following form:

\[
c_j = a e^{i\alpha j}, \quad (6.26)
\]

where the coefficient \( \alpha \) may depend on \( \omega \) (and system’s parameters), but not on the particle number \( j \). Indeed, plugging Eq. (26) into Eq. (25) and canceling the common factor \( e^{ij\alpha} \), we see that it is indeed identically satisfied, provided that \( \alpha \) obeys the following algebraic equation:

\[
\left(-m\omega^2 + 2\kappa_{ef}\right) - \kappa_{ef}e^{i\alpha} - \kappa_{ef}e^{-i\alpha} = 0.
\]  

The physical sense of the solution (26) becomes clear if we use it and Eq. (18) with \( \lambda = \mp i\omega \), to write

\[
q_j(t) = \text{Re}\left[ a \exp\left\{ i(kz_j \mp \omega t) \right\} \right] = \text{Re}\left[ a \exp\{ik(z_j \mp v_{ph} t)\} \right], \quad (6.28)
\]

where the wave number \( k \) is defined as \( k \equiv \alpha/d \). Eq. (28) describes a sinusoidal\(^7\) traveling wave of particle displacements, which propagates, depending on the sign before \( v_{ph} \), to the right or the left along the particle chain, with the so-called phase velocity

\[
v_{ph} \equiv \frac{\omega}{k}. \quad (6.29)
\]

---

\(^{6}\) The re-derivation of Eq. (24) from the Lagrangian formalism, with the simultaneous strict proof that the small oscillations in the longitudinal direction and the two mutually perpendicular transverse directions are all independent of each other, is a very good exercise, left for the reader.

\(^{7}\) In optics and quantum mechanics, such waves are usually called monochromatic; I will not use this term until the corresponding parts (EM and QM) of my series.
Perhaps the most important characteristic of a wave system is the so-called *dispersion relation*, i.e. the relation between the wave’s frequency $\omega$ and its wave number $k$ – one may say, between the temporal and spatial frequencies of the wave. For our current system, this relation is given by Eq. (27) with $\alpha \equiv kd$. Taking into account that $(2 - e^{i\alpha} - e^{-i\alpha}) \equiv 2(1 - \cos\alpha) \equiv 4\sin^2(\alpha/2)$, the dispersion relation may be rewritten in a simpler form:

$$\omega = \pm\omega_{\text{max}} \sin \frac{\alpha}{2} \equiv \pm\omega_{\text{max}} \sin \frac{k d}{2}, \text{ where } \omega_{\text{max}} \equiv 2\left(\frac{\kappa_{\text{ef}}}{m}\right)^{1/2}. \tag{6.30}$$

This result, sketched in Fig. 5, is rather remarkable in several aspects. I will discuss them in detail, because most of these features are typical for waves of any type (including even the “de Broglie waves”, i.e. wavefunctions, in quantum mechanics), propagating in periodic structures.

![Fig. 6.5. The dispersion relation (30).](image)

First, at low frequencies, $\omega \ll \omega_{\text{max}}$, the dispersion relation (31) is linear:

$$\omega = \pm \nu k, \quad \text{where } \nu \equiv \left| \frac{d\omega}{dk} \right|_{k=0} = \frac{\omega_{\text{max}} d}{2} = \left(\frac{\kappa_{\text{ef}}}{m}\right)^{1/2} d. \tag{6.31}$$

Plugging Eq. (31) into Eq. (29), we see that the constant $\nu$ plays, in the low-frequency limit, the role of the same phase velocity for waves of any frequency. Due to its importance, this *acoustic wave*\(^8\) limit will with the subject of the special next section.

Second, when the wave frequency is comparable with $\omega_{\text{max}}$, the dispersion relation is *not* linear, and the system is *dispersive*. This means that as a wave, whose Fourier spectrum has several essential components with frequencies of the order of $\omega_{\text{max}}$, travels along the structure, its *waveform* (which may be defined as the shape of the line connecting all points $q_j(z)$, at the same time) changes.\(^9\) This effect may be analyzed by representing the general solution of Eq. (24) as the sum (more generally, an integral) of the components (28) with different complex amplitudes $a$:

$$q_j(t) = \text{Re} \int_{-\infty}^{\infty} a_k \exp\left[i(kz_j - \omega(k)t)\right] dk. \tag{6.32}$$

This notation emphasizes the dependence of the component wave amplitudes $a_k$ and frequencies $\omega$ on the wave number $k$. While the latter dependence is given by the dispersion relation (in our current case by Eq. (30)), the function $a_k$ is determined by the initial conditions. For applications, the case when

---

\(^8\) This term is purely historical. Though the usual sound waves in air belong to this class, the waves we are discussing may have frequencies both well below and well above the human ear’s sensitivity range.

\(^9\) The waveform deformation due to dispersion (which we are considering now) should be clearly distinguished from its possible change due to *attenuation*, i.e. energy loss – which is not taken into account is our current energy-conserving model – cf. Sec. 6 below.
\(a_k\) is substantially different from zero only in a narrow interval, of a width \(\Delta k \ll k_0\) around some central value \(k_0\), is of special importance. The Fourier transform reciprocal to Eq. (32) shows that this is true, in particular, for the so-called wave packet – a sinusoidal wave modulated by a spatial envelope function of a large width \(\Delta z \sim 1/\Delta k >> 1/k_0\) – see, e.g., Fig. 6.

Using the strong inequality \(\Delta k \ll k_0\), the wave packet’s propagation may be analyzed by expending the dispersion relation \(\omega(k)\) into the Taylor series at point \(k_0\), and, in the first approximation in \(\Delta k / k_0\), restricting the expansion to its first two terms:

\[
\omega(k) \approx \omega_0 + \frac{d\omega}{dk} \bigg|_{k=k_0} \tilde{k}, \quad \text{where} \quad \omega_0 \equiv \omega(k_0), \quad \text{and} \quad \tilde{k} \equiv k - k_0. \tag{6.33}
\]

In this approximation, Eq. (32) yields

\[
q_j(t) \approx \Re \int_{-\infty}^{\infty} a_k \exp \left\{ i \left( k_0 + \tilde{k} \right) z_j - \left[ \omega_0 + \frac{d\omega}{dk} \bigg|_{k=k_0} \tilde{k} \right] t \right\} dk \\
\approx \Re \left[ \exp \left\{ i \left( k_0 z_j - \omega_0 t \right) \right\} \int_{-\infty}^{\infty} a_k \exp \left\{ i\tilde{k} \left( z_j - \frac{d\omega}{dk} \bigg|_{k=k_0} t \right) \right\} dk \right]. \tag{6.34}
\]

Comparing the last expression with the initial form of the wave packet,

\[
q_j(0) = \Re \int_{-\infty}^{\infty} a_k e^{ikz_j} dk \equiv \Re \left[ \exp \left\{ ik_0 z_j \right\} \int_{-\infty}^{\infty} a_k \exp \left\{ i\tilde{k} z_j \right\} dk \right], \tag{6.35}
\]

and taking into account that the phase factors before the integrals in the last forms of Eqs. (34) and (35) do not affect its envelope, we see that in this approximation the envelope sustains its initial form and propagates along the system with the so-called group velocity

\[
V_{gr} = \frac{d\omega}{dk} \bigg|_{k=k_0}. \tag{6.36}
\]

Except for the acoustic wave limit (31), this velocity, which characterizes the propagation of waveform’s envelope, is different from the phase velocity (29), which describes the propagation of the “carrier” sinusoidal wave, e.g., the position of one of its zeros – see the red and blue arrows in Fig. 6. (Taking into account the next term in the Taylor expansion of the function \(\omega(q)\), proportional to \(d^2 \omega / dq^2\), we would find that the dispersion leads to a gradual change of the envelope’s form. Such changes play an important role in quantum mechanics, so that they are discussed in detail in the QM part of these lecture notes.)
Next, for our particular dispersion relation (30), the difference between $v_{ph}$ and $v_{gr}$ increases as $\omega$ approaches $\omega_{max}$, with the group velocity (36) tending to zero, while the phase velocity staying almost constant. The physics of such a maximum frequency available for the wave propagation may be readily understood by noticing that according to Eq. (30), at $\omega = \omega_{max}$, the wave number $k$ equals $n\pi/d$, where $n$ is an odd integer, and hence the phase shift $\alpha \equiv kd$ is an odd multiple of $\pi$. Plugging this value into Eq. (28), we see that at $\omega = \omega_{max}$, the oscillations of two adjacent particles are in anti-phase, for example:

$$q_0(t) = \text{Re}[a \exp(-i\omega t)], \quad q_1(t) = \text{Re}[a \exp(i\omega t)] = -q_0(t). \quad (6.37)$$

It is clear, especially from Fig. 4b for longitudinal oscillations, that at such a phase shift, all the springs are maximally stretched/compressed (just as in the hard mode of the two coupled oscillators analyzed in Sec. 1), so that it is natural that this mode has the highest possible frequency.

This fact invites a natural question: what happens with the system if it is agitated at a frequency $\omega > \omega_{max}$, say by an external force applied at its boundary? Reviewing the calculations that have led to the dispersion relation (30), we see that they are all valid not only for real but also any complex values of $k$. In particular, at $\omega > \omega_{max}$ it gives

$$k = \frac{(2n-1)\pi}{d} \pm \frac{i}{\Lambda}, \quad \text{where} \quad n = 1,2,3,..., \quad \Lambda \equiv \frac{d}{2\cosh^{-1}(\omega/\omega_{max})}. \quad (6.38)$$

Plugging this relation into Eq. (28), we see that the wave’s amplitude becomes an exponential function of the particle’s position:

$$|q_j| = |a| e^{\pm jkd} \propto \exp\{\pm z_j/\Lambda\}. \quad (6.39)$$

Physically this means that penetrating into the structure, the wave decays exponentially (from the excitation point), dropping by a factor of $e \approx 3$ at the so-called penetration depth $\Lambda$. (According to Eq. (38), at $\omega \sim \omega_{max}$ this depth is of the order of the distance $d$ between the adjacent particles, and decreases but rather slowly as the frequency is increased beyond $\omega_{max}$. ) Such a limited penetration is a very common property of waves, including the electromagnetic waves penetrating into various plasmas and superconductors, and the quantum-mechanical de Broglie waves penetrating into classically-forbidden regions of space. Note that this effect of “wave expulsion” from a medium does not require any energy dissipation.

Finally, one more fascinating feature of the dispersion relation (30) is its periodicity: if the relation is satisfied by some wave number $k_0(\omega)$, it is also satisfied at any $k_n(\omega) = k_0(\omega) + 2\pi n/d$, where $n$ is an integer. This property is independent of the particular dynamics of the system and is a common property of all systems that are $d$-periodic in the usual (“direct”) space. It has especially important implications for the quantum de Broglie waves in periodic systems – for example, crystals – leading, in particular, to the famous band/gap structure of their energy spectrum.\(^{10}\)

6.4. Acoustic waves

Now let us return to the limit of low-frequency, dispersion-free acoustic waves, with $|\omega| \ll \omega_0$, propagating with the frequency-independent velocity (31). Such waves are the general property of any

\(^{10}\) For more detail see, e.g., QM Sec. 2.5.
elastic continuous medium and obey a simple (and very important) partial differential equation. To
derive it, let us note that in the acoustic wave limit, \( |kd| << 1 \), the phase shift \( \alpha = kd \) is very close to
\( 2 \pi n \). This means that the differences \( q_{j+1}(t) - q_j(t) \) and \( q_j(t) - q_{j-1}(t) \), participating in Eq. (25), are
relatively small and may be approximated with \( \partial q/\partial j = \partial q/\partial (z/d) = d(\partial q/\partial z) \), with the derivatives taken at
middle points between the particles: respectively, \( z_+ \equiv (z_{j+1} - z_j)/2 \) and \( z_- \equiv (z_j - z_{j-1})/2 \). Let us now
consider \( z \) as a continuous argument, and introduce the particle displacement \( q(z, t) \) - a continuous
function of space and time, satisfying the requirement \( q(z_j, t) = q_j(t) \). In this notation, in the limit \( kd \rightarrow 0 \),
the sum of the last two terms of Eq. (24) becomes \(- \kappa d [\partial^2 q/\partial z^2] \), and hence may be
approximated as \(- \kappa d^2 (\partial^2 q/\partial z^2) \), with the second derivative taken at point \((z_+ - z_-)/2 \equiv z_j \), i.e. exactly at
the same point as the time derivative. As the result, the whole set of *ordinary* differential equations (24), for
different \( j \), is reduced to just one *partial* differential equation

\[
\frac{m}{\kappa} \frac{\partial^2 q}{\partial t^2} - \kappa \frac{d^2}{\partial z^2} q = 0.
\]

(6.40a)

Using Eq. (31), we may rewrite this **1D wave equation** in a more general form

\[
\left( \frac{1}{v^2} \frac{\partial^2}{\partial t^2} - \frac{\partial^2}{\partial z^2} \right) q(z, t) = 0.
\]

(6.40b)

The most important property of the wave equation (40), which may be verified by an elementary
substitution, is that it is satisfied by either of two traveling wave solutions (or their linear superposition):

\[
q_+(z, t) = f_+ (t - z / v), \quad q_-(z, t) = f_- (t + z / v),
\]

(6.41)

where \( f_\pm \) are any smooth functions of one argument. The physical sense of these solutions may be
revealed by noticing that the displacements \( q_\pm \) do not change at the addition of an arbitrary change \( \Delta t \) to
their time argument, provided that it is accompanied by an addition of the proportional addition of \( \mp v \Delta t \)
to their space argument. This means that with time, the waveforms just move (respectively, to the left or
the right), with the constant speed \( v \), retaining their form – see Fig. 7.\(^{12} \)

Returning to the simple model shown in Fig. 4, let me emphasize that the acoustic-wave velocity \( v \) is different for the waves of two types: for the longitudinal waves (with \( \kappa_{ef} = \kappa \), see Fig. 4b),

\[\text{Fig. 6.7. Propagation of a traveling wave in a dispersion-free 1D system.}\]

\[\text{Fig. 7. \quad Returns to the simple model shown in Fig. 4, let me emphasize that the acoustic-wave velocity} v \text{ is different for the waves of two types: for the longitudinal waves (with} \kappa_{ef} = \kappa \text{, see Fig. 4b),}\]

\[\text{\text{11 Strictly speaking, per the discussion at the end of the previous section, in this reasoning \( k \) means the distance of the wave number from the closest point \( 2 \pi n / d \) – see Fig. 5 again.}\}

\[\text{12 From the point of view of Eq. (40), the only requirement to the “smoothness” of the functions} f_\pm \text{ is to be doubly differentiable. However, we should not forget that in our case the wave equation is only an approximation of the discrete Eq. (24), so that according to Eq. (30), the traveling waveform conservation is limited by the acoustic wave limit condition} \omega \ll \omega_{\text{max}}, \text{ which should be fulfilled for any Fourier component of these functions.}\]
\[ v = v_i = \left( \frac{\kappa}{m} \right)^{1/2} d, \quad (6.42) \]

while for the transverse waves (with \( \kappa_{ef} = \mathcal{T}d \), see Fig. 4c):

\[ v = v_i = \left( \frac{\mathcal{T}}{md} \right)^{1/2} d = \left( \frac{\mathcal{T}d}{m} \right)^{1/2} \equiv \left( \frac{\mathcal{T}}{\mu} \right)^{1/2}, \quad (6.43) \]

where the constant \( \mu \equiv m/d \) has a simple physical sense of the particle chain’s mass per unit length. Evidently, these velocities, in the same system, may be rather different.

The wave equation (40), with its only parameter \( v \), may conceal the fact that any wave-supporting system is characterized by one more key parameter. In our current model (Fig. 4), this parameter may be revealed by calculating the forces \( F(z, t) \) accompanying any of the traveling waves (41) of particle displacements. For example, in the acoustic wave limit \( kd \to 0 \) we are considering now, the force exerted by the \( j^{th} \) particle on its right neighbor may be approximated as

\[ F(z_j, t) \equiv \kappa_{ef} \left[ q_j(t) - q_{j+1}(t) \right] \approx -\kappa_{ef} \left. \frac{\partial q}{\partial z} \right|_{z=z_j} d, \quad (6.44) \]

where, as was discussed above, \( \kappa_{ef} \) equals \( \kappa \) for the longitudinal waves, and to \( \mathcal{T}d \) for the transverse waves. But for the traveling waves (41), the partial derivatives \( \partial q_{\pm}/\partial z \) are equal to \( \mp (df_{\pm}/dt)/v \), so that the corresponding forces are equal to

\[ F_{\pm} = \mp \frac{\kappa_{ef} d}{v} \frac{df_{\pm}}{dt}, \quad (6.45) \]

i.e. are proportional to the particle’s velocities \( u = \partial q/\partial t \) in these waves,\(^{13}\) \( u_{\pm} = df_{\pm}/dt \), for the same \( z \) and \( t \). This means that the ratio

\[ \frac{F_{\pm}(z, t)}{u_{\pm}(z, t)} = -\kappa_{ef} d \frac{\partial q_{\pm}}{\partial z} / \partial t = -\kappa_{ef} d \frac{(\mp df_{\pm}/dt)/v}{df_{\pm}/dt} \equiv \pm \frac{\kappa_{ef} d}{v}, \quad (6.46) \]

depends only on the wave propagation direction, but is independent of \( z \) and \( t \), and also of the propagating waveform. Its magnitude,

\[ Z \equiv \left| \frac{F_{\pm}(z, t)}{u_{\pm}(z, t)} \right| = \frac{\kappa_{ef} d}{v} \left( \kappa_{ef} m \right)^{1/2}, \quad (6.47) \]

characterizing the dynamic “stiffness” of the system for the propagating waves, is called the wave impedance.\(^{14}\) Note that the impedance is determined by the product of the system’s generic parameters \( \kappa_{ef} \) and \( m \), while the wave velocity (31) is proportional to their ratio, so that these two parameters are completely independent, and both are important. According to Eq. (47), the wave impedance, just as the wave velocity, is also different for the longitudinal and transverse waves:

\[ Z_l = \frac{kd}{v_i} \equiv \left( \kappa m \right)^{1/2}, \quad Z_t = \frac{\mathcal{T}}{v_i} \equiv \left( \mathcal{T} \mu \right)^{1/2}. \quad (6.48) \]

\(^{13}\) Of course, the particle’s velocity \( u \) (which proportional to the wave amplitude) should not be confused with the wave’s velocity \( v \) (which is independent of this amplitude).

\(^{14}\) This notion is regretfully missing from many physics (but not engineering!) textbooks.
(Note that the first of these expressions for $Z$ coincides with the one used for a single oscillator in Sec. 5.6. In that case, $Z$ may be also recast in a form similar to Eq. (46), namely, as the ratio of the force and velocity amplitudes at free oscillations.)

One of the wave impedance’s key functions is to scale the power carried by a traveling wave:

\[
\mathcal{P}_\pm \equiv F_\pm(z,t)u_\pm(z,t) = -\kappa_{\text{el}} d \frac{\partial q_\pm}{\partial z} \frac{\partial q_\pm}{\partial t} = \pm \frac{\kappa_{\text{el}} d}{v} \left( \frac{df_\pm}{dt} \right)^2 = \pm Z \left( \frac{df_\pm}{dt} \right)^2. \tag{6.49}
\]

Two remarks about this important result. First, the sign of $\mathcal{P}$ depends only on the direction of the wave propagation, but not on the waveform. Second, the instant value of the power does not change if we move with the wave in question, i.e. measure $\mathcal{P}$ at points with $z \pm vt = \text{const}$. This is natural because in the Hamiltonian system we are considering, the wave energy is conserved. Hence, the wave impedance $Z$ characterizes the energy transfer along the system rather than its dissipation.

Another important function of the wave impedance notion becomes clear when we consider waves in non-uniform systems. Indeed, our previous analysis assumed that the 1D system supporting the waves (Fig. 4) is exactly periodic, i.e. macroscopically uniform, and extends all the way from $-\infty$ to $+\infty$. Now let us examine what happens when this is not true. The simplest, and very important example of such nonuniform systems is a sharp interface, i.e. a point (say, $z = 0$) at which system parameters experience a jump while remaining constant on each side of the interface – see Fig. 8.

![Fig. 6.8. Partial reflection of a wave from a sharp interface.](image)

In this case, the wave equation (40) and its partial solutions (41) are still valid for $z < 0$ and $z > 0$ – in the former case, with primed parameters. However, the jump of parameters at the interface leads to a partial reflection of the incident wave from the interface, so that at least on the side of the incidence (in the case shown in Fig. 8, for $z \geq 0$), we need to use two such terms, one describing the incident wave and another one, the reflected wave:

\[
q(z,t) = \begin{cases} 
  f_-'(t + z/v'), & \text{for } z \leq 0, \\
  f_-'(t + z/v) + f_+'(t - z/v), & \text{for } z \geq 0. 
\end{cases} \tag{6.50}
\]

To find the relations between the functions $f_-$, $f_+$, and $f_-'$ (of which the first one, describing the incident wave, may be considered known), we may use two boundary conditions at $z = 0$. First, the displacement $q_0(t)$ of the particle at the interface has to be the same whether it is considered a part of the left or right sub-system, and it participates in Eqs. (50) for both $z \leq 0$ and $z \geq 0$. This gives us the first boundary condition:

\[
f_-'(t) = f_-'(t) + f_+'(t). \tag{6.51}
\]

On the other hand, the forces exerted on the interface from the left and the right should also have equal magnitude, because the interface may be considered as an object with a vanishing mass, and any
nonzero net force would give it an infinite (and hence unphysical) acceleration. Together with Eqs. (45) and (47), this gives us the second boundary condition:

\[
Z' \frac{df_-'(t)}{dt} = Z \left[ \frac{df_-'(t)}{dt} - \frac{df_+(t)}{dt} \right].
\]  

(6.52)

Integrating both parts of this equation over time, and neglecting the integration constant (which describes a common displacement of all particles rather than their oscillations), we get

\[
Z' f_-'(t) = Z [f_-(t) - f_+(t)].
\]  

(6.53)

Now solving the system of two linear equations (51) and (53) for \(f_+(t)\) and \(f_-'(t)\), we see that both these functions are proportional to the incident waveform:

\[
f_+(t) = R f_-(t), \quad f_-'(t) = T f_-(t),
\]  

(6.54)

with the following reflection (\(R\)) and transmission (\(T\)) coefficients:

\[
\begin{align*}
R &= \frac{Z - Z'}{Z + Z'}, \\
T &= \frac{2Z}{Z + Z'}.
\end{align*}
\]  

(6.55)

Later in this series, we will see that with the appropriate re-definition of the impedance, these relations are also valid for waves of other physical nature (including the de Broglie waves in quantum mechanics) propagating in 1D continuous structures, and also in continua of higher dimensions, at the normal wave incidence upon the interface.\(^{15}\) Note that the coefficients \(R\) and \(T\) give the ratios of wave amplitudes, rather than their powers. Combining Eqs. (49) and (55), we get the following relations for the powers – either at the interface or at the corresponding points of the reflected and transmitted waves:

\[
\begin{align*}
\mathcal{P}_+ &= \left( \frac{Z - Z'}{Z + Z'} \right)^2 \mathcal{P}_-, \\
\mathcal{P}_-' &= \frac{4ZZ'}{(Z + Z')^2} \mathcal{P}_-.
\end{align*}
\]  

(6.56)

Note that \(\mathcal{P}_+ + \mathcal{P}_- = \mathcal{P}_-'\), again reflecting the wave energy conservation.

Perhaps the most important corollary of Eqs. (55)–(56) is that the reflected wave completely vanishes, i.e. the incident wave is completely transmitted through the interface (\(\mathcal{P}_-' = \mathcal{P}_-\)), if the so-called impedance matching condition \(Z' = Z\) is satisfied, even if the wave velocities \(v\) (32) are different on the left and the right sides of it. On the contrary, the equality of the acoustic velocities in the two continua does \textit{not} guarantee the full transmission of their interface. Again, this is a very general result.

Finally, let us note that for the important particular case of a sinusoidal incident wave:\(^{16}\)

\[
\begin{align*}
f_-(t) &= \text{Re} \left[ a e^{-i \omega t} \right], \\
\text{so that} \quad f_+'(t) &= \text{Re} \left[ R a e^{-i \omega t} \right],
\end{align*}
\]  

(6.57)

where \(a\) is its complex amplitude, the total wave (50) on the right of the interface is

\[^{15}\text{See, the corresponding parts of the lecture notes: QM Sec. 2.3 and EM Sec. 7.3.}\]

\[^{16}\text{In the acoustic wave limit, when the impedances} \ Z \text{ and} \ Z', \text{and hence the reflection coefficient} \ R, \text{are real,} \ R \text{ and} \ Z \text{ may be taken from under the Re operators in Eqs. (57)-(59). However, in the current, more general form of these relations they are also valid for the case of arbitrary frequencies,} \ \omega \sim \omega_{\text{max}}, \text{when} \ R \text{ and} \ Z \text{ may be complex.}\]

---

Chapter 6  Page 15 of 28
while according to Eq. (45), the corresponding force distribution is
\[ F(z, t) = F_-(z, t) + F_+(z, t) = -Z \frac{\partial f_-(t - z/v)}{\partial t} + Z \frac{\partial f_+(t - z/v)}{\partial t} = \Re \left[ i \omega Z a \left( e^{-ikz} - R e^{ikz} \right) e^{-i\alpha t} \right]. \quad (6.59) \]

These expressions will be used in the next section.

### 6.5. Standing waves

Now let us consider the two limits in which Eqs. (55) predicts a total wave reflection \((T = 0)\): \(Z'/Z \to \infty\) (when \(R = -1\)) and \(Z'/Z \to 0\) (when \(R = +1\)). According to Eq. (53), the former limit corresponds to \(f(t) + f(t) = q(0, t) = 0\), i.e. to vanishing oscillations at the interface. This means that this particular limit describes a perfectly rigid boundary, not allowing the system’s end to oscillate at all. In this case, Eqs. (58)-(59) yield
\[ q(z, t) = \Re \left[ a \left( e^{-ikz} - e^{ikz} \right) e^{-i\alpha t} \right] = -2 \Re \left[ a e^{-i\alpha t} \right] \sin k\zeta, \quad (6.60) \]
\[ F(z, t) = \Re \left[ i \omega Z a \left( e^{-ikz} + e^{ikz} \right) e^{-i\alpha t} \right] = 2\omega Z \Re \left[ a e^{i(\alpha t - \pi/2)} \right] \cos k\zeta. \quad (6.61) \]

These equalities mean that we may interpret the process on the right of the interface using two mathematically equivalent, but physically different languages: either as the sum of two traveling waves (the incident one and the reflected one, traveling in opposite directions), or as a single standing wave. Note that in contrast with the traveling wave (Fig. 9a, cf. Fig. 7), in the standing sinusoidal wave (Fig. 9b) all particles oscillate in time with one phase.

\[ q(z, t) = \Re \left[ a \left( e^{-ikz} - e^{ikz} \right) e^{-i\alpha t} \right] = -2 \Re \left[ a e^{-i\alpha t} \right] \sin k\zeta, \quad (6.60) \]
\[ F(z, t) = \Re \left[ i \omega Z a \left( e^{-ikz} + e^{ikz} \right) e^{-i\alpha t} \right] = 2\omega Z \Re \left[ a e^{i(\alpha t - \pi/2)} \right] \cos k\zeta. \quad (6.61) \]

These equalities mean that we may interpret the process on the right of the interface using two mathematically equivalent, but physically different languages: either as the sum of two traveling waves (the incident one and the reflected one, traveling in opposite directions), or as a single standing wave. Note that in contrast with the traveling wave (Fig. 9a, cf. Fig. 7), in the standing sinusoidal wave (Fig. 9b) all particles oscillate in time with one phase.

\[ q(z, t) = \Re \left[ a \left( e^{-ikz} - e^{ikz} \right) e^{-i\alpha t} \right] = -2 \Re \left[ a e^{-i\alpha t} \right] \sin k\zeta, \quad (6.60) \]
\[ F(z, t) = \Re \left[ i \omega Z a \left( e^{-ikz} + e^{ikz} \right) e^{-i\alpha t} \right] = 2\omega Z \Re \left[ a e^{i(\alpha t - \pi/2)} \right] \cos k\zeta. \quad (6.61) \]

Note also that the phase of the force oscillations (61) is shifted, both in space and in time, by \(\pi/2\) relatively to the particle displacement oscillations. (In particular, at the rigid boundary the force amplitude reaches its maximum.) As a result, the average power flow vanishes, so that the average energy of the standing wave does not change, though its instant energy still oscillates, at each spatial point, between its kinetic and potential components – just as at the usual harmonic oscillations of one particle. A similar standing wave, but with a maximum of the displacement \(q\), and with a zero (“node”) of the force \(F\), is formed at the open boundary, with \(Z'/Z \to 0\), and hence \(R = +1\).
Now I have to explain why I have used the sinusoidal waveform for the wave reflection analysis. Let us consider a 1D wave system, which obeys Eq. (40), of a finite length \( l \), limited by two rigid walls (located, say, at \( z = 0 \) and \( z = l \)), which impose the corresponding boundary conditions,

\[
q(0,t) = q(l,t) = 0, \tag{6.62}
\]
on its motion. Naturally, a sinusoidal traveling wave, induced in the system, will be reflected from both ends, forming the standing wave patterns of the type (60) near each of them. These two patterns are compatible if \( l \) is exactly equal to an integer number (say, \( n \)) of \( \lambda/2 \), where \( \lambda \equiv 2\pi/k \) is the wavelength:

\[
l = n \frac{\lambda}{2} \equiv n \frac{\pi}{k}. \tag{6.63}
\]

This requirement yields the following spectrum of possible wave numbers:

\[
k_n = n \frac{\pi}{l}, \tag{6.64}
\]

where the list of possible integers \( n \) may be limited to non-negative values: \( n = 1, 2, 3, \ldots \) (Indeed, negative values give absolutely similar waves (60), while \( n = 0 \) yields \( k_n = 0 \), and the corresponding wave vanishes at all points: \( \sin(0\cdot z) \equiv 0 \).) In the acoustic wave limit we are discussing, Eq. (31), \( \omega = \pm vk \), may be used to translate this wave-number spectrum into an equally simple spectrum of possible standing-wave frequencies:\(^\text{17}\)

\[
\omega_n = vk_n = n \frac{\pi v}{l}, \quad \text{with} \quad n = 1, 2, 3, \ldots \tag{6.65}
\]

Now let us notice that this spectrum, and the corresponding standing-wave patterns,\(^\text{18}\)

\[
q^{(n)}(z,t) = 2 \text{Re}\left[a_n \exp\{-i\omega_n t\}\right] \sin k_n z, \quad \text{for} \quad 0 \leq z \leq l, \tag{6.66}
\]

may be obtained in a different way, by a direct solution of the wave equation (41) with the boundary conditions (62). Indeed, let us look for the general solution of this partial differential equation in the so-called \textit{variable-separated} form\(^\text{19}\)

\[
q(z,t) = \sum_n Z_n(z)T_n(t), \tag{6.67}
\]

where each partial product \( Z_n(z)T_n(t) \) is supposed to satisfy the equation on its own. Plugging such partial solution into Eq. (40), and then dividing all its terms by the same product, \( Z_nT_n \), we may rewrite the result as

\[
\frac{1}{v^2} \frac{1}{T_n} \frac{d^2 T_n}{dt^2} = \frac{1}{Z_n} \frac{d^2 Z_n}{dz^2}. \tag{6.68}
\]

Here comes the punch line of the variable separation method: since the left-hand side of the equation may depend only on \( t \), while its right-hand side, only on \( z \), Eq. (68) may be valid only if both its sides are constant. Denoting this constant as \(-k_n^2\), we get two similar ordinary differential equations,

\(^{17}\) Again, negative values of \( \omega \) may be dropped, because they give similar real functions \( q(z,t) \).

\(^{18}\) They describe, in particular, the well-known transverse standing waves on a guitar string.

\(^{19}\) This \textit{variable separation method} is very general and is discussed in all parts of this series, especially in EM Chapter 2.
\[
\frac{d^2 Z_n}{dz^2} + k_n^2 Z_n = 0, \quad \frac{d^2 T_n}{dt^2} + \omega_n^2 T_n = 0, \quad \text{where} \quad \omega_n^2 \equiv v^2 k_n^2,
\]  
(6.69)

with well-known (and similar) sinusoidal solutions

\[
Z_n = c_n \cos k_n z + s_n \sin k_n z, \quad T_n = u_n \cos \omega_n t + v_n \sin \omega_n z \equiv \text{Re}[a_n \exp(-i \omega_n t)],
\]  
(6.70)

where \(c_n, v_n, u_n,\) and \(v_n\) (or, alternatively, \(a_n \equiv u_n + iv_n\)) are constants. The first of these relations, with all \(k_n\) different, may satisfy the boundary conditions only if for all \(n, c_n = 0,\) and \(\sin k_n l = 0,\) giving the same wave number spectrum (64) and hence the own frequency spectrum (65), so that the general solution (67) of the so-called boundary problem, given by Eqs. (40) and (62), takes the form

\[
q(z,t) = \text{Re} \sum_n a_n \exp(-i \omega_n t) \sin k_n z,
\]  
(6.71)

where the complex amplitudes \(a_n\) are determined by the initial conditions.

Hence such sinusoidal standing waves (Fig. 10a) are not just an assumption, but a natural property of the 1D wave equation. It is also easy to verify that the result (71) is valid for the same system with different boundary conditions, though with a modified wave number spectrum. For example, if the rigid boundary condition \(q = 0\) is implemented at \(z = 0,\) and the so-called free (or “open”) boundary conditions \((\partial q/\partial z = 0)\) is imposed at \(z = l,\) the spectrum becomes

\[
k_n = \left(n - \frac{1}{2}\right) \frac{\pi}{l}, \quad \text{with} \quad n = 1, 2, 3, \ldots,
\]  
(6.72)

so that the lowest standing waves look like Fig. 10b shows.\(^{20}\)

---

\![Fig. 6.10. The lowest standing wave modes for the 1D systems with (a) two rigid boundaries, and (b) one rigid and one open boundary.](image)

Note that the difference between the sequential values of \(k_n\) is still constant:

\[
k_{n+1} - k_n = \frac{\pi}{l},
\]  
(6.73)

i.e. the same as for the spectrum (64). This is natural because in both cases the transfer from the \(n^{th}\) mode to the \((n + 1)^{th}\) mode corresponds just to an addition of one more half-wave – see Fig. 10. (This conclusion is valid for any combination of rigid and free boundary conditions.) As was discussed above, for the discrete-particle chain we have started with (Fig. 4), the wave equation (40), and hence the above

\(^{20}\) The lowest standing wave of the system, with the smallest \(k_n\) and \(\omega_n,\) is usually called its fundamental mode.
derivation of Eq. (71), are only valid in the acoustic wave limit, i.e. when the distance \( d \) between the particles is much less than the wavelengths \( \lambda_n \equiv 2\pi k_n \) of the mode under analysis. For a chain of length \( l \), this means that the number of particles, \( N \sim l/d \), has to be much larger than 1. However, a remarkable property of Eq. (71) is that it remains valid, with the same wave number spectrum (64), not only in the acoustic limit but also for arbitrary \( N > 0 \). Indeed, since \( \sin k_n z = (\exp{+ik_n z} - \exp{-ik_n z})/2 \), each \( n^{th} \) term of Eq. (71) may be represented as a sum of two traveling waves with equal but opposite wave vectors. As was discussed in Sec. 3, such a wave is a solution of equation (24) describing the discrete-particle system for any \( k_n \), with the only condition that its frequency obeys the general dispersion relation (30), rather than its acoustic limit (65).

Moreover, the expressions for \( k_n \) (with appropriate boundary conditions), such as Eq. (64) or Eq. (72), also survive the transition to arbitrary \( N \), because their derivation above was based only on the sinusoidal form of the standing wave. The only new factor arising in the case of arbitrary \( N \) is that due to the equidistant property (73) of the wave number spectrum, as soon as \( n \) exceeds \( N \), the waveforms (71), at particle locations \( z_j = jd \), start to repeat. For example,

\[
\sin k_{n+N}z_j = \sin(k_n + N\Delta k)jd = \sin k_n z_j + N\Delta k d = \pm \sin k_n z_j .
\] (6.74)

Hence the system has only \( N \) different (linearly-independent) modes. But this result is in full compliance with the general conclusion made in Sec. 2, that any system of \( N \) coupled 1D oscillators has exactly \( N \) own frequencies and corresponding oscillation modes. So, our analysis of a particular system, shown in Fig. 4, just exemplifies this general conclusion. Fig. 11 below illustrates this result for a particular finite value of \( N \); the curve connecting the points shows exactly the same dispersion relation as was shown in Fig. 5, but now it is just a guide for the eye, because for a system with a finite length \( l \), the wave number spectrum is discrete, and the intermediate values of \( k \) and \( \omega \) do not have an immediate physical sense.\(^{21}\) Note that the own frequencies of the system are not equidistant, while the wave numbers are.

This insensitivity of the spacing (73) between the adjacent wave numbers to the particular physics of a macroscopically uniform system is a very general fact, common for waves of any nature, and is broadly used for analyses of systems with a very large number of particles (such as human-size crystals, with \( N \sim 10^{23} \)). For \( N \) so large, the effect of the boundary conditions, e.g., the difference

\(^{21}\) Note that Fig. 11 shows the case of one rigid and one open boundary (see Fig. 10b), where \( l = Nd \); for a conceptually simpler system with two rigid boundaries (Fig. 10a) we would need to take \( l = (N + 1)d \), because neither of the end points can oscillate.
between the spectra (64) and (72) is negligible, and they may be summarized as the following rule for the number of different standing waves within some interval \( \Delta k >> \pi / l \):

\[
\Delta N \equiv \left. \frac{\Delta k}{k_{n+1} - k_n} \right|_{\text{standing}} = \frac{l}{\pi} \Delta k|_{\text{standing}}.
\]  

For such analyses, it is frequently more convenient to work with traveling waves rather than the standing ones. In this case, we have to take into account that (as was just discussed above) each standing wave (66) may be decomposed to two traveling waves with wave numbers \( \pm k_n \), so that size of the interval \( \Delta k \) doubles, and Eq. (75a) becomes\(^{22}\):

\[
\Delta N = \frac{l}{2\pi} \Delta k|_{\text{traveling}}.
\]  

Note that this counting rule is valid for waves of just one type. As was discussed above, for the model system we have studied (Fig. 4), there are 3 types of such waves – one longitudinal and two transverse, so that if we need to count them all, \( \Delta N \) should be multiplied by 3.

6.6 Wave decay and attenuation

Now let us discuss the effects of dissipation on the 1D waves, on the example of the same uniform system shown in Fig. 4. The effects are simplest for a linear drag that may be described, as it was done for a single oscillator in Sec. 5.1, by adding the term \( \eta dq_j/dt \), to Eq. (24) for each particle:

\[
m \ddot{q}_j - \eta q_j - \kappa_{cf}(q_{j+1} - q_j) + \kappa_{cf}(q_j - q_{j-1}) = 0.
\]  

(In a uniform system, the drag coefficient \( \eta \) should be similar for all particles, though it may be different for the longitudinal and transverse oscillations.)

To analyze the dissipation effect on the standing waves, we may again use the variable separation method, i.e. look for the solution of Eq. (76) in the form similar to Eq. (67), naturally re-adjusting it for our current discrete case:

\[
q(z_j, t) = \sum_n Z_n(z_j)T_n(t).
\]  

After dividing all terms by \( mZ_n(z_j)T_n(t) \), and separating the time-dependent and space-dependent terms, we get

\[
\frac{\dot{T}_n}{T_n} + \frac{\eta}{m} \frac{T_n}{T_n} = \frac{\kappa_{cf}}{m} \left[ \frac{Z_n(z_{j+1})}{Z_n(z_j)} + \frac{Z_n(z_{j+1})}{Z_n(z_j)} - 2 \right] = \text{const}.
\]  

As we know from the previous section, the resulting equation for the function \( Z_n(z) \) is satisfied if the variable separation constant is equal to \(-\omega_h^2\), where \( \omega_h \) obeys the dispersion relation (30) for the wave number \( k_n \), properly calculated for the dissipation-free system, with the account of the given boundary

\(^{22}\) Note that this simple, but very important relation is frequently derived using the so-called Born-Carman boundary condition \( q_0(t) \equiv q_N(t) \), which implies bending the system of interest into a closed loop. For a 1D system with \( N >> 1 \), such mental exercise may be somehow justified, but for systems of higher dimension, it is hardly physically plausible – and is unnecessary.
conditions – see, e.g. Eqs. (62) and (72). Hence for the function $T_n(t)$ we are getting the ordinary differential equation

$$\ddot{T}_n + 2\delta \dot{T}_n + \omega_n^2 T_n = 0,$$

with $\delta \equiv \frac{n}{2m}$, \hspace{1cm} (6.79)

which is absolutely similar to Eq. (5.6b) for a single linear oscillator, which was studied in Sec. 5.1. As we already know, it has the solution (5.9), describing the free oscillation decay with the relaxation time given by (5.10), $\tau = 1/\delta$, and hence similar for all modes.\hspace{1cm} (6.10)

Hence, the above analysis of the dissipation effect on the free standing waves has not brought any surprises, but it gives us a hint of how their forced oscillations, induced by some external forces $F_j(t)$ exerted on the particles, may be analyzed. Indeed, representing the force as a sum of spatial harmonics proportional to the system’s modes,

$$F_j(t) = m \sum_n f_n(t) Z_n(z_j),$$ \hspace{1cm} (6.80)

and using the variable separation (77), we arrive at the equation

$$\ddot{T}_n + 2\delta \dot{T}_n + \omega_n^2 T_n = f_n(t),$$ \hspace{1cm} (6.81)

similar to Eq. (5.13b) for a single oscillator. This fact enables using all the methods discussed in Sec. 5.1 for the forced oscillation analysis, besides that the temporal Green’s function, defined by either of the equivalent equations (5.27) and (5.28), now acquires the index $n$, i.e. becomes mode-dependent: $G(\tau) \rightarrow G_n(\tau)$. Performing the weighed summation similar to Eq. (80),

$$G_j(\tau) = \sum_n G_n(\tau) Z_n(z_j),$$ \hspace{1cm} (6.82)

we get the spatial-temporal Green’s function of the system – in this case, for a discrete, 1D set of spatial points $z_j = jd$. As in the single-oscillator case, it has a simple physical sense of the oscillations induced by a delta-functional force (i.e. a very short pulse), exerted on the $j$th particle. We will meet (and use) such spatial-temporal Green’s functions in other parts of this series as well.

Now let us discuss the dissipation effects on the traveling waves, where they may take a completely different form of attenuation. Let us discuss it on a simple example when one end (located at $z = 0$) of a very long chain $(l \rightarrow \infty)$ is externally-forced to perform sinusoidal oscillations of a certain frequency $\omega$ and a fixed amplitude $A_0$. In this case, it is natural to look for the particular solution of Eq. (76) in a form very different from Eq. (77):

$$q_j(z,t) = \text{Re} \left[ c_j e^{-i\omega t} \right],$$ \hspace{1cm} (6.83)

with time-independent but generally complex amplitudes $c_j$. As our discussion of a single oscillator in Sec. 5.1 implies, this is not the general, but rather a partial solution, which describes forced oscillations

\hspace{1cm} 23 Even an elementary experience with acoustic guitars shows that for their strings this particular conclusion of our theory is not valid: higher modes (“overtones”) decay substantially faster, leaving the fundamental mode oscillations for a slower decay. This is a result of another important energy loss (i.e. the wave decay) mechanism, not taken into account in Eq. (76) – the radiation of the sound into the guitar’s body through the string supports, mostly through the bridge. Such radiation may be described by a proper modification of the boundary conditions (62), in terms of the ratio of the wave impedance (47) of the string and those of the supports.
in the system, to which it settles after some initial transient process. (At non-zero damping, we may be sure that this process fades after a finite time, and thus may be ignored for most purposes.)

Plugging Eq. (83) into Eq. (76), we reduce it to an equation for the amplitudes \( c_j \),

\[
\left(-m\omega^2 - i\omega\eta + 2\kappa_{et}\right)c_j - \kappa_{et}c_{j+1} - \kappa_{et}c_{j-1} = 0,
\]

(6.84)

which is a natural generalization of Eq. (25). As a result, partial solutions of the set of these equations (for \( j = 0, 1, 2, \ldots \)) may be looked for in the form (26) again, but now, because of the new, imaginary term in Eq. (84), we should be ready to get a complex phase shift \( \alpha \), and hence a complex wave number \( k = \alpha/d \).

Indeed, the resulting characteristic equation for \( k \),

\[
\sin^2 \frac{kd}{2} = \frac{\omega^2}{\omega_{max}^2} + i\frac{2\omega\delta}{\omega_{max}^2}, \quad (6.85)
\]

(where \( \omega_{max} \) is defined by Eq. (30), and the damping coefficient is defined just as in a single oscillator, \( \delta \equiv \eta/2m \), does not have a real solution even at \( \omega < \omega_{max} \). Using the well-known expressions for the sine function of a complex argument, Eq. (85) may be readily solved in the most important low-damping limit \( \delta \ll \omega \). In the linear approximation in \( \delta \), it does not affect the real part of \( k \), but makes its imaginary part different from zero:

\[
k = \pm \frac{2}{d} \left( \sin^{-1} \frac{\omega}{\omega_{max}} + i \frac{\delta}{\omega_{max}} \right) \equiv \pm \left( \frac{2}{d} \sin^{-1} \frac{\omega}{\omega_{max}} + i \frac{\delta}{v} \right), \quad \text{for } -\pi \leq \text{Re} k \leq \pi, \quad (6.86)
\]

with a periodic extension to other periods – see Fig. 5. Just as was done in Eq. (28), due to two values of the wave number, generally we have to take \( c_j \) in the form of not a single wave (26), but of a linear superposition of two partial solutions:

\[
c_j = \sum c_{\pm} \exp \left\{ \pm i \text{Re} k z_j \mp \frac{\delta}{v} z_j \right\}, \quad (6.87)
\]

where the constants \( c_{\pm} \) should be found from the boundary conditions. In our particular case, \( |c_0| = A_0 \) and \( c_{\infty} = 0 \), so that only one of these two waves, namely the wave exponentially decaying at its penetration into the system, is different from zero: \( |c_j| = A_0, c_{\infty} = 0 \). Hence our solution describes a single wave, with the real amplitude and the oscillation energy decreasing as

\[
A_j \equiv |c_j| = A_0 \exp \left\{ -\frac{\delta}{v} z_j \right\}, \quad E_j \propto A_j^2 \propto \exp \left\{ -\alpha z_j \right\}, \quad \text{with } \alpha = \frac{2\delta}{v}, \quad (6.88)
\]

i.e. with a frequency-independent attenuation constant \( \alpha = 2\delta/v \), so that the spatial scale of wave penetration into a dissipative system is given by \( l_d \equiv 1/\alpha \). Certainly, our simple solution (88) is only valid for a system of length \( l \gg l_d \); otherwise, we would need the second term in the sum (87) to describe the wave reflected from its opposite end.

\[\text{Wave attenuation}\]

---

24 As a reminder, we have already met such a situation in the absence of damping, but at \( \omega > \omega_{max} \) – see Eq. (38).

25 See, e.g., MA Eq. (3.5).

26 I am sorry to use for the attenuation the same letter \( \alpha \) as for the phase shift in Eq. (26) and a few of its corollaries, but both notations are traditional.
6.7 Nonlinear and parametric effects

Now let me discuss (because of the lack of time, very briefly, on a semi-quantitative level), the new nonlinear and parametric phenomena that appear in oscillatory systems with more than one degree of freedom – cf. Secs. 5.4-5.8. One important new effect here is the \textit{mutual phase locking} of (two or more) weakly coupled self-excited oscillators with close frequencies: if the own frequencies of the oscillators are sufficiently close, their oscillation frequencies “stick together” to become exactly equal. Though its dynamics of this process is very close to that of the phase locking of a single oscillator by an external signal, which was discussed in Sec. 5.4, it is rather counter-intuitive in the view of the results of Sec. 1, and in particular, the anticrossing diagram shown in Fig. 2. The analysis of the effect using the van der Pol method (which is highly recommended to the reader, see Problem 16) shows that the origin of the difference is the oscillators’ nonlinearity, which makes oscillation amplitudes virtually independent of the phase evolution – see Eq. (5.68) and its discussion.

One more new effect is the so-called \textit{non-degenerate parametric excitation}. It may be illustrated on the example of just two coupled oscillators – see Sec. 1 above. Let us assume that the coupling constant $\kappa$, participating in Eqs. (5), is not constant, but oscillates in time – say with some frequency $\omega_p$. In this case, the forces acting on each oscillator from its counterpart, described by the right-hand side of Eqs. (5), will be proportional to $\kappa q_{2,1}(1 + \mu \cos \omega_p t)$. Assuming that the oscillations of $q_1$ and $q_2$ are close to sinusoidal ones, with certain frequencies $\omega_{1,2}$, we see that the force exerted on each oscillator will contain the so-called \textit{combinational frequencies}

$$\omega_p \pm \omega_{2,1}. \tag{6.89}$$

If one of these frequencies is close to the own oscillation frequency of the oscillator, we can expect a substantial parametric interaction between the oscillators (on top of the constant coupling effects discussed in Sec. 1). According to Eq. (89), this may happen in two cases:

$$\omega_p = \omega_1 + \omega_2, \quad (6.90a)$$
$$\omega_p = \omega_1 - \omega_2. \quad (6.90b)$$

The quantitative analysis (also highly recommended to the reader, see Problem 18) shows that in the case (90a), the parameter modulation indeed leads to energy “pumping” into the oscillations. As a result, a sufficiently large $\mu$, at sufficiently small damping coefficients $\delta_{1,2}$ and the effective detuning

$$\xi \equiv \omega_p - (\Omega_1 + \Omega_2), \quad (6.91)$$

may lead to a simultaneous self-excitation of two frequency components $\omega_{1,2}$. These frequencies, while being approximately equal to the corresponding own frequencies $\Omega_{1,2}$ of the system, are related to the \textit{pumping frequency} $\omega_p$ by the exact relation (90a), but otherwise are arbitrary, e.g., may be incommensurate (Fig. 12a), thus justifying the term \textit{non-degenerate} parametric excitation.\(^{27}\) (The parametric excitation of a single oscillator, that was analyzed in Sec. 5.5, is a particular, \textit{degenerate} case of such excitation, with $\omega_1 = \omega_2 = \omega_p/2$.) On the other hand, for the case described by Eq. (90b), the parameter modulation always pumps energy \textit{from} the oscillations, effectively increasing the system’s damping.

\(^{27}\) Note that in some publications, the term \textit{parametric down-conversion} (PDC) is used instead.
Somewhat counter-intuitively, this difference between two cases (90) may be simpler interpreted using the basic notions of quantum mechanics. Namely, the equality $\omega_p = \omega_1 + \omega_2$ enables a decay of an external photon of energy $h\omega_p$ into two photons of energies $h\omega_1$ and $h\omega_2$ of the oscillators. (On the contrary, the complementary relation (90b), meaning that $\omega_1 = \omega_p + \omega_2$, results in a pumping-induced decay of photons of frequency $\omega_1$.)

$$\omega = \frac{\omega_1 + \omega_2}{2}$$

(a) 
(b)

Fig. 6.12. Spectra of oscillations at (a) the non-degenerate parametric excitation, and (b) the four-wave mixing. The arrow directions symbolize the energy flows into and out of the system.

Note that even if the frequencies $\omega_1$ and $\omega_2$ of the parametrically excited oscillations are incommensurate, the oscillations are highly correlated. Indeed, the quantum mechanical theory of this effect\(^{28}\) shows that the generated photons are entangled. This fact makes the parametric excitation very popular for a broad class of experiments in several currently active fields including quantum computation and encryption, and the Bell inequality/local reality studies.\(^{29}\)

Proceeding to nonlinear phenomena, let us note, first of all, that the simple reasoning that accompanied Eq. (5.108) in Sec. 5.8, is also valid in the case when oscillations consist of two (or more) sinusoidal components with incommensurate frequencies. Replacing the notation $2\omega$ with $\omega_p$, we see that the non-degenerate parametric excitation of the type (90a) is possible in a system of two coupled oscillators with a quadratic nonlinearity (of the type $\gamma q^2$), “pumped” by an intensive external signal at frequency $\omega_p \approx \Omega_1 + \Omega_2$. In optics, it is often more convenient to have all signals within the same, relatively narrow frequency range. A simple calculation, similar to the one made in Eqs. (5.107)-(5.108), shows that this may be done using the cubic nonlinearity\(^{30}\) of the type $\alpha q^3$, which allows a similar parametric energy exchange at the frequency relation shown in Fig. 12b:

$$2\omega = \omega_1 + \omega_2, \quad \text{with } \omega \approx \omega_1 \approx \omega_2. \quad (6.92a)$$

This process is often called the four-wave mixing, because it may be interpreted quantum-mechanically as the transformation of two externally-delivered photons, each with energy $h\omega$, into two other photons of energies $h\omega_1$ and $h\omega_2$. The word “wave” in this term stems from the fact that at optical frequencies, it is hard to couple a sufficient volume of a nonlinear medium with lumped-type resonators. It is much easier to implement the parametric excitation (as well as other nonlinear phenomena such as the higher harmonic generation) of light in distributed systems of a linear size much larger than the involved wavelengths. In such systems, the energy transfer from the incoming wave of frequency $\omega$ to

\(^{28}\) Which is, surprisingly, not much more complex than the classical theory – see, e.g., QM Sec.5.5.

\(^{29}\) See, e.g., QM Secs. 8.5 and 10.3, respectively.

\(^{30}\) In optics, such nonlinearity is implemented using transparent crystals such as lithium niobate (LiNbO$_3$), with the cubic-nonlinear dependence of the electric polarization on the applied electric field: $\mathbf{P} \propto \mathbf{E} + \alpha \mathbf{E}^3$. 
generated waves of frequencies $\omega_1$ and $\omega_2$ is gradually accumulated at their joint propagation along the system. From the analogy between Eq. (85) (describing the evolution of the wave’s amplitude in space), and the usual equation of the linear oscillator (describing its evolution in time), it is clear that this energy transfer accumulation requires not only the frequencies $\omega$, but also the wave numbers $k$ be in similar relations. For example, the four-wave mixing requires that not only the frequency balance (92a), but also a similar relation

$$2k = k_1 + k_2,$$  

(6.92b)

to be fulfilled. Since all three frequencies are close, this relation is easy to arrange. Unfortunately, due to the lack of time/space, for more discussion of this very interesting subject, called nonlinear optics, I have to refer the reader to special literature.\(^{31}\)

It may look like a dispersion-free media, with $\omega/k = \nu = \text{const}$, is the perfect solution for arranging the parametric interaction of waves, because in such media, for example, Eq. (92b) automatically follows from Eq. (92a). However, in such a media not only the desirable three parametrically interacting waves but also all their harmonics, have the same velocity. At these conditions, the energy transfer rates between all harmonics are of the same order. Perhaps the most important result of such a multi-harmonic interaction is that intensive incident traveling waves, interacting with a nonlinear medium, may develop sharply non-sinusoidal waveforms, in particular those with an almost instant change of the field at a certain moment. Such shock waves, especially those of mechanical nature, are of large interest for certain applications – some of them not quite innocent, e.g., the dynamics of explosion in the usual (chemical) and nuclear bombs.\(^{32}\)

To conclude this chapter, let me note that the above discussion of 1D acoustic waves will be extended, in Sec. 7.7, to elastic 3D media. There we will see that generally, the waves obey a more complex equation than the apparently natural generalization of Eq. (40):

$$\left(1 \frac{\partial^2}{\nu^2 \partial t^2} - \nabla^2 \right)q(r,t) = 0,$$  

(6.93)

where $\nabla^2$ is the Laplace operator. This fact adds to the complexity of traveling-wave and standing-wave phenomena in higher dimensions. Moreover, in multi-dimensional systems, including such pseudo-1D systems as thin rods and pseudo-2D systems such as thin membranes, even static elastic deformations may be very nontrivial. A brief introduction to the general theory of small deformations, with a focus on elastic continua, will be the subject of the next chapter.

### 6.8 Exercise problems

For each of the systems specified in Problems 6.1-6.6:

(i) introduce convenient generalized coordinates $q_j$ of the system,

---

(ii) calculate the frequencies of its small harmonic oscillations near the equilibrium, 
(iii) calculate the corresponding distribution coefficients, and 
(iv) sketch the oscillation modes.

6.1. Two elastically coupled pendula, confined to a vertical plane, with the parameters shown in the figure on the right (see also Problems 1.8 and 2.9).

6.2. The double pendulum, confined to a vertical plane containing the support point (considered in Problem 2.1), with \(m' = m\) and \(l = l'\) – see the figure on the right.

6.3. The chime bell considered in Problem 4.8 (see the figure on the right), for the particular case \(l = l'\).

6.4. The triple pendulum shown in the figure on the right, with the motion confined to a vertical plane containing the support point.

*Hint*: You may use any (e.g., numerical) method to calculate the characteristic equation’s roots.

6.5. A linear, symmetric system of three particles, shown in the figure on the right, where the connections between the particles not only act as usual elastic springs (giving potential energies \(U = \kappa \Delta l^2 / 2\)) but also resist system’s bending, giving additional potential energy \(U' = \kappa' (l \theta)^2 / 2\), where \(\theta\) is the (small) bending angle.\(^{33}\)

6.6. Three similar beads of mass \(m\), which may slide along a circle of radius \(R\) without friction, connected with similar springs with elastic constants \(\kappa\) and equilibrium lengths \(l_0\) – see the figure on the right.

\(^{33}\) This is a good model for small oscillations of linear molecules such as the now-infamous CO2.
6.7. An external longitudinal force $F(t)$ is applied to the right particle of the system shown in Fig. 1, with $\kappa_L = \kappa_R = \kappa'$ and $m_1 = m_2 = m$ (see the figure on the right), and the response $q_1(t)$ of the left particle to this force is being measured.

(i) Calculate the temporal Green’s function for this response.

(ii) Use this function to calculate the response to the following force:

$$ F(t) = \begin{cases} 
0, & \text{for } t < 0, \\
F_0 \sin \omega t, & \text{for } 0 \leq t,
\end{cases} $$

with constant amplitude $F_0$ and frequency $\omega$.

6.8. Use the Lagrangian formalism to re-derive Eqs. (24) for both the longitudinal and the transverse oscillations in the system shown in Fig. 4a.

6.9. Calculate the energy (per unit length) of a sinusoidal traveling wave propagating in the 1D system shown in Fig. 4a. Use your result to calculate the average power flow created by the wave, and compare it with Eq. (49) valid in the acoustic wave limit.

6.10. Calculate the spatial distributions of the kinetic and potential energies in a standing, sinusoidal, 1D acoustic wave, and analyze their evolution in time.

6.11. The midpoint of a guitar string of length $l$ has been slowly pulled off by distance $h << l$ from its equilibrium position, and then let go. Neglecting dissipation, use two different approaches to calculate the midpoint’s displacement as a function of time.

*Hint:* You may like to use the following table series:

$$ \sum_{m=1}^{\xi} \frac{\cos(2m-1)\xi}{(2m-1)^2} = \frac{\pi^2}{8} \left( 1 - \frac{\xi}{\pi/2} \right), \quad \text{for } 0 \leq \xi \leq \pi. $$

6.12. Calculate the dispersion law $\omega(k)$ and the maximum and minimum frequencies of small longitudinal waves in a long chain of similar, spring-coupled pendula – see the figure on the right.

6.13. Calculate and analyze the dispersion relation $\omega(k)$ for small waves in a long chain of elastically coupled particles with alternating masses – see the figure on the right. In particular, discuss the dispersion relation’s period $\Delta k$, and its evolution at $m' \to m$. 

---

Chapter 6
6.14. Analyze the traveling wave’s reflection from a “point inhomogeneity”: a single particle with a different mass \( m_0 \neq m \), within an otherwise uniform 1D chain – see the figure on the right.

6.15.*

(i) Explore an approximate way to analyze waves in a continuous 1D system with parameters slowly varying along its length.
(ii) Apply this method to calculate the frequencies of transverse standing waves on a freely hanging heavy rope of length \( l \), with a constant mass \( \mu \) per unit length – see the figure on the right.
(iii) For the three lowest standing wave modes, compare the results with those obtained in the solution of Problem 4 for the triple pendulum.

Hint: The reader familiar with the WKB approximation in quantum mechanics (see, e.g., QM Sec. 2.4) is welcome to adapt it for this classical application. Another possible starting point is the van der Pol approximation discussed in Sec. 5.3, which should be translated from the time domain to the space domain.

6.16.* Use the van der Pol approximation to analyze the mutual phase locking of two weakly coupled self-oscillators with the dissipative nonlinearity, for the cases of:
(i) the direct coordinate coupling, described by Eq. (5), and
(ii) a bilinear but otherwise arbitrary coupling of two similar oscillators.

Hint: In Task (ii), describe the coupling by a linear operator, and express the result via its Fourier image.

6.17.* Extend the second task of the previous problem to the mutual phase locking of \( N \) similar self-oscillators. In particular, explore the in-phase mode’s stability for the case of the so-called global coupling via a single force \( F \) contributed equally by all oscillators.

6.18.* Find the condition of non-degenerate parametric excitation in a system of two coupled oscillators, described by Eqs. (5), but with a time-dependent coupling: \( \kappa \to \kappa (1 + \mu \cos \omega_p t) \), with \( \omega_p \approx \Omega_1 + \Omega_2 \), and \( \kappa \mu m \ll |\Omega_2 - \Omega_1| \).

Hint: Assuming the modulation depth \( \mu \), static coupling \( \kappa \), and detuning \( \xi \equiv \omega_p - (\Omega_1 + \Omega_2) \) sufficiently small, use the van der Pol approximation for each of the coupled oscillators.

6.19. Show that the cubic nonlinearity of the type \( aq^3 \) indeed enables the parametric interaction (“four-wave mixing”) of oscillations with incommensurate frequencies related by Eqs. (92a).

6.20. Calculate the velocity of the transverse waves propagating on a thin, planar, elastic membrane, with mass \( \mu \) per unit area, pre-stretched with force \( \tau \) per unit width.
Chapter 7. Deformations and Elasticity

The objective of this chapter is a brief discussion of small deformations of 3D continua, with a focus on the elastic properties of solids. The reader will see that such deformations are nontrivial even in the absence of their time evolution, so that several key problems of statics will need to be discussed before proceeding to such dynamic phenomena as elastic waves in infinite media and thin rods.

7.1. Strain

As was discussed in Chapters 4 and 6, in a continuum, i.e. a system of particles so close to each other that the system discreteness may be neglected, the particle displacement \( \mathbf{q} \) may be considered as a continuous function of space and time. In this chapter, we will consider only small deviations from the rigid-body approximation discussed in Chapter 4, i.e. small deformations. The deformation smallness allows one to consider the displacement vector \( \mathbf{q} \) as a function of the initial (pre-deformation) position of the particle, \( \mathbf{r} \), and time \( t \) – just as was done in Chapter 6 for 1D waves.

The first task of the deformation theory is to exclude from consideration the types of motion considered in Chapter 4, namely the translation and rotation, unrelated to deformations. This means, first of all, that the variables describing deformations should not depend on the part of displacement distribution, that is independent of the position \( \mathbf{r} \) (i.e. is common for the whole media), because that part corresponds to a translational shift rather than to a deformation (Fig. 1a). Moreover, even certain non-uniform displacements do not contribute to deformation. For example, Eq. (4.9) (with \( d\mathbf{r} \) replaced with \( dq \) to comply with our current notation) shows that a small displacement of the type

\[ dq_{\text{rotation}} = d\phi \times \mathbf{r}, \]

(7.1)

where \( d\phi = \omega dt \) is an infinitesimal vector common for the whole continuum, corresponds to its rotation about the direction of that vector, and has nothing to do with its deformation (Fig. 1b).

This is why to develop an adequate quantitative characterization of deformation, we should start with finding suitable functions of the spatial distribution of displacements, \( \mathbf{q}(\mathbf{r}) \), that exist only due to deformations. One of such measures is the change of the distance \( dl = |d\mathbf{r}| \) between two close points:
\[(dl)^2\]_{\text{after deformation}} - (dl)^2\]_{\text{before deformation}} = \sum_{j=1}^{3} (dr_j + dq_j)^2 - \sum_{j=1}^{3} (dr_j)^2, \quad (7.2)\]

where \(dq_j\) is the \(j^{th}\) Cartesian component of the difference \(dq\) between the displacements \(q\) of these close points. If the deformation is small in the sense \(|dq| << |dr| = dl\), we may keep in Eq. (2) only the terms proportional to the first power of the infinitesimal vector \(dq\):

\[(dl)^2\]_{\text{after deformation}} - (dl)^2\]_{\text{before deformation}} = \sum_{j=1}^{3} \left[2dr_j dq_j + (dq_j)^2\right] = 2\sum_{j=1}^{3} dr_j dq_j. \quad (7.3)\]

Since \(q_j\) is a function of three independent scalar arguments \(r_j\), its full differential (at fixed time) may be represented as

\[dq_j = \sum_{j'=1}^{3} \frac{\partial q_j}{\partial r_{j'}} dr_{j'}. \quad (7.4)\]

The coefficients \(\frac{\partial q_j}{\partial r_{j'}}\) may be considered as elements of a tensor providing a linear relation between the vectors \(dr\) and \(dq\). Plugging Eq. (4) into Eq. (2), we get

\[(dl)^2\]_{\text{after deformation}} - (dl)^2\]_{\text{before deformation}} = 2\sum_{j,j'=1}^{3} \frac{\partial q_j}{\partial r_{j'}} dr_j dr_{j'}. \quad (7.5)\]

The convenience of the tensor \(\frac{\partial q_j}{\partial r_{j'}}\) for characterizing deformations is that it automatically excludes the translation displacement (Fig. 1a), which is independent of \(r_j\). Its drawback is that its particular components are still affected by the rotation of the body (though the sum (5) is not). Indeed, according to the vector product definition, Eq. (1) may be represented in Cartesian coordinates as

\[dq_j \mid_{\text{rotation}} = (d\varphi_{j'} r_{j'} - d\varphi_{j'} r_{j})\mathcal{E}_{jj'}; \quad (7.6)\]

where \(\mathcal{E}_{jj'}\) is the Levi-Civita symbol. Differentiating Eq. (6) over a particular Cartesian coordinate of vector \(r\), and taking into account that this partial differentiation (\(\partial\)) is independent of (and hence may be swapped with) the differentiation (\(d\)) over the rotation angle \(\varphi\), we get the amounts,

\[d \left( \frac{\partial q_j}{\partial r_{j'}} \right)_{\text{rotation}} = -\mathcal{E}_{jj'} d\varphi_{j'}; \quad d \left( \frac{\partial q_j}{\partial r_{j}} \right)_{\text{rotation}} = -\mathcal{E}_{jj'} d\varphi_{j'} = \mathcal{E}_{jj'} d\varphi_{j'}, \quad (7.7)\]

which may differ from 0. However, notice that the sum of these two differentials equals zero for any \(d\varphi\), which is possible only if

\[\left( \frac{\partial q_{j'}}{\partial r_j} + \frac{\partial q_j}{\partial r_{j'}} \right)_{\text{rotation}} = 0, \quad \text{for} \ j \neq j'. \quad (7.8)\]

This is why it is convenient to rewrite Eq. (5) in a mathematically equivalent form,

---

1. Since both \(dq\) and \(dr\) are legitimate physical vectors (whose Cartesian components are properly transformed as the transfer between reference frames), the 3×3 matrix with elements \(\partial q_j/\partial r_{j'}\) is indeed a legitimate physical tensor – see the discussion in Sec. 4.2.

2. As a result, the full sum (5), which includes three partial sums (8), is not affected by rotation – as we already know.
\[ (dl)^2 \bigg|_{\text{after deformation}} - (dl)^2 \bigg|_{\text{before deformation}} = 2 \sum_{j,j'=1}^{3} s_{jj'} dr_j dr_{j'}, \]  

(7.9a)

where \( s_{jj'} \) are the elements of the so-called symmetrized strain tensor, defined as

\[
s_{jj'} \equiv \frac{1}{2} \left( \frac{\partial q_j}{\partial r_{j'}} + \frac{\partial q_{j'}}{\partial r_j} \right). \tag{7.9b}
\]

(Note that this modification does not affect the diagonal elements: \( s_{jj} = \partial q_j/\partial r_j \)). The advantage of the symmetrized tensor (9b) over the initial tensor with elements \( \partial q_j/\partial r_j \) is that according to Eq. (8), at pure rotation, all elements of the symmetrized strain tensor vanish.

Now let us discuss the physical meaning of this tensor. As was already mentioned in Sec. 4.2, any symmetric tensor may be diagonalized by an appropriate selection of the reference frame axes. In such principal axes, \( s_{jj'} = s_{jj} \delta_{jj'} \), so that Eq. (4) takes a simple form:

\[
dq_j = \frac{\partial q_j}{\partial r_j} dr_j = s_{jj} dr_j. \tag{7.10}
\]

We may use this expression to calculate the change of each side of an elementary cuboid (parallelepiped) with sides \( dq_j \) parallel to the principal axes:

\[
dr_j \bigg|_{\text{after deformation}} - dr_j \bigg|_{\text{before deformation}} \equiv dq_j = s_{jj} dr_j, \tag{7.11}
\]

and of cuboid’s volume \( dV = dr_1 dr_2 dr_3 \):

\[
dV \bigg|_{\text{after deformation}} - dV \bigg|_{\text{before deformation}} = \prod_{j=1}^{3} (dr_j + s_{jj} dr_j) - \prod_{j=1}^{3} dr_j = dV \left[ \prod_{j=1}^{3} (1 + s_{jj}) - 1 \right], \tag{7.12}
\]

Since all our analysis is only valid in the linear approximation in small \( s_{jj} \), Eq. (12) is reduced to

\[
dV \bigg|_{\text{after deformation}} - dV \bigg|_{\text{before deformation}} \approx dV \sum_{j=1}^{3} s_{jj} \equiv dV \text{Tr}(s), \tag{7.13}
\]

where Tr (trace)\(^3\) of any matrix (in particular, any tensor) is the sum of its diagonal elements; in our current case\(^4\)

\[
\text{Tr}(s) \equiv \sum_{j=1}^{3} s_{jj}. \tag{7.14}
\]

So, the diagonal components of the tensor characterize the medium’s compression/extension; then what is the meaning of its off-diagonal components? It may be illustrated on the simplest example of purely shear deformation, shown in Fig. 2 (the geometry is assumed to be uniform along the z-axis normal to the plane of the drawing). In this case, all displacements (assumed small) have just one Cartesian component, in Fig. 2 along the x-axis: \( q = n_x \alpha \nu \) (with \( \alpha \ll 1 \)), so that the only nonzero component of the initial strain tensor \( \partial q_j/\partial r_j \) is \( \partial q_y/\partial \nu = \alpha \), and the symmetrized tensor (9b) is

---

\(^3\) The traditional European notation for Tr is Sp (from the German Spur meaning “trace” or “track”).

\(^4\) Actually, the tensor theory shows that the trace does not depend on the particular choice of the coordinate axes.
\[
s = \begin{bmatrix}
0 & \alpha/2 & 0 \\
\alpha/2 & 0 & 0 \\
0 & 0 & 0
\end{bmatrix}.
\]

(7.15)

Evidently, the change of volume, given by Eq. (13), vanishes in this case. Thus, off-diagonal elements of the tensor \( s \) characterize shear deformations.

To conclude this section, let me note that Eq. (9) is only valid in Cartesian coordinates. For the solution of some important problems with the axial or spherical symmetry, it is frequently convenient to express six different components of the symmetric strain tensor via three components of the displacement vector \( \mathbf{q} \) in either cylindrical or spherical coordinates. A straightforward differentiation of the definitions of these curvilinear coordinates, similar to that used to derive the well-known expressions for spatial derivatives,\(^5\) yields, in particular, the following formulas for the diagonal elements of the tensor:

(i) in the cylindrical coordinates:

\[
s_{\rho\rho} = \frac{\partial q_\rho}{\partial \rho}, \quad s_{\phi\phi} = \frac{1}{\rho} \left( q_\rho + \frac{\partial q_\phi}{\partial \phi} \right), \quad s_{zz} = \frac{\partial q_z}{\partial z}.
\]

(7.16)

(ii) in the spherical coordinates:

\[
s_{rr} = \frac{\partial q_r}{\partial r}, \quad s_{\theta\theta} = \frac{1}{r} \left( q_r + \frac{\partial q_\theta}{\partial \theta} \right), \quad s_{\phi\phi} = \frac{1}{r} \left( q_r + q_\theta \frac{\cos \theta}{\sin \theta} + \frac{1}{\sin \theta} \frac{\partial q_\phi}{\partial \phi} \right).
\]

(7.17)

These expressions, which will be used below for the solution of some problems for symmetrical geometries, may be a bit counter-intuitive. Indeed, Eq. (16) shows that even for a purely radial, axially-symmetric deformation, \( \mathbf{q} = n_q(\rho) \), the angular component of the strain tensor does not vanish: \( s_{\phi\phi} = q/\rho \). (According to Eq. (17), in the spherical coordinates, both angular components of the tensor exhibit the same property.) Note, however, that this relation describes a very simple geometric effect: the change of the lateral distance \( \rho d\phi \ll \rho \) between two close points with the same distance from the symmetry axis, at a small change of \( \rho \), that keeps the angle \( d\phi \) between the directions towards these two points constant.

### 7.2 Stress

Now let us discuss the forces that cause the strain – or, from an alternative point of view, are caused by the strain. Internal forces acting inside (i.e. between arbitrarily defined parts of) a continuum

---

\(^5\) See, e.g., MA Eqs. (10.1)-(10.12).
may be also characterized by a tensor. This stress tensor, with elements $\sigma_{jj'}$, relates the Cartesian components of the vector $d\mathbf{F}$ of the force acting on an elementary area $dA$ of an (in most cases, imagined) interface between two parts of a continuum, with the components of the elementary vector $d\mathbf{A} = n dA$ normal to the area – see Fig. 3:

$$dF_j = \sum_{j'=1}^{3} \sigma_{jj'} dA_{j'}. \quad (7.18)$$

The usual sign convention here is to take the outer normal $dn$, i.e. to direct $d\mathbf{A}$ out of “our” part of the continuum, i.e. the part on which the calculated force $d\mathbf{F}$ is exerted – by the complementary part.

In some cases, the stress tensor’s structure is very simple. For example, as will be discussed in detail in the next chapter, static and ideal fluids (i.e. liquids and gases) may only provide forces normal to any interface, and usually directed toward “our” part of the body, so that

$$d\mathbf{F} = -\mathcal{P}d\mathbf{A}, \quad \text{i.e.} \quad \sigma_{jj'} = -\mathcal{P}\delta_{jj'}, \quad (7.19)$$

where the scalar $\mathcal{P}$ (in most cases positive) is called pressure, and generally may depend on both the spatial position and time. This type of stress, with $\mathcal{P} > 0$, is frequently called hydrostatic compression – even if it takes place in solids, as it may.

However, in the general case, the stress tensor also has off-diagonal terms, which characterize the shear stress. For example, if the shear strain, shown in Fig. 2, is caused by a pair of forces $\pm \mathbf{F}$, they create internal forces $F_x n_x$, with $F_x > 0$ if we speak about the force acting upon a part of the sample below the imaginary horizontal interface we are discussing. To avoid a horizontal acceleration of each horizontal slice of the sample, the forces should not depend on $y$, i.e. $F_y = \text{const} = F$. Superficially, it may look that in this case, the only nonzero component of the stress tensor is $dF_x/dA_y = F/A = \text{const}$, so that tensor is asymmetric, in contrast to the strain tensor (15) of the same system. Note, however, that the pair of forces $\pm \mathbf{F}$ creates not only the shear stress but also a nonzero rotating torque $\mathbf{\tau} = -Fh n_z = -(dF_x/dA_y)Ah n_z = -(dF_y/dA_x)V n_z$, where $V = Ah$ is sample’s volume. So, if we want to perform a static stress experiment, i.e. avoid sample’s rotation, we need to apply some other forces, e.g., a pair of vertical forces creating an equal and opposite torque $\mathbf{\tau}' = (dF_y/dA_x)V n_x$, implying that $dF_x/dA_y = dF_y/dA_x = F/A$. As a result, the stress tensor becomes symmetric, and similar in structure to the symmetrized strain tensor (15):

---

$^6$ It is frequently called the Cauchy stress tensor, partly to honor Augustin-Louis Cauchy who introduced this notion (and is responsible for the development, mostly in the 1820s, much of the theory described in this chapter), and partly to distinguish it from and other possible definitions of the stress tensor, including the 1$^{st}$ and 2$^{nd}$ Piola-Kirchhoff tensors. For the small deformations discussed in this course, all these notions coincide.
In many situations, the body may be stressed not only by forces applied to their surfaces but also by some volume-distributed (bulk) forces \( d\mathbf{F} = \mathbf{f} dV \), whose certain effective bulk density \( f \). (The most evident example of such forces is gravity. If its field is uniform as described by Eq. (1.16), then \( \mathbf{f} = \mathbf{\rho g} \), where \( \mathbf{\rho} \) is the mass density.) Let us derive the key formula describing the summation of the interface and bulk forces. For that, consider again an elementary cuboid with sides \( dr_j \) parallel to the corresponding coordinate axes (Fig. 4) – now not necessarily the principal axes of the stress tensor.

If elements \( \sigma_{j'} \) of the tensor do not depend on position, the force \( d\mathbf{F}^{(j')} \) acting on the \( j' \)-th face of the cuboid is exactly balanced by the equal and opposite force acting on its opposite face, because the vectors \( d\mathbf{A}^{(j')} \) at these faces are equal and opposite. However, if \( \sigma_{j'} \) is a function of \( \mathbf{r} \), then the net force \( d(d\mathbf{F}^{(j')}) \) does not vanish. (In this expression, the first differential sign refers to the elementary shift \( dr_j \), while the second one, to the elementary area \( dA_j \).) Using the expression \( \sigma_{j'} dA_j \) for to the \( j' \) th contribution to the sum (18), in the first order in \( \mathbf{d} \mathbf{r} \) the \( j \) th components of the vector \( d(d\mathbf{F}^{(j')}) \) is

\[
(\sigma_{j'})_{j'} = \frac{\partial \sigma_{j'}}{\partial r_j} \, dr_j dA_j \equiv \frac{\partial \sigma_{j'}}{\partial r_j} \, dV, \tag{7.21}
\]

where the cuboid’s volume \( dV = dr_j dA_j \) evidently does not depend on the index \( j' \). The addition of these force components for all three pairs of cuboid faces, i.e. the summation of Eqs. (21) over all three values of the upper index \( j' \), yields the following relation for the \( j \) th Cartesian component of the net force exerted on the cuboid:

\[
d(dF_j) = \sum_{j'=1}^{3} d(dF_j^{(j')}) = \sum_{j'=1}^{3} \frac{\partial \sigma_{j'}}{\partial r_j} \, dV. \tag{7.22}
\]

Since any volume may be broken into such infinitesimal cuboids, Eq. (22) shows that the space-varying stress is equivalent to a volume-distributed force \( d\mathbf{F}_e = \mathbf{f}_e dV \), whose effective (not real!) bulk density \( \mathbf{f}_e \) has the following Cartesian components

\[
(f_e)_{j} = \sum_{j'=1}^{3} \frac{\partial \sigma_{j'}}{\partial r_j}, \tag{7.23}
\]

so that in the presence of genuinely bulk forces \( d\mathbf{F} = \mathbf{f} dV \), densities \( \mathbf{f}_e \) and \( \mathbf{f} \) just add up. This the so-called Euler-Cauchy stress principle.

Let us use this addition rule to spell out the 2nd Newton law for a unit volume of a continuum:
\[
\rho \frac{\partial^2 \mathbf{q}}{\partial t^2} = \mathbf{f}_{\text{ext}} + \mathbf{f}.
\]  

(7.24)

Using Eq. (23), the \(j\)th Cartesian component of Eq. (24) may be represented as

\[
\rho \frac{\partial^2 q_j}{\partial t^2} = \sum_{j'=1}^{3} \frac{\partial \sigma_{jj'}}{\partial r_{j'}} + f_{j}.
\]

(7.25)

This is the key equation of the continuum’s dynamics (and statics), which will be repeatedly used below.

For the solution of some problems, it is also convenient to have a general expression for the work \(\delta \mathcal{H}\) of the stress forces at a virtual deformation \(\delta \mathbf{q}\) – understood in the same variational sense as the virtual displacements \(\delta \mathbf{r}\) in Sec. 2.1. Using the Euler-Cauchy principle (23), for any volume \(V\) of a medium not affected by volume-distributed forces, we may write\(^7\)

\[
\delta \mathcal{H} = - \int_{V} \mathbf{f}_{\text{ext}} \cdot \delta \mathbf{q} \, d^3 r = - \sum_{j=1}^{3} \int_{V} (f_{\text{ext}})_j \delta q_j d^3 r = - \sum_{j,j'=1}^{3} \int_{V} \frac{\partial \sigma_{jj'}}{\partial r_{j'}} \delta q_j d^3 r.
\]

(7.26)

Let us work out this integral by parts for a volume so large that the deformations \(\delta q_j\) on its surface are negligible. Then, swapping the operations of the variation and the spatial differentiation (just like it was done with the time derivative in Sec. 2.1), we get

\[
\delta \mathcal{H} = \sum_{j,j'=1}^{3} \int_{V} \sigma_{jj'} \frac{\partial \delta q_j}{\partial r_{j'}} \, d^3 r.
\]

(7.27)

Assuming that the tensor \(\sigma_{jj'}\) is symmetric, we may rewrite this expression as

\[
\delta \mathcal{H} = \frac{1}{2} \sum_{j,j'=1}^{3} \int_{V} \left( \sigma_{jj'} \frac{\partial \delta q_j}{\partial r_{j'}} + \sigma_{j'j} \frac{\partial \delta q_j}{\partial r_{j'}} \right) \, d^3 r.
\]

(7.28)

Now, swapping indices \(j\) and \(j'\) in the second expression, we finally get

\[
\delta \mathcal{H} = \frac{1}{2} \sum_{j,j'=1}^{3} \int_{V} \delta \left( \frac{\partial q_j}{\partial r_{j'}} \sigma_{jj'} + \frac{\partial q_{j'}}{\partial r_{j}} \sigma_{j'j} \right) \, d^3 r = - \sum_{j,j'=1}^{3} \int_{V} \sigma_{jj'} \delta s_{jj'} \, d^3 r,
\]

(7.29)

where \(s_{jj'}\) are the components of the strain tensor (9b). It is natural to rewrite this important formula as

\[
\delta \mathcal{H} = \int_{V} \delta \mathbf{w} (\mathbf{r}) \, d^3 r, \quad \text{where} \quad \delta \mathbf{w} (\mathbf{r}) \equiv \sum_{j,j'=1}^{3} \sigma_{jj'} \delta s_{jj'},
\]

(7.30)

and interpret the locally-defined scalar function \(\delta \mathbf{w} (\mathbf{r})\) as the work of the stress forces per unit volume, at a small variation of the deformation.

As a sanity check, for the pure pressure (19), Eq. (30) is reduced to the evidently correct result \(\delta \mathcal{H} = -P \delta V\), where \(V\) is the volume of “our” part of the continuum.

---

\(^7\) Here the sign corresponds to the work of the “external” stress force \(dF\), exerted on “our” part of the continuum by its counterpart – see Fig. 3. Note that some texts consider the opposite definition of \(\delta \mathcal{H}\), leading to its opposite sign.
7.3. Hooke’s law

In order to form a complete system of equations describing the continuum’s dynamics, one needs to complement Eq. (25) with an appropriate constitutive equation describing the relation between the forces described by the stress tensor $\sigma_{ij}$, and the deformations $q$ described (in the small deformation limit) by the strain tensor $\epsilon_{ij}$. This relation depends on the medium, and generally may be rather complex. Even leaving alone various anisotropic solids (e.g., crystals) and macroscopically-inhomogeneous materials (like ceramics or sand), strain typically depends not only on the current value of stress (possibly in a nonlinear way), but also on the previous history of stress application. Indeed, if strain exceeds a certain plasticity threshold, atoms (or nanocrystals) may slip to their new positions and never come back even if the strain is reduced. As a result, deformations become irreversible – see Fig. 5.

Only below the thresholds of nonlinearity and plasticity (which are typically close to each other), the strain is nearly proportional to stress, i.e. obeys the famous Hooke’s law. However, even in this elastic range, the law is not quite simple, and even for an isotropic medium is described not by one but by two constants, called the elastic moduli. The reason for that is that most elastic materials resist the strain accompanied by a volume change (say, the hydrostatic compression) differently from how they resist a shear deformation.

To describe this difference, let us first represent the symmetrized strain tensor (9b) in the following mathematically equivalent form:

$$
s_{ij}\equiv \left( s_{ij} - \frac{1}{3} \delta_{ij} \text{Tr} (s) \right) + \left( \frac{1}{3} \delta_{ij} \text{Tr} (s) \right).
$$

According to Eq. (13), the traceless tensor in the first parentheses of Eq. (31) does not give any contribution to the volume change, e.g., may be used to characterize a purely shear deformation, while the second term describes the hydrostatic compression alone. Hence we may expect that the stress tensor may be represented (again, within the elastic deformation range only!) as

$$
\sigma_{ij} = 2\mu \left( s_{ij} - \frac{1}{3} \text{Tr} (s)\delta_{ij} \right) + 3K \left( \frac{1}{3} \text{Tr} (s)\delta_{ij} \right)\text{,}
$$

8 Named after Robert Hooke (1635-1703), the polymath who was the first to describe the law in its simplest, 1D version.
where $K$ and $\mu$ are constants. (The inclusion of coefficients 2 and 3 into Eq. (32) is justified by the simplicity of some of its corollaries – see, e.g., Eqs. (36) and (41) below.) Indeed, experiments show that Hooke’s law in this form is followed, at small strain, by all isotropic materials. In accordance with the above discussion, the constant $\mu$ (in some texts, denoted as $G$) is called the shear modulus, while the constant $K$ (sometimes denoted $B$), the bulk modulus. The two left columns of Table 1 show the approximate values of these moduli for typical representatives of several major classes of materials.\(^9\)

\(^b\) At the so-called ambient conditions ($T = 20^\circ$C, $P = 1$ bar $\equiv 10^5$ Pa).

Table 7.1. Elastic moduli, density, and sound velocities of a few representative materials (approximate values)

To better appreciate these values, let us first discuss the quantitative meaning of $K$ and $\mu$, using two simple examples of elastic deformation. However, in preparation for that, let us first solve the set of nine (or rather six different) linear equations (32) for $s_{jj'}$. This is easy to do, due to the simple structure of these equations: they relate the components $\sigma_{jj'}$ and $s_{jj'}$ with the same indices, besides the involvement of the tensor’s trace. This slight complication may be readily overcome by noticing that according to Eq. (32),

$$\text{Tr} (\sigma) \equiv \sum_{j=1}^{3} \sigma_{jj} = 3K \text{Tr} (s),$$

so that $\text{Tr} (s) = \frac{1}{3K} \text{Tr} (\sigma)$. \hspace{1cm} (7.33)

Plugging this result into Eq. (32) and solving it for $s_{jj'}$, we readily get the reciprocal relation, which may be represented in a similar form:

$$s_{jj'} = \frac{1}{2\mu} \left( \sigma_{jj'} - \frac{1}{3} \text{Tr}(\sigma) \delta_{jj'} \right) + \frac{1}{3K} \left( \frac{1}{3} \text{Tr}(\sigma) \delta_{jj'} \right).$$

\hspace{1cm} (7.34)

Now let us apply Hooke’s law, in the form of Eqs. (32) or (34), to two simple situations in which the strain and stress tensors may be found without using the full differential equation of the elasticity theory and boundary conditions for them. (That will be the subject of the next section.) The first situation is the hydrostatic compression when the stress tensor is diagonal, and all its diagonal components are equal – see Eq. (19).\(^10\) For this case Eq. (34) yields

\(^9\) Since the strain tensor elements, defined by Eq. (9), are dimensionless, while the strain, defined by Eq. (18), has the dimensionality similar to pressure (of force per unit area), so do the elastic moduli $K$ and $\mu$.

\(^10\) It may be proved that such a situation may be implemented not only in a fluid with pressure $P$ but also in a solid sample of an arbitrary shape, for example by placing it into a compressed fluid.
\[ s_{ij} = -\frac{\sigma}{3K} \delta_{ij}, \quad (7.35) \]

i.e. regardless of the shear modulus, the strain tensor is also diagonal, with all diagonal components equal. According to Eqs. (11) and (13), this means that all linear dimensions of the body are reduced by a similar factor, so that its shape is preserved, while the volume is reduced by

\[ \frac{\Delta V}{V} = \sum_{j=1}^{3} s_{jj} = -\frac{\sigma}{K}. \quad (7.36) \]

This formula clearly shows the physical sense of the bulk modulus \( K \) as the \textit{reciprocal compressibility}. As Table 1 shows, the values of \( K \) may be dramatically different for various materials, and even for such “soft stuff” as water this modulus is actually rather high. For example, even at the bottom of the deepest, 10-km ocean well (\( \sigma \approx 10^3 \) bar \( \approx 0.1 \) GPa), the water’s density increases by just about 5%. As a result, in most human-scale experiments, water may be treated as \textit{incompressible} – a condition that will be widely used in the next chapter. Many solids are even much less compressible – see, for example, the first two rows of Table 1.

Quite naturally, the most compressible media are gases. For a portion of gas, a certain background pressure \( \sigma \) is necessary just for containing it within its volume \( V \), so that Eq. (36) is only valid for small increments of pressure, \( \Delta \sigma \):

\[ \frac{\Delta V}{V} = -\frac{\Delta \sigma}{K}. \quad (7.37) \]

Moreover, the compression of gases also depends on thermodynamic conditions. (In contrast, for most condensed media, the temperature effects are very small.) For example, at ambient conditions most gases are reasonably well described by the equation of state for the model called the \textit{ideal classical gas}:

\[ \sigma V = Nk_B T, \quad \text{i.e. } V = \frac{Nk_B T}{\sigma}. \quad (7.38) \]

where \( N \) is the number of molecules in volume \( V \), and \( k_B \approx 1.38 \times 10^{-23} \) J/K is the Boltzmann constant.\(^{11}\) For a small volume change \( \Delta V \) at a constant temperature \( T \), this equation gives

\[ \Delta \sigma \bigg|_{T=\text{const}} = -\frac{Nk_B T}{V^2} \Delta V = -\frac{\sigma}{V} \Delta V, \quad \text{i.e. } \frac{\Delta V}{V} \bigg|_{T=\text{const}} = -\frac{\Delta \sigma}{\sigma}. \quad (7.39) \]

Comparing this expression with Eq. (36), we get a remarkably simple result for the isothermal compression of gases,

\[ K \bigg|_{T=\text{const}} = \sigma, \quad (7.40) \]

which means in particular that the bulk modulus listed in Table 1 is actually valid, at the ambient conditions, for almost any gas. Note, however, that the change of thermodynamic conditions (say, from isothermal to adiabatic\(^{12})\) may affect the compressibility of the gas..

\(^{11}\) For the derivation and a detailed discussion of Eq. (37) see, e.g., SM Sec. 3.1.

\(^{12}\) See, e.g., SM Sec. 1.3.
Now let us consider the second, rather different, fundamental experiment: a purely shear deformation shown in Fig. 2. Since the traces of the matrices (15) and (20), which describe this situation, are equal to 0, for their off-diagonal elements, Eq. (32) gives merely $\sigma_{ij'} = 2\mu s_{ij'}$, so that the deformation angle $\alpha$ (see Fig. 2) is just

$$\alpha = \frac{1}{\mu} \frac{F}{A}. \quad (7.41)$$

Note that the angle does not depend on the thickness $h$ of the sample, though of course the maximal linear deformation $q_s = \alpha h$ is proportional to the thickness. Naturally, as Table 1 shows, $\mu = 0$ for all fluids, because they do not resist static shear stress.

However, not all situations, even apparently simple ones, involve just either $K$ or $\mu$. Let us consider stretching a long and thin elastic rod of a uniform cross-section of area $A$ – the so-called tensile stress experiment shown in Fig. 6.\(^\text{13}\)

![Fig. 7.6. The tensile stress experiment.](image)

Though the deformation of the rod near its clamped ends depends on the exact way forces $F$ are applied (we will discuss this issue later on), we may expect that over most of its length the tension forces are directed virtually along the rod, $dF = F_n n$, and hence, with the coordinate choice shown in Fig. 6, $\sigma_{ij} = 0$ for all $j$, including the diagonal elements $\sigma_{xx}$ and $\sigma_{yy}$. Moreover, due to the open lateral surfaces, on which, evidently, $dF_x = dF_y = 0$, there cannot be an internal stress force of any direction, acting on any elementary internal boundary parallel to these surfaces. This means that $\sigma_{xz} = \sigma_{zy} = 0$. So, of all components of the stress tensor only one, $\sigma_{zz}$, is not equal to zero, and for a uniform sample, $\sigma_{zz} = \text{const} = F/A$. For this case, Eq. (34) shows that the strain tensor is also diagonal, but with different diagonal elements:

$$s_{zz} = \left(\frac{1}{9K} + \frac{1}{3\mu}\right) \sigma_{zz}, \quad (7.42)$$

$$s_{xx} = s_{yy} = \left(\frac{1}{9K} - \frac{1}{6\mu}\right) \sigma_{zz}. \quad (7.43)$$

Since the tensile stress is most common in engineering practice (and in physical experiment design), both combinations of the elastic moduli participating in these two relations have deserved their own names. In particular, the constant in Eq. (42) is usually denoted as $1/E$ (but in many texts, as $1/Y$), where $E$ is called Young’s modulus:\(^\text{14}\)

---

\(^\text{13}\) Though the analysis of compression in this situation gives similar results, in practical experiments a strong compression of a long sample may lead to the loss of the horizontal stability – the so-called buckling – of the rod.

\(^\text{14}\) Named after another polymath, Thomas Young (1773-1829) – somewhat unfairly, because his work on elasticity was predated by a theoretical analysis by L. Euler in 1727 and detailed experiments by Giordano Riccati in 1782.
As Fig. 6 shows, in the tensile stress geometry \( s_{zz} = \frac{\partial q_z}{\partial z} = \frac{\Delta l}{l} \) so that Young’s modulus scales the linear relation between the relative extension of the rod and the force applied per unit area: \(^{15}\)

\[
\frac{\Delta l}{l} = \frac{1}{E} \frac{F}{A}.
\]  

(7.45)

The third column of Table 1 above shows the values of this modulus for two well-known solids: diamond (with the highest known value of \( E \) of all bulk materials\(^{16} \)) and the steels (solid solutions of \(~10\%\) of carbon in iron) used in construction. Again, for all fluids, Young’s modulus equals zero – as it follows from Eq. (44) for \( \mu = 0 \).

I am confident that the reader of these notes has been familiar with Eq. (42), in the form of Eq. (45), from their undergraduate studies. However, most probably this cannot be said about its counterpart, Eq. (43), which shows that at the tensile stress, the rod’s cross-section dimensions also change. This effect is usually characterized by the following dimensionless Poisson’s ratio:\(^{17}\)

\[
-\frac{s_{xx}}{s_{zz}} = -\frac{s_{yy}}{s_{zz}} = -\left(\frac{1}{9K} - \frac{1}{6\mu}\right) = \frac{1}{2} \frac{3K - 2\mu}{3K + \mu} \equiv \nu,
\]  

(7.46)

According to this formula, for realistic materials with \( K > 0, \mu \geq 0 \), \( \nu \) may vary from \((-1)\) to \((+1/2)\), but for the vast majority of materials,\(^{18}\) its values are between \( 0 \) and \( 1/2 \) – see the corresponding column of Table 1. The lower limit of this range is reached in porous materials like cork, whose lateral dimensions almost do not change at the tensile stress. Some soft materials such as natural and synthetic rubbers present the opposite case: \( \nu \approx 1/2 \).\(^{19}\) Since according to Eqs. (13) and (42), the volume change is

\[
\frac{\Delta V}{V} = s_{xx} + s_{yy} + s_{zz} = \frac{1}{E} \frac{F}{A} (1 - 2\nu) \equiv \left(1 - 2\nu\right) \frac{\Delta l}{l},
\]  

(7.47)

such materials virtually do not change their volume at the tensile stress. The ultimate limit of this trend, \( \Delta V/V = 0 \), is provided by fluids and gases, because, as follows from Eq. (46) with \( \mu = 0 \), their Poisson ratio \( \nu \) is exactly \( 1/2 \). However, for most practicable construction materials such as various steels (see Table 1) the volume change (47) is as high as \(~40\%) of that of the length.

Due to the clear physical sense of the coefficients \( E \) and \( \nu \), they are frequently used as a pair of independent elastic moduli, instead of \( K \) and \( \mu \). Solving Eqs. (44) and (46) for them, we get

---

15 According to Eq. (47), \( E \) may be thought of as the force per unit area, which would double the initial sample’s length, if only the Hooke’s law was valid for deformations that large – as it typically isn’t.

16 It is probably somewhat higher (up to 2,000 GPa) in such nanostructures as carbon nanotubes and monatomic sheets (graphene), though there is still substantial uncertainty in experimentally measured elastic moduli of these structures – for a review see, e.g., G. Dimitrios et al., _Prog. Mater. Sci._ **90**, 75 (2017).

17 In some older texts, the Poisson’s ratio is denoted \( \sigma \), but its notation as \( \nu \) dominates modern literature.

18 The only known exceptions are certain exotic solids with very specific internal microstructure – see, e.g., R. Lakes, _Science_ **235**, 1038 (1987) and references therein.

19 For example, silicone rubbers (synthetic polymers broadly used in engineering and physics experiment design) have, depending on their particular composition, synthesis, and thermal curing, \( \nu = 0.47 \pm 0.49 \), and as a result combine respectable bulk moduli \( K = (1.5 \pm 2) \) GPa with very low Young’s moduli: \( E = (0.0001 \pm 0.05) \) GPa.
Using these formulas, the two (equivalent) formulations of Hooke’s law, expressed by Eqs. (32) and (34), may be rewritten as

\[
\begin{align*}
\sigma_{jj'} &= \frac{E}{1 + \nu} \left( s_{jj'} + \frac{\nu}{1 - 2\nu} \text{Tr} (s) \delta_{jj'} \right), \\
S_{jj'} &= \frac{1 + \nu}{E} \left( \sigma_{jj'} - \frac{\nu}{1 + \nu} \text{Tr} (\sigma) \delta_{jj'} \right).
\end{align*}
\]  
(7.49a)  
(7.49b)

The linear relation between the strain and stress tensor in elastic continua enables one more step in our calculation of the potential energy \( U \) due to deformation, started at the end of Sec. 2. Indeed, to each infinitesimal part of this strain increase, we may apply Eq. (30), with the elementary work \( \delta W \) of the surface forces increasing the potential energy of “our” part of the body by the equal amount \( \delta U \). Let us slowly increase the deformation from a completely unstrained state (in which we may take \( U = 0 \)) to a certain strained state, in the absence of bulk forces \( f \), keeping the deformation type, i.e. the relation between the elements of the stress tensor, intact. In this case, all elements of the tensor \( \sigma_{jj'} \) are proportional to the same single parameter characterizing the stress (say, the total applied force), and according to Hooke’s law, all elements of the tensor \( s_{jj'} \) are proportional to that parameter as well. In this case, integration of Eq. (30) through the variation yields the following final value:

\[
U = \int u(\mathbf{r}) d^3r, \quad u(\mathbf{r}) = \frac{1}{2} \sum_{j,j'=1}^3 \sigma_{jj'} s_{jj'}.
\]
(7.50)

Evidently, this \( u(\mathbf{r}) \) may be interpreted as the volumic density of the potential energy of the elastic deformation.

### 7.4. Equilibrium

Now we are fully equipped to discuss the elastic deformation dynamics, but let us start with statics. The static (equilibrium) state may be described by requiring the right-hand side of Eq. (25) to vanish. To find the elastic deformation, we need to plug \( \sigma_{jj'} \) from Hooke’s law (49a), and then express the elements \( s_{jj'} \) via the displacement distribution – see Eq. (9). For a uniform material, the result is

\[
\frac{E}{2(1 + \nu)} \sum_{j = 1}^3 \frac{\partial^2 q_j}{\partial r_j^2} + \frac{E}{2(1 + \nu)(1 - 2\nu)} \sum_{j = 1}^3 \frac{\partial^2 q_j}{\partial r_j \partial r_{j'}} + f_j = 0.
\]
(7.51)

Taking into account that the first sum in Eq. (51) is just the \( j^{th} \) component of \( \nabla^2 \mathbf{q} \), while the second sum is the \( j^{th} \) component of \( \nabla (\nabla \cdot \mathbf{q}) \), we see that all three equations (51) for three Cartesian components \( (j = 1, 2, \text{ and } 3) \) of the deformation vector \( \mathbf{q} \), may be conveniently merged into one vector equation

\[
(\nabla \cdot \mathbf{f}) = 0.
\]

20 For clarity, let me reproduce this integration for the extension of a simple 1D spring. In this case, \( \delta U = \delta W = F \delta \lambda \), and if the spring’s force is elastic, \( F = k \lambda \), the integration yields \( U = k \lambda^2 / 2 \equiv kx^2 / 2 \).

21 As follows from Eqs. (48), the coefficient before the first sum in Eq. (51) is just the shear modulus \( \mu \), while that before the second sum is equal to \( (K + \mu \lambda / 3) \).
\[
\frac{E}{2(1+\nu)} \nabla^2 \mathbf{q} + \frac{E}{2(1+\nu)(1-2\nu)} \nabla(\nabla \cdot \mathbf{q}) + \mathbf{f} = 0. \tag{7.52}
\]

For some applications, it is more convenient to recast this equation into a different form, using the well-known vector identity\(^{22}\) \(\nabla^2 \mathbf{q} = \nabla (\nabla \cdot \mathbf{q}) - \nabla \times (\nabla \times \mathbf{q})\). The result is

\[
\frac{E(1-\nu)}{(1+\nu)(1-2\nu)} \nabla (\nabla \cdot \mathbf{q}) - \frac{E}{2(1+\nu)} \nabla \times (\nabla \times \mathbf{q}) + \mathbf{f} = 0. \tag{7.53}
\]

It is interesting that in problems without volume-distributed forces \((\mathbf{f} = 0)\), Young’s modulus \(E\) cancels out. Even more fascinating, in this case the equation may be re-written in a form not involving the Poisson ratio \(\nu\) either. Indeed, calculating the divergence of the remaining terms of Eq. (53), taking into account MA Eqs. (9.2) and (11.2), we get a surprisingly simple equation

\[
\nabla^2 (\nabla \cdot \mathbf{q}) = 0. \tag{7.54}
\]

A natural question here is how do the elastic moduli affect the deformation distribution if they do not participate in the differential equation describing it. The answer is different in two cases. If what is fixed at the body’s boundary are deformations, then the moduli are irrelevant, because the deformation distribution through the body does not depend on them. On the other hand, if the boundary conditions describe fixed stress (or a combination of stress and strain), then the elastic constants creep into the solution via the recalculation of these conditions into the strain.

As a simple but representative example, let us calculate the deformation distribution in a (generally, thick) spherical shell under the different pressures inside and outside it – see Fig. 7a.

Fig. 7.7. The spherical shell problem: (a) the general case, and (b) the thin shell limit.

Due to the spherical symmetry of the problem, the deformation is obviously spherically-symmetric and radial, \(\mathbf{q}(\mathbf{r}) = q(r)\mathbf{n}_r\), i.e. is completely described by one scalar function \(q(r)\). Since the curl of such a radial vector field is zero,\(^{23}\) Eq. (53) is reduced to

\[
\nabla (\nabla \cdot \mathbf{q}) = 0, \tag{7.55}
\]

This means that the divergence of the function \(q(r)\) is constant within the shell. In the spherical coordinates:\(^{24}\)

---

\(^{22}\) See, e.g., MA Eq. (11.3).

\(^{23}\) If this is not immediately evident, please have a look at MA Eq. (10.11) with \(\mathbf{f} = f(r)\mathbf{n}_r\).

\(^{24}\) See, e.g., MA Eq. (10.10) with \(\mathbf{f} = q(r)\mathbf{n}_r\).
\[
\frac{1}{r^2} \frac{d}{dr} \left( r^2 q \right) = \text{const.} \quad (7.56)
\]

Naming this constant \(3a\) (with the numerical factor chosen just for the later notation’s convenience), and integrating Eq. (56) over \(r\), we get its solution,

\[
q(r) = ar + \frac{b}{r^2}, \quad (7.57)
\]

which also includes another integration constant, \(b\). The constants \(a\) and \(b\) may be determined from the boundary conditions. Indeed, according to Eq. (19),

\[
\sigma_{rr} = \begin{cases}
-P_1, & \text{at } r = R_1, \\
-P_2, & \text{at } r = R_2.
\end{cases} \quad (7.58)
\]

In order to relate this stress to strain, let us use Hooke’s law, but for that, we first need to calculate the strain tensor components for the deformation distribution (57). Using Eqs. (17), we get

\[
s_{rr} = \frac{\partial q}{\partial r} = a - 2 \frac{b}{r^3}, \quad s_{\theta\theta} = s_{\phi\phi} = \frac{q}{r} = a + \frac{b}{r^3}, \quad (7.59)
\]

so that \(\text{Tr}(s) = 3a\). Plugging these relations into Eq. (49a) for \(\sigma_{rr}\), we get

\[
\sigma_{rr} = \frac{E}{1+\nu} \left[ \frac{a - 2 \frac{b}{r^3}}{1 - 2\nu} + \frac{\nu}{1 - 2\nu} \frac{3a}{r^3} \right]. \quad (7.60)
\]

Now plugging this relation into Eqs. (58), we get a system of two linear equations for the coefficients \(a\) and \(b\). Solving this system, we get:

\[
a = \frac{1 - 2\nu}{E} \frac{P_1 R_1^3 - P_2 R_2^3}{R_2^3 - R_1^3}, \quad b = \frac{1 + \nu}{2E} \frac{(P_1 - P_2)R_1^3 R_2^3}{R_2^3 - R_1^3}. \quad (7.61)
\]

Formulas (57) and (61) give a complete solution to our problem. (Note that the elastic moduli are back, as was promised.) The solution is rich in physical content and deserves at least some analysis. First of all, note that according to Eq. (48), the coefficient \((1 - 2\nu)/E\) in the expression for \(a\) is just \(1/3K\), so that the first term in Eq. (57) for the net deformation describes the hydrostatic compression. Now note that the second of Eqs. (61) yields \(b = 0\) if \(R_1 = 0\). Thus for a solid sphere, we have only the hydrostatic compression, which was discussed in the previous section. Perhaps less intuitively, making two pressures equal also gives \(b = 0\), i.e. the purely hydrostatic compression, for arbitrary \(R_2 > R_1\).

However, in the general case, \(b \neq 0\), so that the second term in the deformation distribution (57), which describes the shear deformation,\(^{25}\) is also substantial. In particular, let us consider the important thin-shell limit, when \(R_2 - R_1 \equiv t \ll R_{1,2} \equiv R \) – see Fig. 7b. In this case, \(q(R_1) \approx q(R_2)\) is just the change of the shell radius \(R\), for which Eqs. (57) and (61) (with \(R_2^3 - R_1^3 \approx 3R_1t\)) give

\[
\Delta R \equiv q(R) \approx aR + \frac{b}{R^2} \approx \left( \frac{P_1 - P_2}{3t} \right) \frac{1 - 2\nu}{E} \left( \frac{1 + \nu}{2E} \right) = \left( \frac{P_1 - P_2}{2} \right) \frac{R_2^3}{2E}. \quad (7.62)
\]

\(^{25}\) Indeed, according to Eq. (48), the material-dependent factor in the second of Eqs. (61) is just \(1/4\mu\).
Naively, one could think that at least in this limit the problem could be analyzed by elementary means. For example, the total force exerted by the pressure difference \((P_1 - P_2)\) on the diametrical cross-section of the shell (see, e.g., the dashed line in Fig. 7b) is
\[
F = \pi R^2 (P_1 - P_2),
\]
giving the stress,
\[
\sigma = \frac{F}{A} = \frac{\pi R^2 (P_1 - P_2)}{2 \pi R t} = \left(\frac{P_1 - P_2}{2t}\right) R,
\] (7.63)
directed along the shell’s walls. One can check that this simple formula may be indeed obtained, in this limit, from the strict expressions for \(\sigma_{\theta \theta}\) and \(\sigma_{\varphi \varphi}\), following from the general treatment carried out above. However, if we now tried to continue this approach by using the simple relation (45) to find the small change \(R_{zz}\) of the sphere’s radius, we would arrive at a result with the structure of Eq. (62), but without the factor \((1 - \nu) < 1\) in the numerator. The reason for this error (which may be as significant as ~30% for typical construction materials – see Table 1) is that Eq. (45), while being valid for thin rods of arbitrary cross-section, is invalid for thin but broad sheets, and in particular the thin shell in our problem. Indeed, while at the tensile stress both lateral dimensions of a thin rod may contract freely, in our problem all dimensions of the shell are under stress – actually, under much more tangential stress than the radial one.\(^{26}\)

7.5. Rod bending

The general approach to the static deformation analysis, outlined in the beginning of the previous section, may be simplified not only for symmetric geometries, but also for the uniform thin structures such as thin plates (also called “membranes” or “thin sheets”) and thin rods. Due to the shortage of time, in this course I will demonstrate typical approaches to such systems only on the example of thin rods. (The theory of thin plates and shells is conceptually similar, but mathematically more involved.\(^{27}\))

Besides the tensile stress analyzed in Sec. 3, two other major types of rod deformation are bending and torsion. Let us start from a “local” analysis of bending caused by a pair of equal and opposite external torques \(\tau = \pm n_y \tau_y\) perpendicular to the rod axis \(z\) (Fig. 8), assuming that the rod is “quasi-uniform”, i.e. that on the longitudinal scale of this analysis (comparable with the linear scale \(a\) of the cross-section) its material parameters and the cross-section \(A\) do not change substantially.

\begin{align*}
\tau_y &\quad \text{Diagonal} \quad \tau_y \quad \text{Vertical} \quad \tau_y \quad \text{Vertical} \\
\text{Fig. 7.8. Rod bending, in a local reference frame (specific for each cross-section).}
\end{align*}

Just as in the tensile stress experiment (Fig. 6), the components of the stress forces \(dF\), normal to the rod length, have to equal zero on the surface of the rod. Repeating the arguments made for the

\(^{26}\) Strictly speaking, this is only true if the pressure difference is not too small, namely, if \(|P_1 - P_2| \gg P_{1,2}/R.\)

tensile stress discussion, we have to conclude that only one diagonal component of the tensor (in Fig. 8, \(\sigma_{zz}\)) may differ from zero:

\[
\sigma_{ij} = \delta_{jz} \sigma_{zz}.
\]  

(7.64)

However, in contrast to the tensile stress, at pure static bending, the net force directed along the rod has to vanish:

\[
F_z = \int S \sigma_{zz} d^2r = 0,
\]  

(7.65)

where \(S\) is the rod’s cross-section, so that \(\sigma_{zz}\) has to change its sign at some point of the \(x\)-axis (in Fig. 8, selected to lie in the plane of the bent rod). Thus, the bending deformation may be viewed as a combination of stretching some layers of the rod (bottom layers in Fig. 8) with compression of other (top) layers.

Since it is hard to make more immediate conclusions about the stress distribution, let us turn over to strain, assuming that the rod’s cross-section is virtually constant on the length of our local analysis. From the above representation of bending as a combination of stretching and compression, it evident that the longitudinal deformation \(q_z\) has to vanish along some neutral line on the rod’s cross-section – in Fig. 8, represented by the dashed line.\(^{28}\) Selecting the origin of the \(x\)-coordinate on this line, and expanding the relative deformation in the Taylor series in \(x\), due to the cross-section smallness we may keep just the first, linear term:

\[
s_{zz} \equiv \frac{dq_z}{dz} = -\frac{x}{R}.
\]  

(7.66)

The constant \(R\) has the sense of the curvature radius of the bent rod. Indeed, on a small segment \(dz\), the cross-section turns by a small angle \(d\phi_y = -dq_z/x\) (Fig. 8b). Using Eq. (66), we get \(d\phi_y = dz/R\), which is the usual definition of the curvature radius \(R\) in the differential geometry, for our special choice of the coordinate axes.\(^{29}\)

Expressions for other components of the strain tensor are harder to guess (like at the tensile stress, not all of them are equal to zero!), but what we already know about \(\sigma_{zz}\) and \(s_{zz}\) is already sufficient to start formal calculations. Indeed, plugging Eq. (64) into Hooke’s law in the form (49b), and comparing the result for \(s_{zz}\) with Eq. (66), we find

\[
\sigma_{zz} = -E \frac{x}{R}.
\]  

(7.67)

From the same Eq. (49b), we could also find the transverse components of the strain tensor, and conclude that they are related to \(s_{zz}\) exactly as at the tensile stress:

\[
s_{xx} = s_{yy} = -\nu s_{zz},
\]  

(7.68)

\(^{28}\) Strictly speaking, that dashed line is the intersection of the neutral surface (the continuous set of such neutral lines for all cross-sections of the rod) with the plane of the drawing.

\(^{29}\) Indeed, for \((dx/dz)^2 \ll 1\), the general formula MA Eq. (4.3) for the curvature (with the appropriate replacements \(f \to x\) and \(x \to z\)) is reduced to \(/R = d^2x/dz^2 = d(dx/dz)/dz = d(tan\phi_y)/dz \approx d\phi_y/dz\).
and then, integrating these relations along the cross-section of the rod, find the deformation of the cross-section’s shape. More important for us, however, is the calculation of the relation between the rod’s curvature and the net torque acting on a given cross-section S (taking $dA_z > 0$):

$$\tau_y = \int_S \langle \mathbf{r} \times d\mathbf{F} \rangle_y = -\int_S x \sigma_z d^2r = \frac{E}{R} \int_S x^2 d^2r = \frac{EI_y}{R},$$

(7.69)

where $I_y$ is a geometric constant defined as

$$I_y \equiv \int_S x^2 dx dy.$$  

(7.70)

Note that this factor, defining the bending rigidity of the rod, grows as fast as $a^4$ with the linear scale $a$ of the cross-section.\(^{30}\)

In these expressions, $x$ has to be counted from the neutral line. Let us see where exactly does this line pass through the rod’s cross-section. Plugging the result (67) into Eq. (65), we get the condition defining the neutral line:

$$\int_S x dx dy = 0.$$  

(7.71)

This condition allows a simple interpretation. Imagine a thin sheet of some material, with a constant mass density $\sigma$ per unit area, cut in the form of the rod’s cross-section. If we place a reference frame into its center of mass, then, by its definition,

$$\sigma \int_S r dx dy = 0.$$  

(7.72)

Comparing this condition with Eq. (71), we see that one of the neutral lines has to pass through the center of mass of the sheet, which may be called the “center of mass of the cross-section”. Using the same analogy, we see that the integral $I_y$ given by Eq. (72) may be interpreted as the moment of inertia of the same imaginary sheet of material, with $\sigma$ formally equal to 1, for its rotation about the neutral line – cf. Eq. (4.24). This analogy is so convenient that the integral is usually called the \textit{moment of inertia of the cross-section} and denoted similarly – just as has been done above. So, our basic result (69) may be re-written as

$$\frac{1}{R} = \frac{\tau_y}{EI_y}.$$  

(7.73)

This relation is only valid if the deformation is small in the sense $R >> a$. Still, since the deviations of the rod from its unstrained shape may accumulate along its length, Eq. (73) may be used for calculations of large “global” deviations of the rod from equilibrium, on a length scale much larger than $a$. To describe such deformations, Eq. (73) has to be complemented by conditions of the balance of the bending forces and torques. Unfortunately, this requires a bit more differential geometry than I have time for, and I will only discuss this procedure for the simplest case of \textit{relatively small} transverse deviations $q \equiv q_z$ of the rod from its initial straight shape, which will be used for the z-axis (Fig. 9a), for example by some bulk-distributed force $\mathbf{f} = n f_i(z)$. (The simplest example is a uniform gravity field, for which $f_i = -\rho g = \text{const.}$) Note that in the forthcoming discussion the reference frame will be global, i.e.

\(^{30}\) In particular, this is the reason why the usual electric wires are made not of a solid copper core, but rather a twisted set of thinner sub-wires, which may slip relative to each other, increasing the wire flexibility.
common for the whole rod, rather than local (pertaining to each cross-section) as it was in the previous analysis – cf. Fig. 8.

![Diagram](image)

**Fig. 7.9.** A global picture of rod bending: (a) the forces acting on a small fragment of a rod, and (b) two bending problem examples, each with two typical but different boundary conditions.

First of all, we may write a differential static relation for the average vertical force $F = n_x F_x(z)$ exerted on the part of the rod located to the left of its cross-section – located at point $z$. This relation expresses the balance of vertical forces acting on a small fragment $dz$ of the rod (Fig. 9a), necessary for the absence of its *linear* acceleration: $F_x(z + dz) - F_x(z) + f_z(z) Adz = 0$, giving

$$\frac{dF_x}{dz} = -f_z A,$$  \hfill (7.74)

where $A$ is the cross-section area. Note that this vertical component of the internal forces has been neglected at our derivation of Eq. (73), and hence our final results will be valid only if the ratio $F_x/A$ is much smaller than the magnitude of $\sigma_{zz}$ described by Eq. (67). However, these forces create the very torque $\tau = n_y \tau_y$ that causes the bending, and thus have to be taken into account at the analysis of the global picture. Such account may be made by writing the balance of torque components, acting on the same rod fragment of length $dz$, necessary for the absence of its *angular* acceleration: $d\tau_y + F_y dz = 0$, giving

$$\frac{d\tau_y}{dz} = -F_y.$$  \hfill (7.75)

These two equations should be complemented by two geometric relations. The first of them is $d\varphi_y/dz = 1/R$, which has already been discussed above. We may immediately combine it with the basic result (73) of the local analysis, getting:

$$\frac{d\varphi_y}{dz} = \frac{\tau_y}{EI_y}.$$  \hfill (7.76)

The final equation is the geometric relation evident from Fig. 9a:

$$\frac{dq_x}{dz} = \varphi_y,$$ \hfill (7.77)

which is (as all expressions of our simple analysis) only valid for small bending angles, $|\varphi_y| \ll 1$./crypto/
The four differential equations (74)-(77) are sufficient for the full solution of the weak bending problem, if complemented by appropriate boundary conditions. Figure 9b shows the conditions most frequently met in practice. Let us solve, for example, the problem shown on the top panel of Fig. 9b: bending of a rod, “clamped” at one end (say, immersed into a rigid wall), under its own weight. Considering, for the sake of simplicity, a uniform rod, we may integrate these equations one by one, each time using the appropriate boundary conditions. To start, Eq. (74) with \( f_x = -\rho g \) yields

\[
F_x = \rho g Az + \text{const} = \rho g A(z - l),
\]

where the integration constant has been selected to satisfy the right-end boundary condition: \( F_x = 0 \) at \( z = l \). As a sanity check, at the left wall (\( z = 0 \)), \( F_x = -\rho g Al = -mg \), meaning that the whole weight of the rod is exerted on the wall – fine.

Next, plugging Eq. (78) into Eq. (75) and integrating, we get

\[
\tau_y = -\frac{\rho g A}{2} (z^2 - 2lz) + \text{const} = -\frac{\rho g A}{2} (z^2 - 2lz + l^2) = -\frac{\rho g A}{2} (z - l)^2,
\]

where the integration constant’s choice ensures the second right-boundary condition: \( \tau_y = 0 \) at \( z = l \) – see Fig. 9b again. Now proceeding in the same fashion to Eq. (76), we get

\[
\varphi_y = -\frac{\rho g A}{2EI_y} \left( z - l \right)^3 + \text{const} = -\frac{\rho g A}{6EI_y} \left[ (z - l)^3 + l^3 \right],
\]

where the integration constant is selected to satisfy the clamping condition at the left end of the rod: \( \varphi_y = 0 \) at \( z = 0 \). (Note that this is different from the support condition illustrated on the lower panel of Fig. 9b, which allows the angle at \( z = 0 \) to be different from zero, but requires the torque to vanish.) Finally, integrating Eq. (77) with \( \varphi_y \) given by Eq. (80), we get the rod’s global deformation law,

\[
q_x(z) = -\frac{\rho g A}{6EI_y} \left[ \frac{(z - l)^4}{4} + l^3 z + \text{const} \right] = -\frac{\rho g A}{6EI_y} \left[ \frac{(z - l)^4}{4} + l^3 z - \frac{l^4}{4} \right],
\]

where the integration constant is selected to satisfy the second left-boundary condition: \( q = 0 \) at \( z = 0 \). So, the bending law is sort of complicated even in this very simple problem. It is also remarkable how fast does the end’s displacement grow with the increase of the rod’s length:

\[
q_x(l) = -\frac{\rho g Al^4}{8EI_y}.
\]

To conclude the solution, let us discuss the validity of this result. First, the geometric relation (77) is only valid if \( |\varphi_y(l)| \ll 1 \), and hence if \( |q_x(l)| \ll l \). Next, the local formula Eq. (76) is valid if \( 1/R = \pi(l)/EI_y \ll 1/a \sim A^{-1/2} \). Using the results (79) and (82), we see that the latter condition is equivalent to \( |q_x(l)| \ll \hat{l}^3/a \), i.e. is weaker than the former one, because all our analysis has been based on the assumption \( l \gg a \).

---

31 As should be clear from their derivation, Eqs. (74)-(77) are valid for any distribution of parameters \( A, E, I_y \), and \( \rho \) over the rod’s length, provided that the rod is quasi-uniform, i.e. its parameters’ changes are so slow that the local relation (76) is still valid at any point.
Another point of concern may be that the off-diagonal stress component \( \sigma_{xz} \sim F_x/A \), which is created by the vertical gravity forces, has been ignored in our local analysis. For that approximation to be valid, this component must be much smaller than the diagonal component \( \sigma_{zz} \sim aE/R = a \pi l_y \) taken into account in that analysis. Using Eqs. (78) and (80), we are getting the following estimates: \( \sigma_{xz} \sim \rho g \), \( \sigma_{zz} \sim a \rho g A l_z / l_y \sim a^3 \rho g l_y l_z / l_y \). According to its definition (70), \( l_y \) may be crudely estimated as \( a^4 \), so that we finally get the simple condition \( a << l \), which has been assumed from the very beginning of our solution.

7.6. Rod torsion

One more class of analytically solvable elasticity problems is torsion of quasi-uniform, straight rods by a couple of axially-oriented torques \( \tau = \pm n_z \tau \) – see Fig. 10.

This problem is simpler than the bending in the sense that due to its longitudinal uniformity, \( d \phi_z / dz = \text{const} \), it is sufficient to relate the torque \( \tau_z \) to the so-called torsion parameter

\[
\kappa \equiv \frac{d \phi_z}{dz}.
\]  

(7.83)

If the deformation is elastic and small (in the sense \( \kappa a << 1 \), where \( a \) is again the characteristic size of the rod’s cross-section), \( \kappa \) is proportional to \( \tau_z \). Hence our task is to calculate their ratio,

\[
C \equiv \frac{\tau_z}{\kappa} \equiv \frac{\tau_z}{d \phi_z / dz},
\]  

(7.84)

called the torsional rigidity of the rod.

As the first guess (as we will see below, of a limited validity), one may assume that the torsion does not change either the shape or size of the rod’s cross-sections, but leads just to their mutual rotation about a certain central line. Using a reference frame with the origin on that line, this assumption immediately enables the calculation of Cartesian components of the displacement vector \( dq \), by using Eq. (6) with \( d \phi = n_z d \phi_z \):

\[
dq_x = -y d \phi_z = -\kappa y dz, \quad dq_y = x d \phi_z = \kappa x dz, \quad dq_z = 0.
\]  

(7.85)

From here, we can calculate all Cartesian components (9) of the symmetrized strain tensor:

\[
s_{xx} = s_{yy} = s_{zz} = 0, \quad s_{xy} = s_{yx} = 0, \quad s_{xz} = s_{zx} = -\frac{\kappa}{2} y, \quad s_{yz} = s_{zy} = \frac{\kappa}{2} x.
\]  

(7.86)
The first of these equalities means that the elementary volume does not change, i.e. we are dealing with purely shear deformation. As a result, all nonzero components of the stress tensor, calculated from Eqs. (32), are proportional to the shear modulus alone:

\[ \sigma_{xx} = \sigma_{yy} = \sigma_{zz} = 0, \quad \sigma_{xy} = \sigma_{yx} = 0, \quad \sigma_{xz} = \sigma_{zx} = -\mu \kappa, \quad \tau_{yz} = \sigma_{yz} = \mu \kappa. \]  

(7.87)

(Note that for this problem, with a purely shear deformation, using alternative elastic moduli \( E \) and \( \nu \) would be rather unnatural. If so desired, we may always use the second of Eqs. (48): \( \mu = E/2(1 + \nu) \).)

Now it is straightforward to use this result to calculate the full torque as an integral over the cross-section’s area \( A \):

\[ \tau_z \equiv \int_A (\mathbf{r} \times d\mathbf{F})_z = \int_A (x dF_y - y dF_x) = \int_A (x \sigma_{yz} - y \sigma_{zx}) \, dx \, dy. \]  

(7.88)

Using Eq. (77), we get \( \tau_z = \mu I_z \), i.e.

\[ C = \mu I_z, \quad \text{where} \quad I_z \equiv \int_A (x^2 + y^2) \, dx \, dy. \]  

(7.89)

Again, just as in the case of thin rod bending, we have got an integral, in this case \( I_z \), similar to a moment of inertia, this time for the rotation about the \( z \)-axis passing through a certain point of the cross-section. For any axially-symmetric cross-section, this evidently should be the central point. Then, for example, for the practically important case of a uniform round pipe with internal radius \( R_1 \) and external radius \( R_2 \), Eq. (89) yields

\[ C = \mu \int_{R_1}^{R_2} \rho^3 \, d\rho = \frac{\pi}{2} \mu \left( R_2^4 - R_1^4 \right). \]  

(7.90)

In particular, for the solid rod of radius \( R \) (which may be treated as a pipe with \( R_1 = 0 \) and \( R_2 = R \)), this result gives the following torsional rigidity

\[ C = \frac{\pi}{2} \mu R^4, \]  

(7.91a)

while for a hollow pipe of small thickness \( t \ll R \), Eq. (90) is reduced to

\[ C = 2\pi \mu R^3 t. \]  

(7.91b)

Note that per unit cross-section area \( A \) (and hence per unit mass of the rod) this rigidity is twice higher than that of a solid rod:

\[ \frac{C}{A}\text{ thin round pipe} = \mu R^2 > \frac{C}{A}\text{ solid round rod} = \frac{1}{2} \mu R^2. \]  

(7.92)

This fact is one reason for the broad use of thin pipes in engineering and physical experiment design.

However, for rods with axially-asymmetric cross-sections, Eq. (89) gives wrong results. For example, for a narrow rectangle of area \( A = w \times t \) with \( t \ll w \), it yields \( C = \mu tw^3/12 \) [WRONG!], even functionally different from the correct result – cf. Eq. (104) below. The reason of the failure of the above analysis is that does not describe possible bending \( q_z(x, y) \) of the rod’s cross-section in the direction \( \mathbf{q}_z \) the rod. (For axially-symmetric rods, such bending is evidently forbidden by the symmetry, so that Eq. (89) is valid, and the results (90)-(92) are absolutely correct.)
Let us describe\(^{32}\) this counter-intuitive effect by taking
\[ q_z = \kappa \psi(x, y), \]  
(7.93)
(where \( \psi \) is some function to be determined), but still keeping Eq. (87) for two other components of the displacement vector. The addition of \( \psi \) does not perturb the equality to zero of the diagonal components of the strain tensor, as well as of \( s_{xy} \) and \( s_{yx} \), but contributes to other off-diagonal components:
\[ s_{xz} = s_{zx} = \frac{\kappa}{2}\left(-y + \frac{\partial \psi}{\partial x}\right), \quad s_{yz} = s_{zy} = \frac{\kappa}{2}\left(x + \frac{\partial \psi}{\partial y}\right), \]  
(7.94)
and hence to the corresponding elements of the stress tensor:
\[ \sigma_{xz} = \sigma_{zx} = \mu \kappa \left(-y + \frac{\partial \psi}{\partial x}\right), \quad \sigma_{yz} = \sigma_{zy} = \mu \kappa \left(x + \frac{\partial \psi}{\partial y}\right), \]  
(7.95)

Now let us find the requirement imposed on the function \( \psi(x, y) \) by the fact that the stress force component parallel to the rod’s axis,
\[ dF_z = \sigma_{xz}dA_x + \sigma_{yz}dA_y = \mu \kappa dA \left[ -y + \frac{\partial \psi}{\partial x} \right] \frac{dA_x}{dA} + \left[ x + \frac{\partial \psi}{\partial y} \right] \frac{dA_y}{dA}, \]  
(7.96)
has to vanish at the rod’s surface(s), i.e. at each border of its cross-section. The coordinates \( \{x, y\} \) of any point at a border may be considered as unique functions, \( x(l) \) and \( y(l) \), of the arc \( l \) of that line – see Fig. 11.

As this sketch shows, the elementary area ratios participating in Eq. (96) may be readily expressed via the derivatives of these functions: \( dA_x/dA = \sin \alpha = dy/dl \), \( dA_y/dA = \cos \alpha = -dx/dl \), so that we may write
\[ \left[ -y + \frac{\partial \psi}{\partial x} \left( \frac{dy}{dl} \right) + \left( x + \frac{\partial \psi}{\partial y} \right) \left( -\frac{dx}{dl} \right) \right] \bigg|_{\text{border}} = 0. \]  
(7.97)

Introducing, instead of \( \psi \), a new function \( \chi(x, y) \), defined by its derivatives as

\(^{32}\) I would not be terribly shocked if the reader skipped the balance of this section at the first reading. Though the calculation described in it is very elegant, instructive, and typical for the advanced theory of elasticity, its results will not be used in other chapters of this course or other parts of this series.
\[ \frac{\partial \chi}{\partial x} = \frac{1}{2} \left( -x - \frac{\partial \psi}{\partial y} \right), \quad \frac{\partial \chi}{\partial y} = \frac{1}{2} \left( -y + \frac{\partial \psi}{\partial x} \right), \quad (7.98) \]

we may rewrite Eq. (97) as
\[ 2 \left( \frac{\partial \chi}{\partial y} \frac{dy}{dl} + \frac{\partial \chi}{\partial x} \frac{dx}{dl} \right)_{\text{border}} = 2 \frac{d\chi}{dl} \bigg|_{\text{border}} = 0, \quad (7.99) \]
so that the function \( \chi \) should be constant at each border of the cross-section.

In particular, for a singly-connected cross-section, limited by just one continuous border line (as in Fig. 11), this constant is arbitrary, because according to Eqs. (98), its choice does not affect the longitudinal deformation function \( \psi(x,y) \) and hence the deformation as the whole. Now let use the definition (98) of the function \( \chi \) to calculate the 2D Laplace operator of this function:
\[ \nabla_{x,y}^2 \chi = \frac{\partial^2 \chi}{\partial x^2} + \frac{\partial^2 \chi}{\partial y^2} = \frac{1}{2} \frac{\partial}{\partial x} \left( -x - \frac{\partial \psi}{\partial y} \right) + \frac{1}{2} \frac{\partial}{\partial y} \left( -y + \frac{\partial \psi}{\partial x} \right) = -1. \quad (7.100) \]

This a 2D Poisson equation (frequently met, for example, in electrostatics), but with a very simple, constant right-hand side. Plugging Eqs. (98) into Eqs. (95), and those into Eq. (88), we may express the torque \( \tau \), and hence the torsional rigidity \( C \), via the same function:

\[
C \equiv \frac{\tau}{\kappa} = -2\mu \int_A \left( x \frac{\partial \chi}{\partial x} + y \frac{\partial \chi}{\partial y} \right) dx dy. \quad (7.101a)
\]

Sometimes, it is easier to use this result in either of its two different forms. The first of them may be readily obtained from Eq. (101a) using integration by parts:
\[
C = -2\mu \left[ \int_A \int_A dx dy x \frac{\partial \chi}{\partial x} + \int_A dx \int_A y d\chi \right] = -2\mu \left[ \int_A \int_A dy \left( x \chi_{\text{border}} - \int_A \chi dx \right) + \int_A dx \left( y \chi_{\text{border}} - \int_A \chi dy \right) \right] \]
\[
= 4\mu \left[ \int_A \chi dx dy - \chi_{\text{border}} \int_A dx dy \right], \quad (7.101b)
\]
while the proof of one more form,
\[
C = 4\mu \int_A \left( \nabla_{x,y} \chi \right)^2 dx dy, \quad (7.101c)
\]
is left for the reader’s exercise.

Thus, if we need to know the rod’s rigidity alone, it is sufficient to calculate the function \( \chi(x,y) \) from Eq. (100) with the boundary condition \( \chi_{\text{border}} = \text{const} \), and then plug it into any of Eqs. (101). Only if we are also curious about the longitudinal deformation (93) of the cross-section, we may continue by using Eq. (98) to find the function \( \psi(x,y) \) describing this deformation. Let us see how does this general result work for the two examples discussed above. For the round cross-section of radius \( R \), both the Poisson equation (100) and the boundary condition, \( \chi = \text{const} \) at \( x^2 + y^2 = R^2 \), are evidently satisfied by the axially-symmetric function
\[
\chi = -\frac{1}{4} (x^2 + y^2) + \text{const}. \quad (7.102)
\]
For this case, either of Eqs. (101) yields

\[ C = 4\mu \int_{\mathcal{A}} \left[ \left( -\frac{1}{2}x \right)^2 + \left( -\frac{1}{2}y \right)^2 \right] \, dx \, dy = \mu \int_{\mathcal{A}} \left( x^2 + y^2 \right) \, d^2 r, \tag{7.103} \]

i.e. the same result (89) that we had for \( \psi = 0 \). Indeed, plugging Eq. (102) into Eqs. (98), we see that in this case \( \partial \psi / \partial x = \partial \psi / \partial y = 0 \), so that \( \psi(x,y) = \text{const} \), i.e. the cross-section is not bent. (As was discussed in Sec. 1, a uniform translation \( dq_z = \kappa \psi = \text{const} \) does not constitute a deformation.)

Now, turning to a rod with a narrow rectangular cross-section \( A = w \times t \) with \( t \ll w \), we may use this strong inequality to solve the Poisson equation (100) approximately, neglecting the second derivative of \( \chi \) along the wider dimension (say, \( y \)). The remaining 1D differential equation \( d^2 \chi / dx^2 = -1 \), with boundary conditions \( \left. \chi \right|_{x=+t/2} = \left. \chi \right|_{x=-t/2} \) has an evident solution: \( \chi = -x^2/2 + \text{const} \). Plugging this expression into any form of Eq. (101), we get the following (correct) result for the torsional rigidity:

\[ C = \frac{1}{6} \mu \psi t^3. \tag{7.104} \]

Now let us have a look at the cross-section bending law (93) for this particular case. Using Eqs. (96), we get

\[ \frac{\partial \psi}{\partial y} = -x - 2 \frac{\partial \chi}{\partial x} = x, \quad \frac{\partial \psi}{\partial x} = y + 2 \frac{\partial \chi}{\partial y} = y. \tag{7.105} \]

Integrating these differential equations over the cross-section, and taking the integration constant (again, not contributing to the deformation) for zero, we get a beautifully simple result:

\[ \psi = xy, \quad \text{i.e.} \quad q_z = \kappa xy. \tag{7.106} \]

It means that the longitudinal deformation of the rod has a “propeller bending” form: while the regions near the opposite corners (on the same diagonal) of the cross-section bend toward one direction of the \( z \)-axis, the corners on the other diagonal bend in the opposite direction. (This qualitative conclusion remains valid for rectangular cross-sections with any “aspect ratio” \( t/w \).)

For rods with several surfaces, i.e. with cross-sections limited by several boundaries (say, hollow pipes), finding the function \( \chi(x, y) \) requires a bit more care, and Eq. (103b) has to be modified, because it may be equal to a different constant at each boundary. Let me leave the calculation of the torsional rigidity for this case for the reader’s exercise.

### 7.7. 3D acoustic waves

Now moving from the statics to dynamics, we may start with Eq. (24), which may be transformed into the vector form exactly as this was done for the static case in the beginning of Sec. 4. Comparing Eqs. (24) and (52), we immediately see that the result may be represented as

\[ \rho \frac{\partial^2 \mathbf{q}}{\partial t^2} = \frac{E}{2(1+\nu)} \nabla^2 \mathbf{q} + \frac{E}{2(1+\nu)(1-2\nu)} \nabla (\nabla \cdot \mathbf{q}) + \mathbf{f}(\mathbf{r},t). \tag{7.107} \]

Let us use this general equation for the analysis of the perhaps most important type of time-dependent deformations: acoustic waves. First, let us consider the simplest case of a virtually infinite,
uniform elastic medium, with no external forces: \( f = 0 \). In this case, due to the linearity and homogeneity of the equation of motion, and taking clues from the analysis of the simple 1D model (see Fig. 6.4a) in Secs. 6.3-6.5,\(^{33}\) we may look for a particular time-dependent solution in the form of a sinusoidal, linearly-polarized, plane traveling wave

\[
q(\mathbf{r}, t) = \text{Re} \left[ a e^{i(\mathbf{k} \cdot \mathbf{r} - \omega t)} \right],
\]

where \( a \) is the constant complex amplitude of a wave (now a vector!), and \( \mathbf{k} \) is the wave vector, whose magnitude is equal to the wave number \( k \). The direction of these two vectors should be clearly distinguished: while \( a \) determines the wave’s polarization, i.e. the direction of particle displacements, the vector \( \mathbf{k} \) is directed along the spatial gradient of the full phase of the wave

\[
\Psi \equiv \mathbf{k} \cdot \mathbf{r} - \omega t + \arg a,
\]

i.e. along the direction of the wave front propagation.

The importance of the angle between these two vectors may be readily seen from the following simple calculation. Let us point the \( z \)-axis of an (inertial) reference frame along the direction of vector \( \mathbf{k} \), and the \( x \)-axis in such direction that the vector \( \mathbf{a} \), and hence \( a \), lie within the \( \{x, z\} \) plane. In this case, all variables may change only along the \( z \)-axis, i.e. \( \nabla = n_z(\partial / \partial z) \), while the amplitude vector may be represented as the sum of just two Cartesian components:

\[
a = a_x n_x + a_z n_z.
\]

Let us first consider a *longitudinal* wave, with the particle motion along the wave direction: \( a_x = 0, a_z = a \). Then the vector \( \mathbf{q} \) in Eq. (107), describing this wave, has only one (\( z \)) component, so that \( \nabla \mathbf{q} = dq_z / dz \) and \( \nabla(\nabla \cdot \mathbf{q}) = n_z(\partial^2 q / \partial z^2) \), and the Laplace operator gives the same expression: \( \nabla^2 \mathbf{q} = n_z(\partial^2 q / \partial z^2) \). As a result, Eq. (107), with \( f = 0 \), is reduced to a 1D wave equation

\[
\rho \frac{\partial^2 q_z}{\partial t^2} = \left[ \frac{E}{2(1 + \nu)} + \frac{E}{2(1 + \nu)(1 - 2\nu)} \right] \frac{\partial^2 q_z}{\partial z^2} \equiv \frac{E(1 - \nu)}{(1 + \nu)(1 - 2\nu)} \frac{\partial^2 q_z}{\partial z^2},
\]

similar to Eq. (6.40). As we already know from Sec. 6.4, this equation is indeed satisfied with the solution (108), provided that \( \omega \) and \( k \) obey a linear dispersion relation, \( \omega = \nu k \), with the following longitudinal wave velocity:

\[
\nu_1^2 = \frac{E(1 - \nu)}{(1 + \nu)(1 - 2\nu)} \rho \equiv \frac{K + (4/3)\mu}{\rho} .
\]

The last expression allows a simple interpretation. Let us consider a static experiment, similar to the tensile test experiment shown in Fig. 6, but with a sample much wider than \( l \) in both directions perpendicular to the force. Then the lateral contraction is impossible \((s_{xx} = s_{yy} = 0)\), and we can calculate the only finite stress component, \( \sigma_{zz} \), directly from Eq. (34) with \( \text{Tr} (s) = s_{zz} \):

\[
\sigma_{zz} = 2\mu \left( s_{zz} - \frac{1}{3} s_{zz} \right) + 3K \left( \frac{1}{3} s_{zz} \right) = \left( K + \frac{4}{3} \mu \right) s_{zz}.
\]

\(^{33}\) Note though that Eq. (107) is more complex than the simple wave equation (6.40).
We see that the numerator in Eq. (112) is nothing more than the static elastic modulus for such a uniaxial deformation, and it is recalculated into the velocity exactly as the spring constant in the 1D waves considered in Secs. 6.3-6.4 – cf. Eq. (6.42).

Formula (114) becomes especially simple in fluids, where $\mu = 0$, and the wave velocity is described by the well-known expression

$$v_1 = \left(\frac{K}{\rho}\right)^{1/2}. \quad (7.114)$$

Note, however, that for gases, with their high compressibility and temperature sensitivity, the value of $K$ participating in this formula may differ, at high frequencies, from that given by Eq. (40), because fast compressions/extensions of gas are usually adiabatic rather than isothermal. This difference is noticeable in Table 1, one of whose columns lists the values of $v_1$ for representative materials.

Now let us consider an opposite case of transverse waves with $a_x = a$, $a_z = 0$. In such a wave, the displacement vector is perpendicular to $n$, so that $\nabla \cdot q = 0$, and the second term on the right-hand side of Eq. (107) vanishes. On the contrary, the Laplace operator acting on such vector still gives the same non-zero contribution, $\nabla^2 q = n_x (\partial^2 q / \partial z^2)$, to Eq. (107) so that the equation yields

$$\rho \frac{\partial^2 q_x}{\partial t^2} = \frac{E}{2(1+v)} \frac{\partial^2 q_x}{\partial z^2}, \quad (7.115)$$

and we again get the linear dispersion relation, $\omega = v_1 k$, but with a different velocity:

$$v_1^2 = \frac{E}{2(1+v)\rho} = \frac{\mu}{\rho}. \quad (7.116)$$

We see that the speed of the transverse waves depends exclusively on the shear modulus $\mu$ of the medium.34 This is also very natural: in such waves, the particle displacements $q = n_x q$ are perpendicular to the elastic forces $dF = n_x dF$, so that the only one component $\sigma_{xz}$ of the stress tensor is involved. Also, the strain tensor $s_{ij}$ has no diagonal components, $\text{Tr} (s) = 0$, so that $\mu$ is the only elastic modulus actively participating in Hooke’s law (32). In particular, fluids cannot carry transverse waves at all (formally, their velocity (116) vanishes), because they do not resist shear deformations. For all other materials, the longitudinal waves are faster than the transverse ones.35 Indeed, for all known natural materials the Poisson ratio is positive so that the velocity ratio that follows from Eqs. (112) and (116),

$$\frac{v_1}{v_1} = \left(\frac{2 - 2\nu}{1 - 2\nu}\right)^{1/2}, \quad (7.117)$$

is above $\sqrt{2} \approx 1.4$. For the most popular construction materials, with $\nu \approx 0.3$, the ratio is about 2 – see Table 1.

---

34 Because of that, one can frequently meet the term shear waves. Note also that in contrast to the transverse waves in the simple 1D model analyzed in Chapter 6 (see Fig. 6.4a), those in a 3D continuum do not need a pre-stretch tension $\mathcal{T}$. We will return to the effect of tension in the next section.

35 Because of this difference between $v_1$ and $v_1$, in geophysics, the longitudinal waves are known as P-waves (with the letter P standing for “primary”) because they arrive at the detection site, say from an earthquake, first – before the transverse waves, called the S-waves, with S standing for “secondary”.

---

Chapter 7  
Page 27 of 38
Let me emphasize again that for both the longitudinal and the transverse waves, the dispersion relation between the wave number and frequency is linear: \( \omega = \nu k \). As was already discussed in Chapter 6, in this case of acoustic waves (or just “sound”), the phase and group velocities are equal, and waves of more complex form, consisting of several (or many) Fourier components of the type (108), preserve their form during propagation. This means that both Eqs. (111) and (115) are satisfied by solutions of the type (6.41):

\[
q_z(z,t) = f_z \left( t \pm \frac{z}{v} \right),
\]

(7.118)

where the functions \( f_z \) describe the propagating waveforms. (However, if the initial wave is a mixture, of the type (110), of the longitudinal and transverse components, then these components, propagating with different velocities, will “run from each other”.) As one may infer from the analysis of a periodic system model in Chapter 6, the wave dispersion becomes essential at very high (hypersound) frequencies where the wave number \( k \) becomes close to the reciprocal distance \( d \) between the particles of the medium (e.g., atoms or molecules), and hence the approximation of the medium as a continuum, used through this chapter, becomes invalid.

As we already know from Chapter 6, besides the velocity, the waves of each type are characterized by one more important parameter, the wave impedance \( Z \) of the continuum, for acoustic waves frequently called its acoustic impedance. Generalizing Eq. (6.46) to the 3D case, we may define the impedance as the magnitude of the ratio of the force per unit area (i.e. the corresponding component of the stress tensor) exerted by the wave, and the particles’ velocity. For the longitudinal waves,

\[
Z_1 \equiv \left| \frac{\sigma_{zz}}{\frac{\partial q_z}{\partial t}} \right| = \left| \frac{\sigma_{zz}}{s_{zz}} \frac{s_{zz}}{\frac{\partial q_z}{\partial t}} \right| = \left| \frac{\sigma_{zz}}{s_{zz}} \frac{\partial q_z}{\partial z} \right| \frac{\partial z}{\partial t}
\]

(7.119)

Plugging in Eqs. (108), (112), and (113), we get

\[
Z_1 = \left[ (K + 4\mu/3)\rho \right]^{1/2},
\]

(7.120)

in a clear analogy with the first of Eqs. (6.48). Similarly, for the transverse waves, the appropriately modified definition, \( Z_t \equiv |\sigma_{zz}/(\partial q_z/\partial z)| \), yields

\[
Z_t = (\mu\rho)^{1/2}.
\]

(7.121)

Just like in the 1D model studied in Chapter 6, one role of the wave impedance is to scale the power carried by the wave. For plane 3D waves in infinite media, with their infinite wave front area, it is more appropriate to speak about the power density, i.e. power \( \rho = dP/dA \) per unit area of the front, and characterize it by not only its magnitude,

\[
\rho = \frac{d\mathbf{F} \cdot \hat{q}}{dA},
\]

(7.122)

but also the direction of the energy propagation, that (for a plane wave in an isotropic medium) coincides with the direction of the wave vector: \( \mathbf{\rho} \equiv \rho \mathbf{n}_k \). Using the definition (18) of the stress tensor, the Cartesian components of this Umov vector\(^{36}\) may be expressed as

---

\(^{36}\) Named after Nikolai Alekseevich Umov, who introduced this concept in 1874 – ten years before a similar notion for electromagnetic waves (see, e.g., EM Sec. 6.4) was suggested by J. Poynting. In a dissipation-free,
\[ \rho_j = \sum_j \sigma_{j'} \frac{\partial q_{j'}}{\partial t}. \]  

(7.123)

Returning to plane waves propagating along axis \( z \), and acting exactly like in Sec. 6., for both the longitudinal and transverse waves we again arrive at Eq. (6.49), but for \( \rho \) rather than \( \mathcal{I} \) (due to a different definition of the wave impedance – per unit area rather than per particle chain). For the sinusoidal waves of the type (108), it yields

\[ \rho_z = \frac{\omega^2 Z}{2} \; a a^*, \]  

(7.124)

with \( Z \) being the corresponding impedance – either \( Z_l \) or \( Z_t \).

Just as in the 1D case, one more important effect, in which the notion of impedance is crucial, is wave reflection from at an interface between two media. The two boundary conditions, necessary for the analysis of these processes, may be obtained from the continuity of the vectors \( \mathbf{q} \) and \( d\mathbf{F} \). (The former condition is evident, while the latter one may be obtained by applying the 2nd Newton law to the infinitesimal volume \( dV = dAdz \), where segment \( dz \) straddles the interface.) Let us start from the simplest case of the normal incidence on a plane interface between two uniform media with different elastic moduli and mass densities. Due to the symmetry, it is evident that the longitudinal/transverse incident wave may only excite similarly polarized reflected and transferred waves. As a result, we may literally repeat the calculations of Sec. 6.4, again arriving at the fundamental relations (6.55) and (6.56), with the only replacement of \( Z \) and \( Z' \) with the corresponding values of either \( Z_l \) (120) or \( Z_t \) (121). Thus, at the normal incidence, the wave reflection is determined solely by the acoustic impedances of the media, while the sound velocities are not involved.

The situation, however, becomes more complicated at a nonzero incidence angle \( \theta^{(i)} \) (Fig. 12), where the transmitted wave is generally also refracted, i.e. propagates under a different angle, \( \theta \neq \theta^{(i)} \), beyond the interface. Moreover, at \( \theta^{(i)} \neq 0 \) the directions of particle motion (vector \( \mathbf{q} \)) and of the stress forces (vector \( d\mathbf{F} \)) in the incident wave are neither exactly parallel nor exactly perpendicular to the interface, and thus this wave serves as an actuator for the reflected and refracted waves of both polarizations – see Fig. 12, drawn for the particular case when the incident wave is transverse. The corresponding four angles, \( \theta_{t}^{(r)}, \theta_{t}^{(s)}, \theta_{l}^{(r)}, \theta_{l}^{(s)} \), may be readily related to \( \theta^{(i)} \) by the “kinematic” condition that the incident wave, as well as the reflected and refracted waves of both types, should have the same spatial distribution along the interface plane, i.e. for the interface particles participating in all five waves. According to Eq. (108), the necessary boundary condition is the equality of the tangential components (in Fig. 12, \( k_{s} \)), of all five wave vectors:

\[ k_{t} \sin \theta_{t}^{(i)} = k_{t} \sin \theta_{t}^{(r)} = k_{t} \sin \theta_{t}^{(s)} = k_{s} \equiv k_{t} \sin \theta_{t}^{(i)}. \]  

(7.125)

Since the acoustic wave vector magnitudes \( k \), at fixed frequency \( \omega \), are inversely proportional to the corresponding wave velocities, we immediately get the following relations:

\[ \theta_{i}^{(r)} = \theta_{i}^{(i)}, \quad \frac{\sin \theta_{i}^{(r)}}{v_{t}} = \frac{\sin \theta_{i}^{(s)}}{v_{t}} = \frac{\sin \theta_{i}^{(i)}}{v_{i}}, \]  

(7.126)

elastic medium, the Umov vector obeys the following continuity equation: \( \partial(\rho v^2/2 + u)/\partial t + \nabla \mathbf{\mathcal{I}} = 0 \), with \( u \) given by Eq. (52), which expresses the conservation of the total (kinetic plus potential) energy of the elastic deformation.
so that generally all four angles are different. (This is of course an analog of the well-known Snell law in optics – where, however, only transverse waves are possible.) These relations show that, just like in optics, the direction of a wave propagating into a medium with lower velocity is closer to the normal (in Fig. 12, the z-axis). In particular, this means that if \( v' > v \), the acoustic waves, at larger angles of incidence, may exhibit the effect of total internal reflection, so well known from optics\(^{37} \), when the refracted wave vanishes. In addition, Eqs. (126) show that in acoustics, the reflected longitudinal wave, with velocity \( v_l > v_t \), may vanish at sufficiently large angles of the transverse wave incidence.

![Fig. 7.12. Deriving the “kinematic” conditions (126) of the acoustic wave reflection and refraction (for the case of a transverse incident wave).](image)

All these facts automatically follow from general expressions for amplitudes of the reflected and refracted waves via the amplitude of the incident wave. These relations are straightforward to derive (again, from the continuity of the vectors \( \mathbf{q} \) and \( d\mathbf{F} \)), but since they are much bulkier than those in the electromagnetic wave theory (where they are called the Fresnel formulas\(^{38} \)), I would not have time/space to spell out and discuss them. Let me only note that, in contrast to the case of normal incidence, these relations involve eight media parameters: the impedances \( Z, Z' \), and the velocities \( v, v' \) on both sides of the interface, and for both the longitudinal and transverse waves.

There is another factor that makes boundary acoustic effects more complex. Within certain frequency ranges, interfaces (and in particular surfaces) of elastic solids may sustain so-called surface acoustic waves (SAW), in particular, the Rayleigh waves and the Love waves\(^{39} \). The main feature that distinguishes such waves from their bulk (longitudinal and transverse) counterparts, discussed above, is that the displacement amplitudes are largest at the interface and decay exponentially into the bulk of both adjacent media. The characteristic depth of this penetration is of the order of the wavelength, though not exactly equal to it.

In the Rayleigh waves, the particle displacement vector \( \mathbf{q} \) has two components: one longitudinal (and hence parallel to the interface) and another transverse (perpendicular to the interface). In contrast to the bulk waves, these components are coupled (via their interaction with the interface) and hence propagate with a single velocity \( v_R \). As a result, the trajectory of each particle in the Rayleigh wave is an

\(^{37}\) See, e.g., EM Sec. 7.5.

\(^{38}\) Their discussion may be also found in EM Sec. 7.5.

\(^{39}\) Named, respectively, after Lord Rayleigh (born J. Strutt, 1842-1919) who has theoretically predicted the very existence of surface acoustic waves, and A. Love (1863-1940).
ellipse in the plane perpendicular to the interface. A straightforward analysis of the Rayleigh waves on the surface of an elastic solid (i.e. its interface with vacuum) yields the following equation for $v_R$:

$$\left(2 - \frac{v_R^2}{v_t^2}\right)^4 = 16 \left(1 - \frac{v_R^2}{v_t^2}\right)^2 \left(1 - \frac{v_R^2}{v_t^2}\right)^2.$$  \hspace{1cm} (7.127)

According to this formula, and Eqs. (112) and (116), for realistic materials with the Poisson index between 0 and $\frac{1}{2}$, the Rayleigh waves are slightly (by 4 to 13%) slower than the bulk transverse waves – and hence substantially slower than the bulk longitudinal waves.

In contrast, the Love waves are purely transverse, with $q$ oriented parallel to the interface. However, the interaction of these waves with the interface reduces their velocity $v_L$ in comparison with that ($v_t$) of the bulk transverse waves, keeping it within the narrow interval between $v_t$ and $v_R$:

$$v_R < v_L < v_t.$$  \hspace{1cm} (7.128)

The practical importance of surface acoustic waves is that their amplitude decays very slowly with distance $r$ from their point-like source: $a \propto 1/r^{1/2}$, while any bulk waves decay much faster, as $a \propto 1/r$. (Indeed, in the latter case the power $P \propto a^2$, emitted by such source, is distributed over a spherical surface area proportional to $r^2$, while in the former case all the power goes into a thin surface circle whose length scales as $r$.) At least two areas of applications of the surface acoustic waves have to be mentioned: in geophysics (for the earthquake detection and the Earth crust seismology), and electronics (for signal processing, with a focus on frequency filtering). Unfortunately, I cannot dwell on these interesting topics and I have to refer the reader to special literature.\footnote{See, for example, K. Aki and P. Richards, \textit{Quantitative Seismology}, 2nd ed., University Science Books, 2002 and D. Morgan, \textit{Surface Acoustic Waves}, 2nd ed., Academic Press, 2007.}

### 7.8. Elastic waves in restricted geometries

From what we have discussed at the end of the last section, it should be pretty clear that generally, the propagation of acoustic waves in elastic bodies of finite size may be very complicated. There is, however, one important limit in which several important results may be readily obtained. This is the limit of (relatively) low frequencies, where the corresponding wavelength is much larger than at least one dimension of a system. Let us consider, for example, various waves that may propagate along thin rods, in this case “thin” meaning that the characteristic size $a$ of the rod’s cross-section is much smaller than not only the length of the rod, but also the wavelength $\lambda = 2\pi/k$. In this case, there is a considerable range of distances $z$ along the rod,

$$a << \Delta z << \lambda,$$  \hspace{1cm} (7.129)

in that we can neglect the material’s inertia, and apply the results of our earlier static analyses.

For example, for a longitudinal wave of stress, which is essentially a wave of periodic tensile extensions and compressions of the rod, within the range (129) we may use the static relation (42):
\[ \sigma_{zz} = E s_{zz}. \] (7.130)

For what follows, it is easier to use the general equation of elastic dynamics not in its vector form (107), but rather in the precursor, Cartesian-component form (25), with \( f_j = 0 \). For plane waves propagating along the \( z \)-axis, only one component (with \( j' \to z \)) of the sum on the right-hand side of this equation is not equal to zero, and it is reduced to
\[ \rho \frac{\partial^2 q_j}{\partial t^2} = \frac{\partial \sigma_{zz}}{\partial z}. \] (7.131)

In our current case of longitudinal waves, all components of the stress tensor but \( \sigma_{zz} \) are equal to zero. With \( \sigma_{zz} \) from Eq. (130), and using the definition \( s_{zz} = \partial q_z/\partial z \), Eq. (131) is reduced to a simple wave equation,
\[ \rho \frac{\partial^2 q_z}{\partial t^2} = E \frac{\partial^2 q_z}{\partial z^2}, \] (7.132)

which shows that the velocity of such tensile waves is
\[ v = \left( \frac{E}{\rho} \right)^{1/2}. \] (7.133)

Comparing this result with Eq. (112), we see that the tensile wave velocity, for any realistic material with a positive Poisson ratio, is lower than the velocity \( v_l \) of longitudinal waves in the bulk of the same material. The reason for this difference is simple: in thin rods, the cross-section is free to oscillate (e.g., shrink in the longitudinal extension phase of the passing wave),\(^{42}\) so that the effective force resisting the longitudinal deformation is smaller than in a border-free space. Since (as it is clearly visible from the wave equation), the scale of the force determines that of \( v \), this difference translates into slower waves in rods. Of course, as the wave frequency is increased to \( ka \sim 1 \), there is a (rather complex and cross-section-depending) crossover from Eq. (133) to Eq. (112).

Proceeding to transverse waves in rods, let us first have a look at long bending waves, for which the condition (129) is satisfied, so that the vector \( q = n_q q \) (with the \( x \)-axis being the bending direction – see Fig. 8) is virtually constant in the whole cross-section. In this case, the only component of the stress tensor contributing to the net transverse force \( F_x \) is \( \sigma_{xz} \), so that the integral of Eq. (131) over the cross-section is
\[ \rho A \frac{\partial^2 q_x}{\partial t^2} = \frac{\partial F_x}{\partial z}, \quad \text{with} \quad F_x = \int_A \sigma_{xz} d^2r. \] (7.134)

Now, if Eq. (129) is satisfied, we again may use the static local relations (75)-(77), with all derivatives \( d/dz \) duly replaced with their partial form \( \partial/\partial z \), to express the force \( F_x \) via the bending deformation \( q_x \). Plugging these relations into each other one by one, we arrive at a rather unusual differential equation
\[ \rho A \frac{\partial^2 q_x}{\partial t^2} = -EI_y \frac{\partial^4 q_x}{\partial z^4}. \] (7.135)

\(^{42}\) For this reason, the tensile waves can be called longitudinal only in a limited sense: while the stress wave is purely longitudinal: \( \sigma_{xx} = \sigma_{yy} = 0 \), the strain wave is not: \( s_{xx} = s_{yy} = -\alpha_{zz} \neq 0 \), i.e. \( q(r, t) \neq n_x q \).
Looking for its solution in the form of a sinusoidal wave (108), we get the following nonlinear dispersion relation:\(^{43}\)

\[
\omega = \left( \frac{EI_y}{\rho A} \right)^{1/2} k^2. \tag{7.136}
\]

Such relation means that the bending waves are not acoustic at any frequency, and cannot be characterized by a single velocity that would be valid for all wave numbers \(k\), i.e. for all spatial Fourier components of a waveform. According to our discussion in Sec. 6.3, such strongly dispersive systems cannot pass non-sinusoidal waveforms too far without changing their waveform rather considerably.

This situation changes, however, if the rod is pre-stretched with a tension force \(\mathcal{T}\) – just as in the discrete 1D model that was analyzed in Sec. 6.3. The calculation of the effect of this force is essentially similar; let us repeat it for the continuous case, for a minute neglecting the bending stress – see Fig. 13.

\[\begin{align*}
\varphi_y(z) &\quad \mathcal{T}(z + dz) \\
-\mathcal{T}(z) &\quad \varphi_y(z + dz) \\
q_x &\quad q_x + dq_x \\
z &\quad z + dz
\end{align*}\]

Fig. 7.13. Additional forces in a thin rod (“string”), due to the background tension \(\mathcal{T}\).

Still sticking to the limit of small angles \(\varphi\), the additional vertical component \(d\mathcal{T}_x\) of the net force acting on a small rod fragment of length \(dz\) is \(\mathcal{T}_x(z - dz) - \mathcal{T}_x(z) = \mathcal{T} \varphi_y(z + dz) - \mathcal{T} \varphi_y(z) \approx \mathcal{T} (\partial \varphi_y / \partial z) dz\), so that \(\partial F_x / \partial z = \mathcal{T} (\partial \varphi_y / \partial z)\). With the geometric relation (77) in its partial-derivative form \(\partial q_y / \partial z = \varphi_y\), this additional term becomes \(\mathcal{T} (\partial^2 q_y / \partial z^2)\). Now adding it to the right-hand side of Eq. (135), we get the following dispersion relation

\[
\omega^2 = \frac{1}{\rho A} \left( EI_y k^4 + \mathcal{T}^2 \right). \tag{7.137}
\]

Since the product \(\rho A\) in the denominator of this expression is just the rod’s mass per unit length (which was denoted \(\mu\) in Chapter 6), at low \(k\) (and hence low frequencies), this expression is reduced to the linear dispersion law, with the velocity given by Eq. (6.43):

\[
v = \left( \frac{\mathcal{T}}{\rho A} \right)^{1/2}. \tag{7.138}
\]

So Eq. (137) describes a smooth crossover from the “guitar-string” acoustic waves to the highly dispersive bending waves (136).

\(^{43}\) Note that since the “moment of inertia” \(I_y\), defined by Eq. (70), may depend on the bending direction (unless the cross-section is sufficiently symmetric), the dispersion relation (136) may give different results for different directions of the bending wave polarization.
Now let us consider another type of transverse waves in thin rods – the so-called *torsional waves*, which are essentially the dynamic propagation of the torsional deformation discussed in Sec. 6. The easiest way to describe these waves, again within the limits (129), is to write the equation of rotation of a small segment $dz$ of the rod about the $z$-axis, passing through the “center of mass” of its cross-section, under the difference of torques $\tau = n_z \tau_z$ applied on its ends – see Fig. 10:

$$\rho I_z dz \frac{\partial^2 \varphi_z}{\partial t^2} = d \tau_z,$$

(7.139)

where $I_z$ is the “moment of inertia” defined by Eq. (91), which now, after its multiplication by $\rho dz$, i.e. by the mass per unit area, has turned into the genuine moment of inertia of a $dz$-thick slice of the rod. Dividing both sides of Eq. (139) by $dz$, and using the static local relation (84), $\tau_z = C \kappa = C (\partial \varphi_z / \partial z)$, we get the following differential equation

$$\rho I_z \frac{\partial^2 \varphi_z}{\partial t^2} = C \frac{\partial^2 \varphi_z}{\partial z^2}.$$

(7.140)

Just as Eqs. (111), (115), and (132), this equation describes an acoustic (dispersion-free) wave, which propagates with the following frequency-independent velocity

$$v = \left( \frac{C}{\rho I_z} \right)^{1/2}.$$

(7.141)

As we have seen in Sec. 6, for rods with axially-symmetric cross-sections, the torsional rigidity $C$ is described by the simple relation (89), $C = \mu I_z$, so that Eq. (141) is reduced to Eq. (116) for the transverse waves in infinite media. The reason for this similarity is simple: in a torsional wave, particles oscillate along small arcs (Fig. 14a), so that if the rod’s cross-section is round, its surface is stress-free, and does not perturb or modify the motion in any way, and hence does not affect the transverse velocity.

This fact raises an interesting issue of the relation between the torsional and *circularly-polarized* waves. Indeed, in Sec. 7, I have not emphasized enough that Eq. (116) is valid for a transverse wave polarized in any direction perpendicular to vector $k$ (in our notation, directed along the $z$-axis). In particular, this means that such waves are doubly-degenerate: any isotropic elastic continuum can carry simultaneously two non-interacting transverse waves propagating in the same direction with the same velocity (116), with two mutually perpendicular linear polarizations (directions of the vector $a_c$), for
example, directed along the $x$- and $y$-axes.\textsuperscript{44} If both waves are sinusoidal (108), with the same frequency, each point of the medium participates in two simultaneous sinusoidal motions within the $[x, y]$ plane:

$$q_x = \text{Re} \left[ a_x e^{i(kz - \omega t)} \right] = A_x \cos \Psi, \quad q_y = \text{Re} \left[ a_y e^{i(kz - \omega t)} \right] = A_y \cos(\Psi + \varphi),$$

(7.142)

where $\Psi \equiv kz - \omega t + \varphi_x$, and $\varphi \equiv \varphi_y - \varphi_x$. Basic geometry tells us that the trajectory of such a motion on the $[x, y]$ plane is an ellipse (Fig. 15), so that such waves are called \textit{elliptically polarized}. The most important particular cases of such polarization are:

(i) $\varphi = 0$ or $\pi$: a \textit{linearly-polarized} wave, with vector $a$ is directed at angle $\theta = \tan^{-1}(A_y/A_x)$ relatively the axis $x$; and

(ii) $\varphi = \pm \pi/2$ and $A_x = A_y$: two possible \textit{circularly-polarized} waves, with the right or left polarization, respectively.\textsuperscript{45}

Now comparing the trajectories of particles in the torsional wave in a thin round rod (or pipe) and the circularly-polarized wave in a broad sample (Fig. 14), we see that, despite the same wave propagation velocity, these transverse waves are rather different. In the former case (Fig. 14a) each particle moves back and forth along an arc, with the arc length different for different particles (and vanishing at the rod’s center), so that the waves are \textit{not} plane. On the other hand, in a circularly polarized wave, all particles move along similar, circular trajectories, so that such wave \textit{is} plane.

To conclude this chapter, let me briefly mention the opposite limit, when the size of the body, from whose boundary the waves are completely reflected,\textsuperscript{46} is much larger than the wavelength. In this case, the waves propagate almost as in an infinite 3D continuum (which was analyzed in Sec. 7), and the most important new effect is the finite numbers of wave modes in the body. Repeating the 1D analysis at the end of Sec. 6.5, for each dimension of a 3D cuboid of volume $V = l_1l_2l_3$, and taking into account that the numbers $k_n$ in each of 3 dimensions are independent, we get the following generalization of Eq.

---

\textsuperscript{44} As was shown in Sec. 6.3, this is true even in the simple 1D model shown in Fig. 6.4a.

\textsuperscript{45} The circularly polarized waves play an important role in quantum mechanics, where they may be most naturally quantized, with their elementary excitations (in the case of mechanical waves we are discussing, called \textit{phonons}) having either positive or negative angular momentum $L_z = \pm \hbar$.

\textsuperscript{46} For acoustic waves, such a condition is easy to implement. Indeed, from Sec. 7 we already know that the strong inequality of wave impedances $Z$ is sufficient for such reflection. The numbers of Table 1 show that, for example, the impedance of a longitudinal wave in a typical metal (say, steel) is almost two orders of magnitude higher than that in air, ensuring their virtually full reflection from the surface.
\[(6.75)\) for the number \(\Delta N\) of different traveling waves with wave vectors within a relatively small volume \(d^3k\) of the wave vector space:

\[
dN = g \frac{V}{(2\pi)^3} d^3k \gg 1, \quad \text{for } \frac{1}{V} \ll d^3k \ll k^3, \tag{7.143}
\]

where \(k \gg 1/l_{1,2,3}\) is the center of this volume, and \(g\) is the number of different possible wave modes with the same wave vector \(k\). For the mechanical waves analyzed above, with one longitudinal mode, and two transverse modes with different polarizations, \(g = 3\).

Note that since the derivation of Eqs. (6.75) and (143) does not use other properties of the waves (in particular, their dispersion relations), the mode counting rule is ubiquitous in physics, being valid, in particular, for electromagnetic waves (where \(g = 2\)) and quantum “de Broglie waves” (i.e. wavefunctions), whose degeneracy factor \(g\) is usually determined by the particle’s spin.\(^{47}\)

### 7.9. Exercise problems

**7.1.** A uniform thin sheet of an isotropic, elastic material, of thickness \(t\) and area \(A \gg t^2\), is compressed by two plane, parallel, broad, rigid surfaces – see the figure on the right. Assuming no slippage between the sheet and the surfaces, calculate the relative compression \((-\Delta t/t)\) as a function of the compressing force. Compare the result with that for the tensile stress, calculated in Sec. 7.

![Exercise problem 7.1](image)

**7.2.** Two opposite edges of a thin, very wide sheet of an isotropic, elastic material have been clamped in two rigid, plane, parallel walls that are pulled apart with force \(F\), along the sheet’s length \(l\). Find the relative extension \(\Delta l/l\) of the sheet in the direction of the force, and its relative compression \(\Delta t/t\) in the perpendicular direction, and compare the results with Eqs. (7.45)-(7.46) for the tensile stress and the solution of the previous problem.

**7.3.** Calculate the radial extension \(\Delta R\) of a thin, long, round cylindrical pipe, due to its rotation with a constant angular velocity \(\omega\) about its symmetry axis (see the figure on the right), in terms of the elastic moduli \(E\) and \(\nu\). The external pressure both inside and outside the pipe is negligible.

![Exercise problem 7.3](image)

**7.4.** A long, uniform rail with the cross-section shown in the figure on the right, is being bent with the same (small) torque twice: first within the \(xz\)-plane and then within the \(yz\)-plane. Assuming that \(t \ll l\), find the ratio of the rail bending deformations in these two cases.

\(^{47}\) See, e.g., EM Secs. 7.8 and QM Sec. 1.7.
7.5. Two thin rods of the same length and mass are made of the same elastic, isotropic material. The cross-section of one of them is a circle, while the other one is an equilateral triangle – see the figure on the right. Which of the rods is stiffer for bending along its length? Quantify the relation. Does the result depend on the bending plane orientation?

7.6. A thin, elastic, uniform, initially straight beam is placed on two point supports at the same height – see the figure on the right. What support placement minimizes the largest deviation of the beam from the horizontal baseline, under its own weight?

*Hint:* An approximate answer (with an accuracy better than 1%) is acceptable.

7.7. Calculate the largest longitudinal compression force \(T\) that may be withstood by a thin, straight, elastic rod without bucking (see the figure on the right) for two shown cases:

(i) the rod’s ends are clamped, and

(ii) the rod is free to turn about the support points.

7.8. An elastic, light, thin poll with a square cross-section of area \(A = a \times a\), had been firmly dug into the ground in the vertical position, sticking out by height \(h \gg a\). What largest compact mass \(M\) may be placed straight on the top of the poll without the stability loss?

7.9. Calculate the potential energy of a small and slowly changing, but otherwise arbitrary bending deformation of a uniform, elastic, initially straight rod. Can the result be used to derive the dispersion relation (136)?

7.10. Calculate the torsional rigidity of a thin, uniform rod whose cross-section is an ellipse with semi-axes \(a\) and \(b\).

7.11. Calculate the potential energy of a small but otherwise arbitrary torsional deformation \(\varphi(z)\) of a uniform, straight, elastic rod.

7.12. Calculate the spring constant \(\kappa \equiv dF/dl\) of a coil spring made of a uniform, elastic wire, with circular cross-section of diameter \(d\), wound as a dense round spiral of \(N \gg 1\) turns of radius \(R \gg d\) – see the figure on the right.
7.13. The coil spring, described in the previous problem, is now used as what is sometimes called the torsion spring – see the figure on the right. Find the corresponding spring constant \( d\tau/d\varphi \), where \( \tau \) is the torque of the external forces \( \mathbf{F} \) relative to the center of the coil (point 0).

7.14. Use Eqs. (99) and (100) to recast Eq. (101b) for the torsional rigidity \( C \) of a thin rod into the form given by Eq. (101c).

7.15. Generalize Eq. (101b) to the case of rods with more than one cross-section’s boundary. Use the result to calculate the torsional rigidity of a thin round pipe, and compare it with Eq. (91).

7.16. A long steel wire has a circular cross-section with a 3-mm diameter, and is pre-stretched with a constant force of 10 N. Which of the longitudinal and transverse waves with frequency 1 kHz has the largest group velocity in the wire? Accept the following parameters for the steel (see Table 1): \( E = 170 \text{ GPa}, \ \nu = 0.30, \ \rho = 7.8 \text{ g/cm}^3 \).

7.17. Define and calculate the wave impedances for (i) tensile and (ii) torsional waves in a thin rod, appropriate in the long-wave limit. Use the results to calculate the fraction of each wave’s power \( P \) reflected from a firm connection of a long rod with a round cross-section to a similar rod, but with a twice smaller diameter – see the figure on the right.
Chapter 8. Fluid Mechanics

This chapter describes the basic notions of fluid mechanics, discusses a few core problems of statics and dynamics of ideal and viscous fluids, and gives a very brief, rather superficial review of such a complicated phenomenon as turbulence. In addition, the viscous fluid flow discussion is used as a platform for an elementary introduction to numerical methods of the partial differential equation solution – whose importance extends well beyond this particular field.

8.1. Hydrostatics

The mechanics of fluids (defined as the materials that cannot keep their geometric form on their own, and include both liquids and gases) is both more simple and more complex than that of the elastic solids, with the simplicity falling squarely to the domain of statics. Indeed, fluids, by definition, cannot resist static shear deformations. There are two ways to express this fact. First, we can formally take the shear modulus $\mu$, describing this resistance, to equal zero. Then the Hooke’s law (7.32) shows that the stress tensor is diagonal:

$$\sigma_{ij} = \sigma_{ii} \delta_{ij}. \quad (8.1)$$

Alternatively, the same conclusion may be reached just by looking at the stress tensor definition (7.19) and/or Fig. 7.3, and saying that in the absence of shear stress, the elementary interface $dF$ has to be perpendicular to the area element $dA$, i.e. parallel to the vector $dA$.

Moreover, in fluids at equilibrium, all three diagonal components $\sigma_{ii}$ of the stress tensor have to be equal. To prove that, it is sufficient to single out (mentally rather than physically), from a static fluid, a small volume in the shape of a right prism, with mutually perpendicular faces normal to the two directions we are interested in – in Fig. 1, along the $x$- and $y$-axes.

The prism is in equilibrium if each Cartesian component of the vector of the total force exerted on all its faces equals zero. For the $x$-component this balance may be expressed as $\sigma_{xx} dA_x - (\sigma_{ad} dA) \cos \alpha = 0$. However, from the geometry (Fig. 1), $dA_x = dA \cos \alpha$, so that the above expression yields $\sigma_{xx} = \sigma_{yy}$. A similar argument for the $y$-component gives $\sigma_{yy} = \sigma_{yy}$ so that $\sigma_{xx} = \sigma_{yy}$. Changing the orientation of the prism, we can get such equalities for any pair of diagonal components of the stress tensor, $\sigma_{ii}$, so that all three of them have to be equal.

---

1 It is often called hydrostatics because water has always been the most important liquid for the human race and hence for science and engineering.
This common diagonal element of the stress matrix is usually denoted as \(-P\), because in the vast majority of cases, the parameter \(P\), called *pressure*, is positive. Thus we arrive at the key relation (which has already been mentioned in Sec. 7.2):

\[
\sigma_{jj'} = -P \delta_{jj'}.
\]  

(8.2) Pressure

In the absence of bulk forces, pressure should be constant through the volume of fluid, due to the translational symmetry. Let us see how this result is affected by bulk forces. With the simple stress tensor (2), the general condition of equilibrium of a continuous medium, expressed by Eq. (7.25) with the left-hand side equal to zero, becomes

\[
-\frac{\partial P}{\partial r_j} + f_j = 0,
\]

(8.3) and may be re-written in the following convenient vector form:

\[
-\nabla P + \mathbf{f} = 0.
\]

(8.4) In the simplest case of a heavy fluid with mass density \(\rho\), in a uniform gravity field \(\mathbf{f} = \rho \mathbf{g}\), the equation of equilibrium becomes,

\[
-\nabla P + \rho \mathbf{g} = 0,
\]

(8.5) with only one nonzero component (vertical, near the Earth surface). If, in addition, the fluid may be considered *incompressible,* with its density \(\rho\) constant,\(^2\) this equation may be readily integrated over the vertical coordinate (say, \(y\)) to give the so-called *Pascal equation:*\(^3\)

\[
P + \rho g y = \text{const},
\]

(8.6) Pascal equation

where the direction of the \(y\)-axis is taken opposite to that of vector \(\mathbf{g}\).

Two manifestations of this key equation are well known. The first one is the fact that in interconnected vessels filled with a fluid, its pressure is equal at all points at the same height \((y)\), regardless of the vessel shape, provided that the fluid is in equilibrium. The second result is the *buoyant force* \(\mathbf{F}_b\) exerted by a liquid on a (possibly, partly) submerged body, i.e. the vector sum of the elementary pressure forces \(d\mathbf{F} = P d\mathbf{A}\) exerted on all elementary areas \(dA\) of the submerged part of the body’s surface – see Fig. 2. According to Eq. (6), with the constant equal to zero (corresponding to zero pressure at the liquid’s surface taken for \(y = 0\), see Fig. 2a), the vertical component of this elementary force is

\[
dF_y = dF \cos \varphi = P d\mathbf{A} \cos \varphi = -\rho g y \cos \varphi dA = -\rho g y dA_h.
\]

(8.7) where \(dA_h = \cos \varphi dA\) is the horizontal footprint (say, \(dx dz\)) of the elementary area \(dA\). Now integrating this relation over all the surface, we get the total vertical buoyant force:\(^4\)

---

\(^2\) As was discussed in Sec. 7.3 in the context of Table 7.1, this is an excellent approximation, for example, for human-scale experiments with water.

\(^3\) The equation, and the SI unit of pressure \(1 \text{ Pa} = 1 \text{N/m}^2\), are named after Blaise Pascal (1623-1662) who has not only pioneered hydrostatics, but also invented the first mechanical calculator, and made several other important contributions to mathematics – and to Christian philosophy!
where $V$ is the volume of the submerged part of the body’s volume, while $\rho$ is the liquid’s density, so that by magnitude, $F_b$ equals the weight of the liquid which would fill the submerged volume.

This well-known Archimedes principle may be proved even more simply using the following argument: the fluid’s pressure forces, and hence the resulting buoyant force, cannot depend on what is inside the body’s volume. Hence $F_b$ would be the same if we filled the volume $V$ in question with a fluid similar to the surrounding one. But in this case, the surface does not play any role, and the fluid should be still in equilibrium, so that both forces acting on it, the buoyant force $F_b$ and the internal liquid’s weight $mg = \rho Vg$, have to be equal and opposite, thus proving Eq. (8) again.

Despite the simplicity of the Archimedes principle, its different, erroneous formulations, such as “The buoyant force’s magnitude is equal to the weight of the displaced liquid” [WRONG!] creep from one undergraduate textbook to another, leading to application errors. A typical example is shown in Fig. 2b, where a solid vertical cylinder with the base area $A$ is pressed into a liquid inside a container of comparable size, pushing the liquid’s level up. The correct answer for the buoyant force, following from Eq. (8), is

$$F_b = \rho g V = \rho g A(a + b), \quad (8.9a)$$

because the volume $V$ of the submerged part of the cylinder is evidently $A(a + b)$. But the wrong formulation cited above, using the term displaced liquid, would give a different answer:

$$F_b = \rho g V_{\text{displaced}} = \rho g Ab \quad \text{[WRONG!]} \quad (8.9b)$$

(The latter result is correct only asymptotically, in the limit of a very large container.)

Another frequent error in hydrostatics concerns the angular stability of a freely floating body – the problem evidently of vital importance for the boat/ship design. It is sometimes claimed that the body is stable only if the so-called buoyancy center, the effective point of buoyant force application (in Fig. 3, point B), is above the center of mass (0) of the whole floating body.\(^5\) However, as Fig. 3 shows, this is unnecessary; indeed in the shown case, point B (which is just the center of mass the liquid would have

---

\(^4\) The force is strictly vertical, because the horizontal components of the elementary forces $dF$ exerted on opposite elementary areas $dA$, at the same height $y$, cancel.

\(^5\) Please note the crucial difference between the whole body and that of its submerged part.
in the submerged part) is below point 0, even at a small tilt. Still, in this case, the torque created by the pair of forces \( F_b \) and \( mg \) tries to return the body to the equilibrium position, which is therefore stable. As Fig. 3 shows, the actual condition of the angular stability may be expressed as the requirement for point M (in shipbuilding, called the metacenter of the ship’s hull) to be above the ship’s center of mass 0.6

![Fig. 8.3. Angular stability of a floating body.](image-url)

To conclude this section, let me note that the integration of Eq. (4) may be more complex in the case if the bulk forces \( f \) depend on position,7 and/or if the fluid is substantially compressible. In the latter case, Eq. (4) has to be solved together with the medium-specific equation of state \( \rho = \rho(P) \) describing its compressibility law – whose example is given by Eq. (7.38) for ideal gases: \( \rho \equiv mN/V = m\mathcal{P}/k_B T \), where \( m \) is the mass of one gas molecule.

### 8.2. Surface tension effects

Besides the bulk (volume-distributed) forces, one more possible source of pressure is surface tension. This effect results from the difference between the potential energy of atomic interactions on the interface between two different fluids and that in their bulks, and thus may be described by an additional potential energy

\[
U_i = \gamma A ,
\]

where \( A \) is the interface area, and \( \gamma \) is called the surface tension constant – or just the “surface tension”. For a stable interface of any two fluids, \( \gamma \) is always positive.8 For surfaces of typical liquids (or their interfaces with air), at room temperature, the surface tension equals a few \( 10^{-2} \) J/m², corresponding to the potential energy \( U_i \) of a few \( 10^{-2} \) eV per surface molecule – i.e. just a fraction of the full binding (or “cohesive”) energy of the same liquid, which is typically of the order of \( 10^{-1} \) eV per molecule.

In the absence of other forces, the surface tension makes a liquid drop spherical to minimize its surface area \( A \) at a fixed volume. For the analysis of the surface tension effects for more complex geometries, and in the presence of other forces, it is convenient to reduce it to a certain additional effective pressure drop \( \Delta P_{ef} \) at the interface. To calculate \( \Delta P_{ef} \), let us consider the condition of

---

6 A small tilt of the body leads to a small lateral displacement of point B, but does not affect the position of the metacenter M.

7 A simple example of such a problem is given by the fluid equilibrium in a container rotating with a constant angular velocity \( \omega \). If we solve such a problem in a reference frame rotating together with the container, the real bulk forces should be complemented by the centrifugal “force” (4.93), depending on \( r \).

8 Indeed, if the \( \gamma \) of the interface of certain two fluids is negative, it self-reconfigures to decrease \( U_i \), i.e. increase \( |U_i| \), by increasing the interface area, i.e. fragments the system into a macroscopically-uniform solution.
equilibrium of a small part $dA$ of a smooth interface between two fluids (Fig. 2), in the absence of bulk forces.

If the pressures $P_{1,2}$ on the two sides of the interface are different, the work of stress forces on fluid 1 at a small virtual displacement $\delta r = n \delta \hat{r}$ of the interface (where $n = dA/dA$ is the unit vector normal to the interface) equals

$$
\delta W = dA \delta r (P_1 - P_2).
$$

(8.11)

For equilibrium, this work has to be compensated by an equal change of the interface energy, $\delta U_1 = \gamma \delta (dA)$. Differential geometry tells us that in the linear approximation in $\delta r$, the relative change of the elementary surface area, corresponding to a fixed solid angle $d\Omega$, may be expressed as

$$
\frac{\delta (dA)}{dA} = \frac{\delta r}{R_1} + \frac{\delta r}{R_2},
$$

(8.12)

where $R_{1,2}$ are the so-called principal radii of the interface curvature.\(^{10}\) Combining Eqs. (10)-(12), we get the Young-Laplace formula\(^{11}\)

$$
P_1 - P_2 = \Delta P_{\text{ef}} \equiv \gamma \left( \frac{1}{R_1} + \frac{1}{R_2} \right).
$$

(8.13)

In particular, this formula shows that the additional pressure created by surface tension inside a spherical drop of a liquid, of radius $R$, equals \(2\gamma R\), i.e. decreases with $R$. In contrast, according to Eqs. (5)-(6), the effects of bulk forces, for example gravity, grow as $\rho g R$. The comparison of these two pressure components shows that if the drop radius (or more generally, the characteristic linear size of a fluid sample) is much larger than the so-called capillary length.

---

9 This equality follows from the general relation (7.30), with the stress tensor elements expressed by Eq. (2), but in this simple case of the net stress force $d\mathbf{F} = (P_1 - P_2)dA$ parallel to the interface element vector $dA$, it may be even more simply obtained just from the definition of work: $\delta W = d\mathbf{F} \cdot \delta \hat{r}$ at the virtual displacement $\delta r = n \delta \hat{r}$.

10 This general formula may be verified by elementary means for a sphere of radius $r$ (for which $R_1 = R_2 = r$ and $dA = r^2 d\Omega$), so that $\delta (dA)/dA = (r^2)/r^2 = \delta \hat{r}/r$, and for a round cylindrical interface of radius $R$ (for which $R_1 = r$, $R_2 = \infty$, and $dA = rd\phi dz$, so that $\delta (dA)/dA = \delta \hat{r}/r$). For more on curvature, see, for example, M. do Camo, Differential Geometry of Curves and Surfaces, 2nd ed., Dover, 2016.

11 This result (not to be confused with Eq. (15), called Young’s equation) was derived in 1806 by Pierre-Simon Laplace (of the Laplace operator/equation fame) on the basis of the first analysis of the surface tension effects by Thomas Young (yes, the same Young who performed the famous two-slit experiment with light!) a year earlier.
the surface tension may be safely ignored – as will be done in all following sections of this chapter, besides a brief discussion at the end of Sec. 4. For the water surface, or more exactly its interface with air at ambient conditions, \( \gamma \approx 0.073 \text{ J/m}^2 \) (i.e. \( \text{N/m} \)), while \( \rho \approx 1,000 \text{ kg/m}^3 \), so that \( a_c \approx 4 \text{ mm} \).

On the other hand, in very narrow tubes, such as blood capillary vessels with radius \( a \approx 1 \mu\text{m} \), i.e. \( a << a_c \), the surface tension effects are very important. The key notion for the analysis of these effects is the contact angle \( \theta_c \) (also called the “wetting angle”) at an equilibrium edge of a liquid wetting a solid – see Fig. 5.

According to its definition (10), the constant \( \gamma \) may be interpreted as a force (per unit length of the interface boundary) directed normally to the boundary, and “trying” to reduce the interface area. As a result, the balance of horizontal components of the three such forces, shown in Fig. 5a, immediately yields the Young’s equation

\[
\gamma_{\text{sl}} + \gamma_{\text{lg}} \cos \theta_c = \gamma_{\text{sg}},
\]

where the indices of constants \( \gamma \) correspond to three possible interfaces between the liquid, solid, and gas. For the so-called hydrophilic surfaces that “like to be wet” by a particular liquid (not necessarily water), meaning that \( \gamma_{\text{sl}} < \gamma_{\text{sg}} \), this relation yields \( \cos \theta_c > 0 \), i.e. \( \theta_c < \pi/2 \) – the situation shown in Fig. 5a. On the other hand, for hydrophobic surfaces with \( \gamma_{\text{sl}} > \gamma_{\text{sg}} \), Eq. (15) yields larger contact angles, \( \theta_c > \pi/2 \) – see Fig. 5b.

Let us use this notion to solve the simplest and perhaps the most practically important problem of this field – find the height \( h \) of the fluid column lifted by the surface tension forces in a narrow vertical tube made of a hydrophilic material, assuming its internal surface to be a round cylinder of radius \( a \) – see Fig. 6. Inside an incompressible fluid, pressure drops with height according to the Pascal equation (6), so that just below the surface, \( P \approx P_0 - \rho gh \), where \( P_0 \) is the background (e.g., atmospheric) pressure. This means that at \( a << h \) the pressure variation along the concave surface (called the meniscus) of the liquid is negligible, so that according to the Young-Poisson equation (13), the sum \( (1/R_1 + 1/R_2) \) has to be virtually constant along the surface. Due to the axial symmetry of the problem, this means that the surface has to be a part of a sphere. From the contact angle definition, the radius \( R \) of the sphere is equal to \( a/\cos \theta_c \) – see Fig. 6. Plugging this relation into Eq. (3) with \( P_1 - P_2 = \rho gh \), we get the following result for \( h \):

\[
\rho gh = \frac{2\gamma \cos \theta_c}{a}. \tag{8.16a}
\]
In hindsight, this result might be obtained more directly – by requiring the total weight $\rho g V = \rho g (\pi a^2 h)$ of the lifted liquid’s column to be equal to the vertical component $F \cos \theta_c$ of the full surface tension force $F = \gamma p$, acting on the perimeter $p = 2\pi a$ of the meniscus. Using the definition (11) of the capillary length $a_c$, Eq. (16a) may be represented as the so-called Jurin rule:

$$h = \frac{a_c^2}{a} \cos \theta_c \leq \frac{a_c^2}{a};$$

(8.16b)

according to our initial assumption $h \gg a$, Eq. (16) is only valid for narrow tubes, with radius $a \ll a_c$.

![Fig. 8.6. Liquid’s rise in a vertical capillary tube.](image)

This capillary rise is the basic mechanism of lifting water with nutrients from roots to the branches and leaves of plants, so that the tallest tree heights correspond to the Jurin rule (16), with $\cos \theta_c \approx 1$, and the pore radius $a$ limited from below by a few microns, because of the viscosity effects restricting the fluid discharge – see Sec. 5 below.

### 8.3. Kinematics

In contrast to the stress tensor, which is useful and simple – see Eq. (2), the strain tensor is not a very useful notion in fluid mechanics. Indeed, besides a very few situations, typical problems of this field involve fluid flow, i.e. a state when the velocity of fluid particles has some nonzero time average. This means that the trajectory of each particle is a long line, and the notion of its displacement $\mathbf{q}$ becomes impracticable. However, particle’s velocity $\mathbf{v} = d\mathbf{q}/dt$ remains a very useful notion, especially if it is considered as a function of the observation point $\mathbf{r}$ and (generally) time $t$. In an important class of fluid dynamics problem, the so-called stationary (or “steady”, or “static”) flow, the velocity defined in this way does not depend on time, $\mathbf{v} = \mathbf{v}(\mathbf{r})$.

There is, however, a price to pay for the convenience of this notion: namely, due to the difference between the vectors $\mathbf{q}$ and $\mathbf{r}$, particle’s acceleration $\mathbf{a} = d^2 \mathbf{q} / dt^2$ (that participates, in particular, in the 2nd Newton law) cannot be calculated just as the time derivative of the velocity $\mathbf{v}(\mathbf{r}, t)$. This fact is evident, for example, for the static flow case, in which the acceleration of individual fluid particles may be very significant even if $\mathbf{v}(\mathbf{r})$ does not depend on time – just think about the acceleration of a drop of

---

12 One of them is sound propagation, where the particle displacements $\mathbf{q}$ are typically small, so that results of Sec. 7.7 are applicable. As a reminder, they show that in fluids, with $\mu = 0$, the transverse sound cannot propagate, while the longitudinal sound can – see Eq. (7.114).
water flowing over the Niagara Falls’ rim, first accelerating fast and then virtually stopping below, while the water velocity \( v \) at every particular point, as measured from a bank-based reference frame, is nearly constant. Thus the main task of fluid kinematics is to express \( \mathbf{a} \) via \( \mathbf{v}(\mathbf{r},t) \); let us do this.

Since each Cartesian component \( v_j \) of the velocity \( \mathbf{v} \) has to be considered as a function of four independent scalar variables: three Cartesian components \( r_j \) of the vector \( \mathbf{r} \) and time \( t \), its full time derivative may be represented as

\[
\frac{dv_j}{dt} = \frac{\partial v_j}{\partial t} + \sum_{j=1}^{3} v_j \frac{\partial r_j}{\partial t}.
\]  

Let us apply this general relation to a specific set of infinitesimal changes \( \{dr_1, dr_2, dr_3\} \) that follows a small displacement \( dq \) of a certain particular particle of the fluid, \( d\mathbf{r} = dq = v dt \), i.e.

\[
\frac{dv_j}{dt} = v_j dt.
\]  

In this case, \( dv_j/dt \) is the \( j \)th component \( a_j \) of the particle’s acceleration \( \mathbf{a} \), so that Eq. (17) yields the following key relation of fluid kinematics:

\[
a_j = \frac{\partial v_j}{\partial t} + \sum_{j=1}^{3} v_j \frac{\partial r_j}{\partial t}.
\]  

Using the del operator \( \nabla \), this result may be rewritten in the following compact vector form:

\[
\mathbf{a} = \frac{\partial \mathbf{v}}{\partial t} + (\mathbf{v} \cdot \nabla)\mathbf{v}.
\]  

This relation already signals the main technical problem of the fluid dynamics: many equations involving particle’s acceleration are nonlinear in velocity, excluding such a powerful tool as the linear superposition principle (which was used so frequently in the previous chapters of this course) from the applicable mathematical arsenal.

One more basic relation of the fluid kinematics is the so-called continuity equation, which is essentially just the differential version of the mass conservation law. Let us mark, inside a fluid flow, an arbitrary volume \( V \) limited by a stationary (time-independent) surface \( S \). The total mass of the fluid inside the volume may change only due to its flow through the boundary:

\[
\frac{dM}{dt} \equiv \frac{d}{dt} \int_v \rho \, d^3r = -\int_S \rho v_n d^2r \equiv -\int_S \rho \mathbf{v} \cdot d\mathbf{A},
\]  

where the elementary area vector \( d\mathbf{A} \) is defined just as in Sec. 7.2 – see Fig. 7. Now using the same divergence theorem that has been used several times in this course, the surface integral in Eq. (20a) may be transformed into the integral of \( \nabla(\rho \mathbf{v}) \) over the volume \( V \), so that this relation may be rewritten as

\[13\] Note that the operator relation \( d/dt = \partial/\partial t + (\mathbf{v} \cdot \nabla) \) is applicable to an arbitrary (scalar or vector) function; it is frequently called the convective derivative. (Alternative adjectives, such as “Lagrangian”, “substantial”, or “Stokes”, are sometimes used for this derivative as well.) The relation has numerous applications well beyond the fluid dynamics – see, e.g., EM Chapter 9 and QM Chapter 1.

\[14\] If the reader still needs a reminder, see MA Eq. (12.1).
where the vector \( \mathbf{j} = \rho \mathbf{v} \) is called either the mass flux density (or the “mass current”). Since Eq. (20b) is valid for an arbitrary stationary volume \( V \), the function under the integral has to vanish at any point:

\[
\int \left( \frac{\partial \rho}{\partial t} + \nabla \cdot \mathbf{j} \right) d^3 r = 0, \tag{8.20b}
\]

Note that this continuity equation is valid not only for mass, but also for other conserved physics quantities (e.g., the electric charge, probability, etc.), with the proper re-definition of \( \rho \) and \( \mathbf{j} \).15

### 8.4. Dynamics: Ideal fluids

Let us start our discussion of fluid dynamics from the simplest case when the stress tensor obeys Eq. (2) even in motion. Physically, this means that the fluid viscosity effects, leading to mechanical energy loss, are negligible. (The conditions of this assumption will be discussed in the next section.) Then the equation of motion of such an ideal fluid (essentially the 2\textsuperscript{nd} Newton law for its unit volume) may be obtained from Eq. (7.25) using the simplifications of its right-hand side, discussed in Sec. 1:

\[
\rho \mathbf{a} = -\nabla \mathcal{P} + \mathbf{f}. \tag{8.22}
\]

Now using the basic kinematic relation (19), we arrive at the following Euler equation:16

\[
\rho \frac{\partial \mathbf{v}}{\partial t} + \rho (\mathbf{v} \cdot \nabla) \mathbf{v} = -\nabla \mathcal{P} + \mathbf{f}. \tag{8.23}
\]

Generally, this equation has to be solved together with the continuity equation (21) and the equation of state of the particular fluid, \( \rho = \rho(\mathcal{P}) \). However, as we have already discussed, in many situations the compressibility of water and other important liquids is very low and may be ignored, so that \( \rho \) may be treated as a given constant. Moreover, in many cases the bulk forces \( \mathbf{f} \) are conservative and may be represented as a gradient of a certain potential function \( u(\mathbf{r}) \) – the potential energy per unit volume:

\[
\mathbf{f} = -\nabla u; \tag{8.24}
\]

---

15 See, e.g., EM Sec. 4.1, QM Sec. 1.4, and SM Sec. 5.6.

16 It was derived in 1755 by the same Leonhard Euler whose name has already been (reverently) mentioned several times in this course.
for example, for a uniform, vertical gravity field, \( u(r) = \rho gy \), where \( y \) is referred to some (arbitrary) horizontal level. In this case, the right-hand side of Eq. (23) becomes \(-\nabla(\rho + u)\). For these cases, it is beneficial to recast the left-hand of that equation as well, using the following well-known identity of vector algebra\(^{17}\)

\[
(v \cdot \nabla)v = \nabla \left( \frac{v^2}{2} \right) - v \times (\nabla \times v).
\]

\[(8.25)\]

As a result, the Euler equation takes the following form:

\[
\rho \frac{\partial v}{\partial t} - \rho v \times (\nabla \times v) + \nabla \left( \rho u + \rho \frac{v^2}{2} \right) = 0.
\]

\[(8.26)\]

In a stationary flow, the first term of this equation vanishes. If the second term, describing fluid’s \textit{vorticity}, is zero as well, then equation (26) has the first integral of motion,

\[
\rho + u + \frac{\rho}{2} v^2 = \text{const},
\]

\[(8.27)\]

called the \textit{Bernoulli equation}.\(^\text{18}\) Numerous examples of the application of Eq. (27) to simple problems of stationary flow in pipes, in the Earth gravity field, should be well known to the readers from their undergraduate courses, so I hope I can skip their discussion without much harm.

In the general case, an ideal fluid may have vorticity, so that Eq. (27) is not always valid. Moreover, due to the absence of viscosity in an ideal fluid, the vorticity, once created, does not decrease along the so-called \textit{streamline} – the fluid particle’s trajectory, to which the velocity is tangential at every point.\(^\text{19}\) Mathematically, this fact\(^\text{20}\) is expressed by the following \textit{Kelvin theorem}: \( (\nabla \times v) \cdot dA = \text{const} \) along any small contiguous group of streamlines crossing an elementary area \( dA \).\(^\text{21}\)

However, in many important cases, the vorticity of fluid is negligible. For example, if the vorticity exists in some part of the fluid volume (say, induced by local turbulence, see Sec. 6 below), but decays due to the fluid’s viscosity, to be discussed in Sec. 5, well before it reaches the region of our interest. (If this viscosity is sufficiently small, its effects on the fluid’s flow in the region of interest are negligible, i.e. the ideal-fluid approximation is still acceptable.) Another important case is when a solid body of an arbitrary shape is embedded into an ideal fluid whose flow is uniform (meaning, by definition, that \( v(r,t) = v_0 = \text{const} \)) at large distances,\(^\text{22}\) its vorticity is zero everywhere. Indeed, since

\(^{17}\) It readily follows, for example, from MA Eq. (11.6) with \( g = f = v \).

\(^{18}\) Named after Daniel Bernoulli (1700-1782), not to be confused with Jacob Bernoulli or one of several Johanns of the same famous Bernoulli family, which gave the world so many famous mathematicians and scientists.

\(^{19}\) Perhaps the most spectacular manifestation of the vorticity conservation is the famous \textit{toroidal vortex rings} (see, e.g., a nice photo and a movie at https://en.wikipedia.org/wiki/Vortex_ring), predicted in 1858 by H. von Helmholtz, and then demonstrated by P. Tait in a series of spectacular experiments with smoke in the air. The persistence of such a ring, once created, is only limited by the fluid’s viscosity – see the next section.

\(^{20}\) This theorem was first formulated (verbally) by Hermann von Helmholtz.

\(^{21}\) Its proof may be found, e.g., in Sec. 8 of L. Landau and E. Lifshitz, \textit{Fluid Mechanics}, 2\textsuperscript{nd} ed., Butterworth-Heinemann, 1987.

\(^{22}\) This case is very important, because the motion of a solid body, with a constant velocity \( u \), in the otherwise stationary fluid, gives exactly the same problem (with \( v_0 = -u \)), in a reference frame bound to the body.
\( \nabla \times \mathbf{v} = 0 \) at the uniform flow, the vorticity is zero at distant points of any streamline, and according to the Kelvin theorem, should equal zero everywhere.

In such cases, the velocity distribution, as any curl-free vector field, may be represented as a gradient of some effective potential function,

\[
\mathbf{v} = -\nabla \phi. \tag{8.28}
\]

Such potential flow may be described by a simple differential equation. Indeed, the continuity equation (21) for a steady flow of an incompressible fluid is reduced to \( \nabla \cdot \mathbf{v} = 0 \). Plugging Eq. (28) into this relation, we get the scalar Laplace equation,

\[
\nabla^2 \phi = 0, \tag{8.29}
\]

which should be solved with appropriate boundary conditions. For example, the fluid flow may be limited by solid bodies, inside which the fluid cannot penetrate. Then the fluid velocity \( \mathbf{v} \) at the solid body boundaries should not have a normal component; according to Eq. (28), this means

\[
\left. \frac{\partial \phi}{\partial n} \right|_{\text{surfaces}} = 0. \tag{8.30}
\]

On the other hand, if at large distances the fluid flow is known, e.g., uniform, then:

\[
\nabla \phi = -\mathbf{v}_0 = \text{const}, \quad \text{at } r \to \infty. \tag{8.31}
\]

As the reader may already know (for example, from a course of electrodynamics\textsuperscript{23}), the Laplace equation (29) is readily solvable analytically in several simple (symmetric) but important situations. Let us consider, for example, the case of a round cylinder, with radius \( R \), immersed into a flow with the initial velocity \( \mathbf{v}_0 \) perpendicular to the cylinder’s axis (Fig. 8). For this problem, it is natural to use the cylindrical coordinates, with the \( z \)-axis coinciding with the cylinder’s axis. In this case, the velocity distribution is obviously independent of \( z \), so that we may simplify the general expression of the Laplace operator in cylindrical coordinates\textsuperscript{24} by taking \( \partial / \partial z = 0 \). As a result, Eq. (29) is reduced to\textsuperscript{25}

\[
\frac{1}{\rho} \frac{\partial}{\partial \rho} \left( \rho \frac{\partial \phi}{\partial \rho} \right) + \frac{1}{\rho^2} \frac{\partial^2 \phi}{\partial \theta^2} = 0, \quad \text{at } \rho \geq R. \tag{8.32}
\]

The general solution of this equation may be obtained using the variable separation method, similar to that used in Sec. 6.5 – see Eq. (6.67). The result is\textsuperscript{26}

\[
\phi = a_0 + b_0 \ln \rho + \sum_{n=1}^{\infty} \left( c_n \cos n\varphi + s_n \sin n\varphi \right) \left( a_n \rho^n + b_n \rho^{-n} \right) \tag{8.33}
\]

\textsuperscript{23} See, e.g., EM Secs. 2.3-2.8.
\textsuperscript{24} See, e.g., MA Eq. (10.3).
\textsuperscript{25} Let me hope that the letter \( \rho \), used here to denote the magnitude of the 2D radius-vector \( \rho = \{ x, y \} \), will not be confused with the fluid’s density – which does not participate in this boundary problem.
\textsuperscript{26} See, e.g., EM Eq. (2.112). Note that the most general solution of Eq. (32) also includes a term proportional to \( \varphi \), but this term should be zero for such a single-valued function as the velocity potential.
where the coefficients \( a_n \) and \( b_n \) have to be found from the boundary conditions (30) and (31). Choosing the \( x \)-axis to be parallel to the vector \( \mathbf{v}_0 \) (Fig. 8a), so that \( x = r \cos \varphi \), we may spell out these conditions in the following form:

\[
\frac{\partial \phi}{\partial r} = 0, \quad \text{at} \quad r = R, \tag{8.34}
\]

\[
\phi \to -v_0 r \cos \varphi + \phi_0, \quad \text{at} \quad r \gg R, \tag{8.35}
\]

where \( \phi_0 \) is an arbitrary constant, which does not affect the velocity distribution and may be taken for zero. The condition (35) is incompatible with any term of the sum (33) except the term with \( n = 1 \) (with \( s_1 = 0 \) and \( c_1 a_1 = -v_0 \)), so that Eq. (33) is reduced to

\[
\phi = \left( -v_0 r + \frac{c_1 b_1}{r} \right) \cos \varphi. \tag{8.36}
\]

Now, plugging this solution into Eq. (34), we get \( c_1 b_1 = -v_0 R^2 \), so that, finally,

\[
\phi = -v_0 \left( r + \frac{R^2}{r} \right) \cos \varphi. \tag{8.37a}
\]

Figure 8a shows the surfaces of constant velocity potential \( \phi \) given by Eq. (37a). To find the fluid velocity, it is easier to rewrite that equality in the Cartesian coordinates \( x = r \cos \varphi, y = r \sin \varphi \):

\[
\phi = -v_0 r \left( 1 + \frac{R^2}{r^2} \right) = -v_0 x \left( 1 + \frac{R^2}{x^2 + y^2} \right). \tag{8.37b}
\]

From here, we may readily calculate the Cartesian components \( v_x = -\frac{\partial \phi}{\partial x} \) and \( v_y = -\frac{\partial \phi}{\partial y} \) of fluid’s velocity. Figure 8b shows the flow streamlines. (They may be found by integration of the evident equation \( dy/dx = v_y(x, y)/v_x(x, y) \). For our simple problem, this integration may be done analytically,
giving \( y[1 - R^2/(x^2 + y^2)] = \text{const} \), where the constant is specific for each streamline.) One can see that the largest potential gradient, and hence the maximum fluid’s speed, is achieved at the vertical diameter’s ends \((\rho = R, \varphi = \pm \pi/2)\), where

\[
\nu = \nu_x = -\frac{\partial \phi}{\partial x} \bigg|_{x=0} = 2\nu_0.
\] (8.38)

Now the pressure distribution may be calculated by plugging Eq. (37) into the Bernoulli equation (27) with \( u(r) = 0 \). The result shows that the pressure reaches its maximum at the ends of the longitudinal diameter \( y = 0 \), while at the ends of the transverse diameter \( x = 0 \), where the velocity is largest, it is lower by \( 2\rho \nu_0^2 \). (Here \( \rho \) is the fluid density again – sorry for the notation jitters!) Note that the distributions of both the velocity and the pressure are symmetric with respect to the transverse axis \( x = 0 \), so that the fluid flow does not create any net drag force in its direction. It may be shown that this result, which stems from the conservation of the mechanical energy of an ideal fluid, remains valid for a solid body of arbitrary shape moving inside an infinite volume of an ideal fluid – the so-called D’Alambert paradox. However, if a body moves near an ideal fluid’s surface, its energy may be transformed into that of the surface waves, and the drag becomes possible.

Speaking about the surface waves: the description of such waves in a gravity field\(^{27}\) is one more classical problem of the ideal fluid dynamics.\(^{28}\) Let us consider an open surface of an ideal fluid of density \( \rho \) in a uniform gravity field \( \mathbf{f} = \rho \mathbf{g} = -\rho \mathbf{g}_y \), – see Fig. 9. If the wave amplitude \( A \) is sufficiently small, we can neglect the nonlinear term \((\mathbf{v} \cdot \nabla)\mathbf{v} \propto A^2\) in the Euler equation (23) in comparison with the first term, \( \partial \mathbf{v}/\partial t \), which is linear in \( A \). For a wave with frequency \( \omega \) and wave number \( k \), the particle’s velocity \( \mathbf{v} = dq/dt \) is of the order of \( \omega A \), so that this approximation is legitimate if \( \omega^2 A >> k(\omega A)^2 \), i.e. when

\[
kA << 1,
\] (8.39)

i.e. when the wave’s amplitude \( A \) is much smaller than its wavelength \( \lambda = 2\pi/k \). Due to this assumption, we may neglect the fluid vorticity effects, and (for an incompressible fluid) again use the Laplace equation (29) for the wave’s analysis.

Looking for its solution in the natural form of a sinusoidal wave, uniform in one of the horizontal directions (\( x \)),

\(^{27}\) The alternative, historic term “gravity waves” for this phenomenon may nowadays lead to confusion with the relativistic effect of gravity waves – which may propagate in free space.

\(^{28}\) It was solved by Sir George Biddell Airy (1801-19892), of the Airy functions fame. (He was also a prominent astronomer and, in particular, established Greenwich as the prime meridian.)
we get a very simple equation

\[ \frac{d^2 \Phi}{dy^2} - k^2 \Phi = 0, \]

with an exponential solution (properly decaying at \( y \to -\infty \)), \( \Phi = \Phi_0 \exp\{ky\} \), so that Eq. (40) becomes

\[ \phi = \text{Re}\left[ \Phi(y) e^{i(kz - \omega t)} \right], \]

(8.40)

where the last form is valid if \( \Phi_0 \) is real – which may be always arranged by a proper selection of the origins of \( z \) and/or \( t \). Note that the rate \( k \) of the wave’s decay in the vertical direction is exactly equal to the wave number of its propagation in the horizontal direction – along the fluid’s surface. Because of that, the trajectories of fluid particles are exactly circular – see Fig. 9. Indeed, using Eqs. (28) and (42) to calculate velocity components,

\[ v_x = 0, \quad v_y = -\frac{\partial \phi}{\partial y} = -k \Phi_0 e^{ky} \cos(kz - \omega t), \quad v_z = -\frac{\partial \phi}{\partial z} = k \Phi_0 e^{ky} \sin(kz - \omega t), \]

(8.43)

we see that \( v_y \) and \( v_z \), at the same height \( y \), have equal real amplitudes, and are phase-shifted by \( \pi/2 \). This result becomes even more clear if we use the velocity definition \( v = dq/dt \) to integrate Eqs. (43) over time to recover the particle displacement law \( q(t) \). Due to the strong inequality (39), the integration may be done at fixed \( y \) and \( z \):

\[ q_y = q_y e^{ky} \sin(kz - \omega t), \quad q_z = q_z e^{ky} \cos(kz - \omega t), \quad \text{with} \quad q_y = \frac{k}{\omega} \Phi_0. \]

(8.44)

Note that the phase of oscillations of \( v_z \) coincides with that of \( q_y \). This means, in particular, that at the wave’s “crest”, particles are moving in the direction of the wave’s propagation – see arrows in Fig. 9.

It is remarkable that all this picture follows from the Laplace equation alone! The “only” remaining feature to calculate is the dispersion law \( \omega(k) \), and for that, we need to combine Eq. (42) with what remains, in our linear approximation, of the Euler equation (23). In this approximation, and with the bulk force potential \( u = \rho gy \), the equation is reduced to

\[ \nabla \left( -\rho \frac{\partial \phi}{\partial t} + \mathcal{P} + \rho gy \right) = 0. \]

(8.45)

This equality means that the function in the parentheses is constant in space; at the surface, and at negligible surface tension, it should be equal to the pressure \( \mathcal{P}_0 \) above the surface (say, the atmospheric pressure), which we assume to be constant. This means that on the surface, the contributions to \( \mathcal{P} \) that come from the first and the third term in Eq. (45), should compensate each other. Let us take the average surface position for \( y = 0 \); then the surface with waves is described by the relation \( y(z, t) = q_y(y, z, t) \) – see Fig. 9. Due to the strong relation (39), we can use Eqs. (42) and (44) with \( y = 0 \), so that the above compensation condition yields

\[ -\rho \omega \Phi_0 \sin(kz - \omega t) + \rho g k \frac{\omega}{\omega} \Phi_0 \sin(kz - \omega t) = 0. \]

(8.46)
This condition is identically satisfied on the whole surface (and for any \( \Phi_A \)) as soon as

\[
\omega^2 = g k ,
\]  
(8.47)

This equality is the dispersion relation we were looking for. Looking at this simple result (which includes just one constant, \( g \)), note, first of all, that it does not involve the fluid’s density. This is not too surprising, because due to the weak equivalence principle, particle masses always drop out from the solutions of problems involving gravitational forces alone. Second, the dispersion law (47) is strongly nonlinear, and in particular does not have an acoustic wave limit at all. This means that the surface wave propagation is strongly dispersive, with both the phase velocity \( v_{ph} = \omega / k = g / \omega \) and the group velocity \( v_{gr} = d\omega / dk = g / 2 \omega \equiv v_{ph} / 2 \) diverging at \( \omega \to 0 \).

This divergence is an artifact of our assumption of the infinitely thick fluid’s layer. A rather straightforward generalization of the above calculations to a layer of a finite thickness \( h \), using the additional boundary condition \( v_y |_{y=-h} = 0 \) (left for the reader’s exercise), yields a more general dispersion relation:

\[
\omega^2 = g k \tanh kh .
\]  
(8.48)

It shows that relatively long waves, with \( \lambda >> h \), i.e. with \( kh << 1 \), propagate without dispersion (i.e. have \( \omega / k = \text{const} \equiv v \)), with the following velocity:

\[
v = (gh)^{1/2} .
\]  
(8.49)

For the Earth’s oceans, this velocity is rather high, approaching 300 m/s (!) for \( h = 10 \) km. This result explains, in particular, the very fast propagation of tsunami waves.

In the opposite limit of very short waves (large \( k \)), Eq. (47) also does not give a good description of experimental data, due to surface tension effects – see Sec. 2 above. Using Eq. (13), it is easy (and hence also left for the reader’s exercise) to show that their account leads (at \( kh >> 1 \)) to the following modification of Eq. (47):

\[
\omega^2 = g k + \frac{\sqrt{k^3}}{\rho} .
\]  
(8.50)

According to this formula, the surface tension is important at wavelengths smaller than the capillary constant \( a_c \) given by Eq. (14). Much shorter waves, for that Eq. (50) yields \( \omega \propto k^{3/2} \), are called the \textit{capillary waves} – or just “ripples”.

### 8.5. Dynamics: Viscous fluids

The viscosity of many fluids, at not overly high velocities, may be described surprisingly well by adding, to the static stress tensor (2), additional components proportional to the velocity \( v \equiv dq / dt \):

\[
\sigma_{ij} = -\rho \delta_{ij} + \sigma_{ij}^{\prime} (v) .
\]  
(8.51)

In the view of our experience with the Hooke’s law (7.32) expressing a stress tensor proportional to particle displacements \( q \), we may expect a similar expression with the replacement \( q \to v = dq / dt \):
\[
\tilde{\sigma}_{ij'} = 2\eta \left( e_{ij} - \frac{1}{3} \delta_{ij'} \text{Tr}(e) \right) + 3\zeta \left( \frac{1}{3} \delta_{ij'} \text{Tr}(e) \right),
\]  

(8.52a)

where \( e_{ij} \) are the elements of the symmetrized strain derivative tensor:

\[
e_{ij'} \equiv \frac{ds_{ij'}}{dt} = \frac{1}{2} \left( \frac{\partial v_j}{\partial r_{j'}} + \frac{\partial v_{j'}}{\partial r_j} \right).
\]  

(8.52b)

Experiment confirms that Eq. (52) gives a good description of the viscosity effects in a broad range of isotropic fluids. The coefficient \( \eta \) is called either the shear viscosity, or the dynamic viscosity, or just viscosity, while \( \zeta \) is called the second (or bulk) viscosity.

In the most frequent case of virtually incompressible fluids, \( \text{Tr} (e) = \frac{d[\text{Tr} (s)]}{dt} = \frac{(dV/dt)/V}{V} = 0 \), so that the term proportional to \( \zeta \) vanishes, and \( \eta \) is the only important viscosity parameter. Table 1 shows the approximate values of the viscosity, together with the mass density \( \rho \), for several representative fluids.

One can see that \( \eta \) may vary in very broad limits; the extreme cases of liquids are glasses (which, somewhat counter-intuitively, are not stable solids even at room temperature, but rather may “flow”, though extremely slowly, until they eventually crystallize) and liquid helium (whose viscosity is of the order of that of gases, despite its much higher density).

Incorporating the additional components of \( \sigma_{ij'} \) to the equation (23) of fluid motion, absolutely similarly to how it was done at the derivation of Eq. (7.107) of the elasticity theory, and with the account of Eq. (19), we arrive at the famous Navier-Stokes equation:

\[\text{Navier-Stokes equation.}\]  

\[\text{Named after Claude-Louis Navier (1785-1836) who had suggested the equation, and Sir George Gabriel Stokes (1819-1903) who has demonstrated its relevance by solving the equation for several key situations.}\]
The apparent simplicity of this equation should not mask an enormous range of phenomena, notably including turbulence (see the next section), that are described by it, and the complexity of its solutions even for some simple geometries. In most problems interesting for practice, the only option is to use numerical methods, but due to a large number of parameters ($\rho$, $\eta$, $\zeta$, plus geometrical parameters of the involved bodies, plus the distribution of bulk forces $\mathbf{f}$, plus boundary conditions), this way is strongly plagued by the curse of dimensionality that was discussed in the end of Sec. 5.8.

Let us see how does the Navier-Stokes equation work, on several simple examples. As the simplest case, let us consider the so-called Couette flow of an incompressible fluid layer between two wide, horizontal plates (Fig. 10), caused by their mutual sliding with a constant relative velocity $v_0$.

Let us assume a laminar (vorticity-free) fluid flow. (As will be discussed in the next section, this assumption is only valid within certain limits.) Then we may use the evident symmetry of the problem, to take, in the reference frame shown in Fig. 10, $v = n_z v(y)$. Let the bulk forces be vertical, $\mathbf{f} = n_y f$, so they do not give an additional drive to the fluid flow. Then for the stationary flow ($\partial v / \partial t = 0$), the vertical, $y$-component of the Navier-Stokes equation is reduced to the static Pascal equation (6), showing that the pressure distribution is not affected by the plate (and fluid) motion. In the horizontal, $z$-component of the equation, only one term, $\nabla^2 v$, survives, so that for the only Cartesian component of the fluid’s velocity we get the 1D Laplace equation

$$\frac{d^2 v}{dy^2} = 0.$$  

(8.54)

In contrast to the ideal fluid (see, e.g., Fig. 8b), the relative velocity of a viscous fluid and a solid wall it flows by should approach zero at the wall,\(^{32}\) so that Eq. (54) should be solved with boundary conditions

$$v = \begin{cases} 0, & \text{at } y = 0, \\ v_0, & \text{at } y = d. \end{cases}$$  

(8.55)

Using the evident solution of this boundary problem, $v(y) = (y/d)v_0$, illustrated by arrows in Fig. 10, we can now calculate the horizontal drag force acting on a unit area of each plate. For the bottom plate,

\(^{32}\)This is essentially an additional experimental fact, but may be understood as follows. The tangential component of the velocity should be continuous at the interface between two viscous fluids, in order to avoid infinite stress – see Eq. (52), and solid may be considered as an ultimate case of fluid, with infinite viscosity.
Essential Graduate Physics

Chapter 8

(For the top plate, the derivative \( \frac{\partial v}{\partial y} \) has the same value, but the sign of \( dA_y \) has to be changed to reflect the direction of the outer normal to the solid surface so that we get a similar force but with the negative sign.) The well-known result (56) is often used, in undergraduate physics courses, for a definition of the dynamic viscosity \( \eta \), and indeed shows its meaning very well.\(^{33} \)

As the next, slightly less trivial example let us consider the so-called Poiseuille problem:\(^{34} \) finding the relation between the constant external pressure gradient \( \chi \equiv -\frac{\partial P}{\partial z} \) applied along a round pipe with internal radius \( R \) (Fig. 11), and the so-called discharge \( Q \) – defined as the mass of fluid flowing through the pipe’s cross-section in unit time.

![Fig. 8.11. The Poiseuille problem.](image)

Again assuming a laminar flow, we can involve the problem’s uniformity along the \( z \)-axis and its axial symmetry to infer that \( v = n_z v(\rho) \), and \( P = -\chi z + f(\rho, \phi) + \text{const} \) (where \( \rho = \{\rho, \phi\} \) is again the 2D radius-vector rather than the fluid density), so that the Navier-Stokes equation (53) for an incompressible fluid (with \( \nabla \cdot v = 0 \)) is reduced to the following 2D Poisson equation:

\[
\eta \nabla_z^2 v = -\chi. \tag{8.57}
\]

After spelling out the 2D Laplace operator in polar coordinates for our axially-symmetric case \( \frac{\partial}{\partial \phi} = 0 \), Eq. (57) becomes a simple ordinary differential equation,

\[
\eta \frac{1}{\rho} \frac{d}{d\rho} \left( \rho \frac{dv}{d\rho} \right) = -\chi, \tag{8.58}
\]

which has to be solved on the segment \( 0 \leq \rho \leq R \), with the following boundary conditions:

\[
v = 0, \quad \text{at } \rho = R, \tag{8.59}
\]

\[
\frac{dv}{d\rho} = 0, \quad \text{at } \rho = 0.
\]

(The latter condition is required by the axial symmetry.) A straightforward double integration yields:

\(^{33} \) The very notion of viscosity \( \eta \) was introduced (by nobody other than the same Sir Isaac Newton) via a formula similar to Eq. (56), so that any effect resulting in a drag force proportional to velocity is frequently called the Newtonian viscosity.

\(^{34} \) It was solved by G. Stokes in 1845 to explain the experimental results obtained by Gotthilf Hagen in 1839 and (independently) by Jean Poiseuille in 1840-41.
\[ v = \frac{X}{4\eta} \left( R^2 - \rho^2 \right), \]  

so that the (easy) integration of the mass flow density over the cross-section of the pipe,

\[ Q \equiv \int_A \rho v d^2 r = 2\pi R^2 \frac{X}{4\eta} \int_0^{R^2} (R^2 - \rho'^2) \rho' d\rho', \]

immediately gives us the so-called Poiseuille (or “Hagen-Poiseuille”) law for the fluid discharge:

\[ Q = \frac{\pi}{8} \rho \frac{X}{\eta} R^4, \]  

where (sorry!) \( \rho \) is the mass density again. The most prominent (and practically important) feature of this result is the very strong dependence of the discharge on the pipe’s radius.

Of course, not for each cross-section shape the 2D Poisson equation (57) is so readily solvable. For example, consider a very simple, square-shape cross-section with side \( a \) (Fig. 12). In this case, it is natural to use the Cartesian coordinates, so that Eq. (57) becomes

\[ \frac{\partial^2 v}{\partial x^2} + \frac{\partial^2 v}{\partial y^2} = -\frac{X}{\eta} \text{ const}, \quad \text{for } 0 \leq x, y \leq a, \]  

and (for the coordinate choice shown in Fig. 12) has to be solved with boundary conditions

\[ v = 0, \quad \text{at } x, y = 0, a. \]

For this boundary problem, analytical methods such as the variable separation give answers in the form of infinite sums (series),\(^{35}\) which ultimately require computers anyway – for their plotting and comprehension. Let me use this pretext to discuss how explicitly numerical methods may be used for such problems – or for any partial differential equations involving the Laplace operator. The simplest of them is the finite-difference method\(^{36}\) in which the function to be calculated, \( f(\mathbf{r}) \), is represented by its values \( f(\mathbf{r}_1), f(\mathbf{r}_2), ... \) in discrete points of a rectangular grid (frequently called the mesh) of the corresponding dimensionality (Fig. 13).

---

\(^{35}\) See, e.g., EM Sec. 2.5.

In Sec. 5.7, we have already discussed how to use such a grid to approximate the first derivative of the function – see Eq. (5.97). Its extension to the second derivative is straightforward – see Fig. 13a:

\[
\frac{\partial^2 f}{\partial r_j^2} \approx \frac{1}{h} \left( \frac{f_{++} - f_{--}}{2h^2} - \frac{f_{-+} - f_{+-}}{h^2} \right) \approx \frac{1}{h^2} \left[ \frac{f_{++} - f_{--}}{h^2} + \frac{f_{-+} - f_{+-}}{h^2} - \frac{f_{+-} - f_{-+}}{h^2} \right] \equiv \frac{f_+ + f_- - 2f}{h^2}. \quad (8.65)
\]

The relative error of this approximation is of the order of \(h^2/\partial f/\partial r_j^4\), quite acceptable in many cases. As a result, the left-hand side of Eq. (63), treated on a square mesh with step \(h\) (Fig. 13b), may be approximated with the so-called five-point scheme:

\[
\frac{\partial^2 v}{\partial x^2} + \frac{\partial^2 v}{\partial y^2} \approx \frac{v_{++} + v_{--} - 2v_{+-}}{h^2} + \frac{v_{-+} + v_{++} - 2v_{-+}}{h^2} = \frac{v_{++} + v_{--} + v_{-+} + v_{+-} - 4v}{h^2}. \quad (8.66)
\]

(The generalization to the seven-point scheme, appropriate for 3D problems, is straightforward.) Let us apply this scheme to the pipe with the square cross-section, using an extremely coarse mesh with step \(h = a/2\) (Fig. 12). In this case, the fluid velocity \(v\) should equal zero at the walls, i.e. in all points of the five-point scheme except for the central point (in which the velocity is evidently the largest), so that Eqs. (63) and (66) yield

\[
0 + 0 + 0 + 0 - 4v_{\text{max}} \approx -\frac{Z}{\eta}, \quad \text{i.e. } v_{\text{max}} \approx \frac{1}{16} \frac{Za^2}{\eta}. \quad (8.67)
\]

This result for the maximal velocity is only \(\approx 20\%\) different from the exact value. Using a slightly finer mesh with \(h = a/4\), which gives a readily solvable system of three linear equations for three different velocity values (the exercise left for the reader), brings us within just a couple of percent from the exact result. So such numerical methods may be practically more efficient than the “analytical” ones, even if the only available tool is a calculator app on your smartphone rather than an advanced computer.

Of course, many practical problems of fluid dynamics do require high-performance computing, especially in conditions of turbulence (see the next section) with its complex, irregular spatial-temporal structure. In these conditions, the finite-difference approach discussed above may become

---

37 As a reminder, at the beginning of Sec. 6.4 we have already discussed the reciprocal transition – from a similar sum to the second derivative in the continuous limit (\(h \rightarrow 0\)).

38 Note that value (67) of \(v_{\text{max}}\) is exactly the same as given by the analytical formula (60) for the round cross-section with the radius \(R = a/2\). This is not an occasional coincidence. The velocity distribution given by (60) is a quadratic function of both \(x\) and \(y\). For such functions, with all derivatives higher than \(\partial^2 f/\partial r_j^2\) equal to zero, equation (66) is exact rather than approximate.
unsatisfactory, because it implies the same accuracy of the derivative approximation through the whole area of interest. A more powerful (but also much more complex for implementation) approach is the finite-element method in which the discrete-point mesh is based on triangles with uneven sides, and is (in most cases, automatically) generated in accordance with the system geometry, giving many more mesh points at the location(s) of the highest gradients of the calculated function (Fig. 14), and hence a better calculation accuracy for the same total number of points. Unfortunately, I do not have time for going into the details of that method, so the interested reader is referred to the special literature on this subject.39

Before proceeding to our next topic, let me mention one more important problem that is analytically solvable using the Navier-Stokes equation: a slow motion of a solid sphere of radius $R$, with a constant velocity $v_0$, through an incompressible viscous fluid – or equivalently, a slow flow of the fluid (uniform at large distances) around an immobile sphere. Indeed, in the limit $v \to 0$, the second term on the left-hand side of Eq. (53) is negligible (just as at the surface wave analysis in Sec. 3), and the equation takes the form

$$- \nabla P + \eta \nabla^2 \mathbf{v} = 0, \tag{8.68}$$

which should be complemented with the incompressibility condition $\nabla \cdot \mathbf{v} = 0$ and boundary conditions

$$\mathbf{v} = 0, \quad \text{at } r = R,$$

$$\mathbf{v} \to \mathbf{v}_0, \quad \text{at } r \to \infty. \tag{8.69}$$

In spherical coordinates, with the polar axis directed along the vector $v_0$, this boundary problem has the axial symmetry (so that $\partial v / \partial \varphi = 0$ and $v_\varphi = 0$), and allows the following analytical solution:

$$v_r = v_0 \cos \theta \left(1 - \frac{3R}{2r} + \frac{R^3}{2r^2}\right), \quad v_\varphi = -v_0 \sin \theta \left(1 - \frac{3R}{4r} - \frac{R^3}{4r^2}\right). \tag{8.70}$$

Calculating the pressure distribution from Eq. (68), and integrating it over the surface of the sphere, it is now straightforward to obtain the famous Stokes formula for the drag force acting on the sphere:

$$F = 6\pi \eta R v_0.$$  \hfill (8.71)  

Historically, this formula has played an important role in the first precise (better than 1%) calculation of the fundamental electric charge $e$ by R. Millikan and H. Fletcher from their famous oil drop experiments in 1909-1913.

For what follows in the next section, it is convenient to recast this result into the following form:

$$C_d = \frac{24}{Re},$$  \hfill (8.72)  

where $C_d$ is the drag coefficient defined as

$$C_d \equiv \frac{F}{\rho v_0^2 A/2},$$  \hfill (8.73)  

with $A \equiv \pi R^2$ being the sphere’s cross-section “as seen by the incident fluid flow”, and $Re$ is the so-called Reynolds number.\(^{40}\) In the general case, the number is defined as

$$Re \equiv \frac{\rho v l}{\eta},$$  \hfill (8.74)  

where $l$ is the linear-size scale of the problem, and $v$ is its velocity scale. (In the particular case of Eq. (72) for the sphere, $l$ is identified with the sphere’s diameter $D = 2R$, and $v$ with $v_0$). The physical sense of these two definitions will be discussed in the next section.

8.6. Turbulence

As Fig. 15 shows, the Stokes’ result (71)-(72) is only valid at $Re \ll 1$, while for larger values of the Reynolds number, i.e. at higher velocities $v_0$, the drag force is larger. This very fact is not quite surprising, because at the derivation of the Stokes’ result, the nonlinear term $(\mathbf{v} \cdot \nabla) \mathbf{v}$ in the Navier-Stokes equation (53), which scales as $v^2$, was neglected in comparison with the linear terms, scaling as $v$. What is more surprising is that the function $C_d(Re)$ exhibits such a complicated behavior over many orders of velocity’s magnitude, giving a hint that the fluid flow at large Reynolds numbers should be also very complicated. Indeed, the reason for this complexity is a gradual development of very intricate, time-dependent fluid patterns, called turbulence, rich with vortices – for example, see Fig. 16. These vortices are especially pronounced in the region behind the moving body (the so-called wake), while the region before the body remains almost unperturbed. As Fig. 15 indicates, the turbulence exhibits rather different behaviors at various velocities (i.e. values of $Re$), and sometimes changes rather abruptly – see, for example, the significant drag drop at $Re \approx 5 \times 10^5$.

In order to understand the conditions of this phenomenon, let us estimate the scale of various terms of the Navier-Stokes equation (53) for the generic case of a body with characteristic size $l$, moving in an otherwise static, incompressible fluid, with velocity $v$. In this case, the characteristic time scale of

\(^{40}\) This notion was introduced in 1851 by the same G. Stokes but eventually named after O. Reynolds who popularized it three decades later.
possible non-stationary phenomena is given by the ratio \( l/v \),\(^{41}\) so that we arrive at the following estimates:

\[
\begin{align*}
\text{Equation term:} & \quad \rho \frac{\partial \mathbf{v}}{\partial t} + \rho (\mathbf{v} \cdot \nabla) \mathbf{v} & = & f + \eta \nabla^2 \mathbf{v} \\
\text{Order of magnitude:} & \quad \rho \frac{v^2}{l} & \approx & \rho \frac{v^2}{l} + \rho g \eta \frac{v}{l^2} 
\end{align*}
\] \quad (8.75)

(I have skipped the term \( \nabla P \) because as we saw in the previous section, in typical fluid flow problems it balances the viscosity term, and hence is of the same order of magnitude.) Eq. (75) shows that the relative importance of the terms may be characterized by two dimensionless ratios.\(^{42}\)

The first of them is the so-called \textit{Froude number}\(^{43}\)

\[
F \equiv \frac{\rho v^2 / l}{\rho g \eta / l} \equiv \frac{v^2}{l g},
\] \quad (8.76)

\(41\) The time scale of phenomena in non-autonomous systems may be different from \( l/v \); for example, for forced oscillations of fluid flow with frequency \( \omega \), it is given by the oscillation period \( T = 2\pi/\omega \). For such problems, the ratio \( S = (l/v)/T \) serves as another, independent dimensionless constant, commonly called either the \textit{Strouhal number} or the \textit{reduced frequency}.

\(42\) For substantially compressible fluids (e.g., gases), the most important additional dimensionless parameter is the \textit{Mach number} \( M \equiv v/v_1 \), where \( v_1 = (K/\rho)^{1/2} \) is the velocity of the longitudinal sound – which is, as we already know from Chapter 7, the only wave mode possible in an infinite fluid. Especially significant for practice are \textit{supersonic effects} (including the shock wave in the form of the famous \textit{Mach cone} with half-angle \( \theta_M = \sin^{-1}M^{-1} \)) that arise at \( M > 1 \). For a more thorough discussion of these issues, I have to refer the reader to more specialized texts – either Chapter IX of the Landau-Lifshitz volume cited above or Chapter 15 in I. Cohen and P. Kundu, \textit{Fluid Mechanics}, 4th ed., Academic Press, 2007 – which is generally a good book on the subject. Another popular, rather basic textbook is R. Granger, \textit{Fluid Mechanics}, Dover, 1995.

\(43\) Named after William Froude (1810-1879) who has made several important contributions to applied hydrodynamics.
which characterizes the relative importance of the gravity – or, upon appropriate modification, of other bulk forces. In most practical problems (with the important exception of surface waves, see Sec. 4 above) \( F \gg 1 \), so that the gravity effects may be neglected.

Fig. 8.16. A snapshot of the turbulent tail (wake) behind a sphere moving in a fluid with a high Reynolds number, showing the so-called von Kármán vortex street. Adapted from the original (actually, a very nice animation, http://www.mcef.ep.usp.br/staff/jmeneg/cesareo/vort2.gif) by Cesareo de La Rosa Siqueira, as a copyright-free material, available at https://commons.wikimedia.org/w/index.php?curid=87351.

Much more important is another ratio, the Reynolds number (74), which may be rewritten as

\[
Re \equiv \frac{\rho vl}{\eta} \equiv \frac{\rho v^2}{\eta v/1^2},
\]

and hence is a measure of the relative importance of the fluid particle’s inertia in comparison with the viscosity effects.\(^{44}\) So again, it is natural that for a sphere, the role of the vorticity-creating term \( (\mathbf{v} \cdot \nabla)\mathbf{v} \) becomes noticeable already at \( Re \sim 1 \) – see Fig. 15. What is very counter-intuitive is the onset of turbulence in systems where the laminar (turbulence-free) flow is formally an exact solution to the Navier-Stokes equation for any \( Re \). For example, at \( Re > Re_t \approx 2,100 \) (with \( l \equiv 2R \) and \( v \equiv v_{\text{max}} \)) the laminar flow in a round pipe, described by Eq. (60), becomes unstable, and the resulting turbulence decreases the fluid discharge \( Q \) in comparison with the Poiseuille law (62). Even more strikingly, the critical value of \( Re \) is rather insensitive to the pipe wall roughness and does not diverge even in the limit of perfectly smooth walls.

Since \( Re \gg 1 \) in many real-life situations,\(^{45}\) turbulence is very important for practice. However, despite nearly a century of intensive research, there is no general, quantitative analytical theory of this phenomenon,\(^{46}\) and most results are still obtained either by rather approximate analytical treatments, or by the numerical solution of the Navier-Stokes equations using the approaches discussed in the previous section, or in experiments (e.g., on scaled models\(^{47}\) in wind tunnels). Only certain general, semi-quantitative features may be readily understood from simple arguments.

\(^{44}\) Note that the “dynamic” viscosity \( \eta \) participates in this number (and many other problems of fluid dynamics) only in the combination \( \eta/\rho \), which thereby has deserved a special name of kinematic viscosity.

\(^{45}\) Indeed, the values of \( \eta \) and \( \rho \) for water listed in Table 1 imply that even for a few-meter-sized object (such as a human body or a small boat), \( Re > 1,000 \) at any speed above just \( \sim 1 \) mm/s.

\(^{46}\) A rare exception is the relatively recent theoretical result by S. Orszag (1971) for the turbulence threshold in a flow of an incompressible fluid through a gap of thickness \( t \) between two parallel plane walls (see Fig. 10): \( Re_t \approx 5,772 \) (for \( l = t/2 \), \( v = v_{\text{max}} \)). However, this result does not predict the turbulence patterns at \( Re > Re_t \).

\(^{47}\) The crucial condition of correct modeling is the equality of the Reynolds numbers (74) (and if relevant, also of the Froude numbers and/or the Mach numbers) of the object of interest and its model.
For example, Fig. 15 shows that within a very broad range of Reynolds numbers, from $\sim 10^2$ to $\sim 3 \times 10^5$, $C_d$ of a sphere is of the order of 1. Moreover, for a flat, thin, round disk, perpendicular to the incident flow, $C_d$ is very close to 1.1 for any $Re > 10^3$. The approximate equality $C_d \approx 1$, meaning the drag force $F \approx \rho v_0^2 A/2$, may be understood (in the picture where the object is moved by an external force $F$ with the velocity $v_0$ through a fluid which was initially at rest) as the equality of the force-delivered power $Fv_0$ and the fluid’s kinetic energy $(\rho v_0^2/2)V$ created in volume $V = v_0 A$ in unit time. This relation would be exact if the object gave its velocity $v_0$ to each and every fluid particle its cross-section runs into, for example by dragging all such particles behind itself. In reality, much of this kinetic energy goes into vortices, where the particle velocity may differ from $v_0$, so that the equality $C_d \approx 1$ is only approximate.

Unfortunately, due to the time/space restrictions, for a more detailed discussion of these results I have to refer the reader to more specialized literature, and will conclude this chapter with a brief discussion of just one issue: can the turbulence be “explained by a single mechanism”? (In other words, can it be reduced, at least on a semi-quantitative level, to a set of simpler phenomena that are commonly considered “well understood”?) Apparently the answer is no, though nonlinear dynamics of simpler systems may provide some useful insights.

At the middle of the last century, the most popular qualitative explanation of turbulence had been the formation of an “energy cascade” that would transfer the energy from the regular fluid flow to a hierarchy of vortices of various sizes. With our background, it is easier to retell that story in the time-domain language (with the velocity $v$ serving as the conversion factor), using the fact that in a rotating vortex each Cartesian component of a particle’s radius-vector oscillates in time, so that to some extent the vortex plays the role of an oscillatory motion mode.

Let us consider the passage of a solid body between two, initially close, small parts of the fluid. The body pushes them apart, but after its passage, these partial volumes are free to return to their initial positions. However, the dominance of inertia effects at motion with $Re \gg 1$ means that the volumes continue to “oscillate” for a while about those equilibrium positions. (Since elementary volumes of an incompressible fluid cannot merge, these oscillations take the form of rotating vortices – see Fig. 16 again.)

Now, from Sec. 5.8 we know that intensive oscillations in a system with the quadratic nonlinearity, in this case provided by the convective term $(\mathbf{v} \cdot \nabla) \mathbf{v}$, are equivalent, for small perturbations, to the oscillation of the system’s parameters at the corresponding frequency. On the other hand, as was briefly discussed in Sec. 6.7, in a system with two oscillatory degrees of freedom, a periodic parameter change with frequency $\omega_p$ may lead to the non-degenerate parametric excitation (“down-conversion”) of oscillations with frequencies $\omega_{1,2}$ satisfying the relation $\omega_1 + \omega_2 = \omega_p$. Moreover, the spectrum of oscillations in such a system also has higher combinational frequencies such as $(\omega_p + \omega_1)$, thus pushing the oscillation energy up the frequency scale (“up-conversion”). In the presence of other oscillatory modes, these oscillations may in turn produce, via the same nonlinearity, even higher frequencies, etc.

49 The following famous quote is attributed to Werner Heisenberg on his deathbed: “When I meet God, I will ask him two questions: Why relativity? And why turbulence? I think he will have an answer for the first question.” Though probably inaccurate, this story reflects rather well the understandable frustration of the fundamental physics community, renown for their reductionist mentality, with the enormous complexity of phenomena which obey simple (e.g., the Navier-Stokes) equations, i.e. from their point of view, do not describe any new physics.
a fluid, the spectrum of these “oscillatory modes” (actually, vortex structures) is essentially continuous, so that the above arguments make very plausible a sequential transfer of the energy from the moving body to a broad range of oscillatory modes – whose frequency spectrum is limited from above by the energy dissipation due to the fluid’s viscosity. When excited, these modes interact (in particular, mutually phase-lock) via the system’s nonlinearity, creating the complex motion we call turbulence.

Though not having much quantitative predictive power, such handwaving explanations, which are essentially based on the excitation of a large number of effective degrees of freedom, had been dominating the turbulence reviews until the mid-1960s. At that point, the discovery (or rather re-discovery) of quasi-random motions in classical dynamic systems with just a few degrees of freedom altered the discussion substantially. Since this phenomenon, called the deterministic chaos, extends well beyond the fluid dynamics, and I will devote to it a separate (albeit short) next chapter, and in its end will briefly return to the discussion of turbulence.

8.7. Exercise problems

8.1. Find the first-order correction to the Pascal equation (6) for a liquid, due to its low but nonzero compressibility, and evaluate this correction for the water at the bottom of the Earth’s oceans.

8.2. Find the stationary shape of the open surface of an incompressible, heavy fluid in a container rotated about its vertical axis with a constant angular velocity \( \omega \) – see the figure on the right.

\[
\begin{align*}
g & \quad \omega
\end{align*}
\]

8.3. Use two different approaches to calculate the stationary shape of the surface of an incompressible fluid of density \( \rho \) near a vertical plane wall, in a uniform gravity field – see the figure on the right. In particular, find the height \( h \) of liquid’s rise at the wall surface as a function of the contact angle \( \theta_c \).

\[
\begin{align*}
\rho & \quad g \quad h = ?
\end{align*}
\]

8.4. A soap film with surface tension \( \gamma \) is stretched between two similar, coaxial, thin, round rings of radius \( R \), separated by distance \( d \) – see the figure on the right. Neglecting gravity, calculate the equilibrium shape of the film, and the force needed for keeping the rings at the fixed distance.

\[
\begin{align*}
& \quad 2R \\
g & \quad \gamma \\
d & \quad \gamma
\end{align*}
\]

8.5. A solid sphere of radius \( R \) is kept in a steady, vorticity-free flow of an ideal incompressible fluid, with velocity \( v_0 \). Find the spatial distribution of velocity and pressure, and in particular their extreme values. Compare the results with those obtained in Sec. 4 for a round cylinder.
8.6. A small source, located at distance \( d \) from a plane wall of a container filled with an ideal, incompressible fluid of density \( \rho \), injects additional fluid isotropically, at a constant mass current ("discharge") \( Q \equiv dM/dt \) – see the figure on the right. Calculate the fluid’s velocity distribution, and its pressure on the wall, created by the flow.

*Hint:* Recall the charge image method in electrostatics,\(^{50}\) and contemplate its possible analog.

8.7. Calculate the average kinetic, potential, and full energies (per unit area) of a traveling sinusoidal wave, of a small amplitude \( q_A \), on the horizontal surface on an ideal, incompressible, deep fluid of density \( \rho \), in a uniform gravity field \( g \).

8.8. Calculate the average power (per unit width of wave’s front) carried by the surface wave discussed in the previous problem, and relate the result to the wave’s energy.

8.9. Derive Eq. (48) for the surface waves on a finite-thickness layer of a heavy liquid.

8.10. Derive Eq. (50) for the capillary waves (“ripples”).

8.11. Derive a 2D differential equation describing the propagation of relatively long (\( \lambda \gg h \)) waves on the surface of a broad, plane layer of thickness \( h \), of an ideal, incompressible fluid, and use it to calculate the longest standing wave modes and frequencies in a layer covering a spherical planet of radius \( R \gg h \).

*Hint:* The second task requires some familiarity with the basic properties of spherical harmonics.\(^{51}\)

8.12. Calculate the velocity distribution and the dispersion relation of the waves propagating along the horizontal interface of two ideal, incompressible fluids of different densities.

8.13. Use the finite-difference approximation for the Laplace operator, with the mesh step \( h = a/4 \), to find the maximum velocity and total mass flow \( Q \) of a viscous, incompressible fluid through a long pipe with a square-shaped cross-section of side \( a \). Compare the results with those described in Sec. 5 for the same problem with the mesh step \( h = a/2 \), and for a pipe with the circular cross-section of the same area.

8.14. A layer, of thickness \( h \), of a heavy, viscous, incompressible fluid flows down a long and wide incline plane, under its own weight – see the figure on the right. Find the stationary velocity distribution profile, and the total fluid discharge (per unit width.)

---

\(^{50}\) See, e.g., EM Secs. 2.9, 3.3, and 4.3.

\(^{51}\) See, e.g., EM Sec. 2.8 and/or QM Sec. 3.6.
8.15. Calculate the drag torque exerted on a unit length of a solid round cylinder of radius $R$ that rotates about its axis, with angular velocity $\omega$, inside an incompressible fluid with viscosity $\eta$, kept static far from the cylinder.

8.16. Calculate the tangential force (per unit area) exerted by an incompressible fluid, with density $\rho$ and viscosity $\eta$, on a broad solid plane placed over its surface and forced to oscillate, along the surface, with amplitude $a$ and frequency $\omega$.

8.17. A massive barge, with a flat bottom of area $A$, floats in shallow water, with clearance $h \ll A^{1/2}$. See the figure on the right. Analyze the time dependence of the barge’s velocity $V(t)$, and the water velocity profile, after the barge’s engine has been turned off. Discuss the limits of large and small values of the dimensionless parameter $M/\rho Ah$.

8.18.* Derive a general expression for mechanical energy loss rate in a viscous incompressible fluid that obeys the Navier-Stokes equation, and use this expression to calculate the attenuation coefficient of the surface waves, assuming that the viscosity is small. (Quantify this condition).

8.19. Use the Navier-Stokes equation to calculate the coefficient of attenuation of a plane, sinusoidal acoustic wave.
Chapter 9. Deterministic Chaos

This chapter gives a very brief review of chaotic phenomena in deterministic maps and dynamic systems with and without dissipation, and an even shorter discussion of the possible role of chaos in fluid turbulence.

9.1. Chaos in maps

The possibility of quasi-random dynamics of deterministic systems with a few degrees of freedom (nowadays called the deterministic chaos – or just “chaos”) had been noticed before the 20th century,1 but has become broadly recognized only after the publication of a 1963 paper by theoretical meteorologist Edward Lorenz. In that work, he examined numerical solutions of the following system of three nonlinear, ordinary differential equations,

\[ \begin{align*}
\dot{q}_1 &= a_1 (q_2 - q_1), \\
\dot{q}_2 &= a_2 q_1 - q_2 - q_1 q_3, \\
\dot{q}_3 &= q_1 q_2 - a_3 q_3,
\end{align*} \tag{9.1} \]

as a rudimentary model of heat transfer through a horizontal layer of fluid separating two solid plates. (Experiment shows that if the bottom plate is kept hotter than the top one, the liquid may exhibit turbulent convection.) He has found that within a certain range of the constants \(a_{1,2,3}\), the solution to Eq. (1) follows complex, unpredictable, non-repeating trajectories in the 3D \(q\)-space. Moreover, the functions \(q_j(t)\) (where \(j = 1, 2, 3\)) are so sensitive to initial conditions \(q_j(0)\) that at sufficiently large times \(t\), solutions corresponding to slightly different initial conditions become completely different.

Very soon it was realized that such behavior is typical for even simpler mathematical objects called maps so that I will start my discussion of chaos from these objects. A 1D map is essentially a rule for finding the next number \(q_{n+1}\) of a discrete sequence numbered by the integer index \(n\), in the simplest cases using only its last known value \(q_n\). The most famous example is the so-called logistic map:2

\[ q_{n+1} = f(q_n) \equiv rq_n (1 - q_n). \tag{9.2} \]

The basic properties of this map may be understood using the (hopefully, self-explanatory) graphical representation shown in Fig. 1.3 One can readily see that at \(r < 1\) (Fig. 1a) the logistic map sequence rapidly converges to the trivial fixed point \(q^{(0)} = 0\), because each next value of \(q\) is less than the previous one. However, if \(r\) is increased above 1 (as in the example shown in Fig. 1b), the fixed

---

1. It may be traced back at least to an 1892 paper by the same Jules Henri Poincaré who was already reverently mentioned in Chapter 5. Citing it: “...it may happen that small differences in the initial conditions produce very great ones in the final phenomena. […] Prediction becomes impossible.”

2. Its chaotic properties were first discussed in 1976 by Robert May, though the map itself is one of the simple ecological models repeatedly discussed much earlier, and may be traced back at least to the 1838 work by Pierre François Verhulst.

3. Since the maximum value of the function \(f(q)\), achieved at \(q = 1/2\), equals \(r/4\), the mapping may be limited to segment \(x = [0, 1]\), if the parameter \(r\) is between 0 and 4. Since all interesting properties of the map, including chaos, may be found within these limits, I will discuss only this range of \(r\).
point $q^{(0)}$ becomes unstable. Indeed, at $q_n << 1$, the map yields $q_{n+1} \approx rq_n$, so that at $r > 1$, the values $q_n$ grow with each iteration. Instead of the unstable point $q^{(0)} = 0$, in the range $1 < r < r_1$, where $r_1 \equiv 3$, the map has a stable fixed point $q^{(1)}$ that may be found by plugging this value into both parts of Eq. (2):

$$q^{(1)} = f(q^{(1)}) \equiv rq^{(1)}(1 - q^{(1)}),$$

(9.3)
giving $q^{(1)} = 1 - 1/r$ – see the left branch of the plot shown in Fig. 2.

However, at $r > r_1 = 3$, the fixed point $q^{(1)}$ also becomes unstable. To prove that, let us take $q_n \equiv q^{(1)} + \tilde{q}_n$, assume that the deviation $\tilde{q}_n$ from the fixed point $q^{(1)}$ is small, and linearize the map (2) in $\tilde{q}_n$ – just as we repeatedly did for differential equations earlier in this course. The result is

$$\tilde{q}_{n+1} = \frac{df}{dq} |_{q=q^{(1)}} \tilde{q}_n = r(1 - 2q^{(1)})\tilde{q}_n = (2-r)\tilde{q}_n.$$

(9.4)

It shows that at $0 < 2 - r < 1$, i.e. at $1 < r < 2$, the deviations $\tilde{q}_n$ decrease monotonically. At $-1 < 2 - r < 0$, i.e. in the range $2 < r < 3$, the deviations’ sign alternates, but their magnitude still decreases – as in a
stable focus, see Sec. 5.6. However, at $-1 < 2 - r$, i.e. $r > r_1 \equiv 3$, the deviations grow by magnitude, while still changing their sign, at each step. Since Eq. (2) has no other fixed points, this means that at $n \to \infty$, the values $q_n$ do not converge to one point; rather, within the range $r_1 < r < r_2$, they approach a limit cycle of alternation of two points, $q^2_+$ and $q^2_-$, which satisfy the following system of algebraic equations:

$$q^2_+ = f(q^2_-), \quad q^2_- = f(q^2_+).$$  \hspace{1cm} (9.5)

These points are also plotted in Fig. 2, as functions of the parameter $r$. What has happened at the point $r_1 = 3$ is called the period-doubling bifurcation.

The story repeats at $r = r_2 \equiv 1 + \sqrt{6} \approx 3.45$, where the system goes from the 2-point limit cycle to a 4-point cycle, then at $r = r_3 \approx 3.54$, where the limit cycle becomes consisting of 8 alternating points, etc. Most remarkably, the period-doubling bifurcation points $r_n$, at that the number of points in the limit cycle doubles from $2^{n-1}$ points to $2^n$ points, become closer and closer. Numerical calculations show that at $n \to \infty$, these points obey the following asymptotic behavior:

$$r_n \to r_\infty = \frac{C}{\delta^n}, \quad \text{where} \quad r_\infty = 3.5699..., \quad \delta = 4.6692...$$  \hspace{1cm} (9.6)

The parameter $\delta$ is called the Feigenbaum constant; for other maps, and some dynamic systems (see the next section), period-doubling sequences follow a similar law, but with different values of $\delta$.

More important for us, however, is what happens at $r > r_\infty$. Numerous numerical experiments, repeated with increasing precision, have confirmed that here the system is fully disordered, with no reproducible limit cycle, though (as Fig. 2 shows) at $r \approx r_\infty$, all sequential values $q_n$ are still confined to a few narrow regions. However, as parameter $r$ is increased well beyond $r_\infty$, these regions broaden and merge. This is the so-called deep chaos, with no apparent order at all.

The most important feature of the chaos (in this and any other system) is the exponential divergence of trajectories. For a 1D map, this means that even if the initial conditions $q_1$ in two map implementations differ by a very small amount $\Delta q_1$, the difference $\Delta q_n$ between the corresponding sequences $q_n$ is growing, on average, exponentially with $n$. Such exponents may be used to characterize chaos. Indeed, an evident generalization of Eq. (4) to an arbitrary point $q_n$ is

$$\Delta q_{n+1} = e_n \Delta q_n, \quad e_n \equiv \left. \frac{df}{dq} \right|_{q=q_n}.$$  \hspace{1cm} (9.7)

Let us assume that $\Delta q_1$ is so small that $N$ first values $q_n$ are relatively close to each other. Then using Eq. (7) iteratively for these steps, we get

---

4 The reader should remember that just as the usual (“nature”) experiments, numerical experiments also have limited accuracy, due to unavoidable rounding errors.

5 The geometry of these regions is essentially fractal, i.e. has a dimensionality intermediate between 0 (which any final set of geometric points would have) and 1 (pertinent to a 1D continuum). An extensive discussion of fractal geometries and their relation to the deterministic chaos may be found, e.g., in the book by B. Mandelbrot, *The Fractal Geometry of Nature*, W. H. Freeman, 1983.

6 This does not mean that chaos’ development is always a monotonic function of $r$. As Fig. 2 shows, within certain intervals of this parameter, the chaotic behavior suddenly disappears, being replaced, typically, with a few-point limit cycle, just to resume on the other side of the interval. Sometimes (but not always!) the “route to chaos” on the borders of these intervals follows the same Feigenbaum sequence of period-doubling bifurcations.
\[ \Delta q_N = \Delta q_1 \prod_{n=1}^{N} e_n, \quad \text{so that} \quad \ln \left| \frac{\Delta q_N}{\Delta q_1} \right| = \sum_{n=1}^{N} \ln |e_n|. \] (9.8)

Numerical experiments show that in most chaotic regimes, at \( N \to \infty \) such a sum fluctuates about an average, which grows as \( \lambda N \), with the parameter

\[ \lambda \equiv \lim_{\Delta q_1 \to 0} \lim_{N \to \infty} \frac{1}{N} \sum_{n=1}^{N} \ln |e_n|, \] (9.9)

called the Lyapunov exponent,\(^7\) being independent of the initial conditions. The bottom panel in Fig. 3 shows \( \lambda \) as a function of the parameter \( r \) for the logistic map (2). (Its top panel shows the same data as Fig. 2, and it reproduced here just for the sake of comparison.)

Note that at \( r < r_\infty \), \( \lambda \) is negative, indicating the sequence’s stability, besides the points \( r_1, r_2, \ldots \) where \( \lambda \) would become positive if the limit cycle changes (bifurcations) had not brought it back into the negative territory. However, at \( r > r_\infty \), \( \lambda \) becomes positive, returning to negative values only in limited intervals of stable limit cycles. It is evident that in numerical experiments (which dominate the studies of deterministic chaos) the Lyapunov exponent may be used as a good measure of the chaos’ depth.\(^8\)

\(^7\) After Alexandr Mikhailovich Lyapunov (1857-1918), famous for his studies of the stability of dynamic systems.

\(^8\) \( N \)-dimensional maps that relate \( N \)-dimensional vectors rather than scalars, may be characterized by \( N \) Lyapunov exponents rather than one. For chaotic behavior, it is sufficient for just one of them to become positive. For such systems, another measure of chaos, the Kolmogorov entropy, may be more relevant. This measure, and its relation with the Lyapunov exponents, are discussed, for example, in SM Sec. 2.2.
Despite all the abundance of results published for particular maps, and several interesting general observations (like the existence of the Feigenbaum bifurcation sequences), to the best of my knowledge, nobody can yet predict the patterns like those shown in Fig. 2 and 3 from just looking at the mapping rule itself, i.e. without carrying out actual numerical experiments. Unfortunately, the understanding of deterministic chaos in other systems is not much better.

9.2. Chaos in dynamic systems

Proceeding to the discussion of chaos in dynamic systems, it is more natural, with our background, to illustrate this discussion not with the Lorenz Eqs. (1), but with the system of equations describing a dissipative pendulum driven by a sinusoidal external force, which was repeatedly discussed in Chapter 5. Introducing two new variables, the normalized momentum \( p = (dq/dt)/\omega_0 \) and the external force’s full phase \( \psi = \omega t \), we may rewrite Eq. (5.42) describing the pendulum, in a form similar to Eq. (1), i.e. as a system of three first-order ordinary differential equations:

\[
\begin{align*}
\dot{q} &= \omega_0 p, \\
\dot{p} &= -\omega_0 \sin q - 2\delta p + (f_0/\omega_0) \cos \psi, \\
\dot{\psi} &= \omega_0.
\end{align*}
\] (9.10)

Figure 4 several results of a numerical solution of Eq. (10). In all cases, parameters \( \delta, \omega_0, \) and \( f_0 \) are fixed, while the external frequency \( \omega \) is gradually changed. For the case shown on the top panel, the system still tends to a stable periodic solution, with very low contents of higher harmonics. If the external force frequency is reduced by a just few percent, the 3rd subharmonic may be excited. (This effect has already been discussed in Sec. 5.8 – see, e.g., Fig. 5.15.) The next panel shows that just a small further reduction of the frequency \( \omega \) leads to a new tripling of the period, i.e. the generation of a complex waveform with the 9th subharmonic. Finally (see the bottom panel of Fig. 4), even a minor further change of \( \omega \) leads to oscillations without any visible period, e.g., to the chaos.

In order to trace this transition, a direct inspection of the oscillation waveforms \( q(t) \) is not very convenient, and trajectories on the phase plane \([q, p]\) also become messy if plotted for many periods of the external frequency. In situations like this, the Poincaré (or “stroboscopic”) plane, already discussed in Sec. 5.6, is much more useful. As a reminder, this is essentially just the phase plane \([q, p]\), but with the points highlighted only once a period, e.g., at \( \psi = 2\pi n \), with \( n = 1, 2, … \) On this plane, periodic oscillations of frequency \( \omega \) are represented just as one fixed point – see, e.g. the top panel in the right column of Fig. 4. The 3rd subharmonic generation, shown on the next panel, means the oscillation period’s tripling and is reflected on the Poincaré plane as splitting of the fixed point into three. It is evident that this transition is similar to the period-doubling bifurcation in the logistic map, besides the fact (already discussed in Sec. 5.8) that in systems with an asymmetric nonlinearity, such as the pendulum (10), the 3rd subharmonic is easier to excite. From this point, the 9th harmonic generation (shown on the 3rd panel of Fig. 4), i.e. one more splitting of the points on the Poincaré plane, may be understood as one more step on the Feigenbaum-like route to chaos – see the bottom panel of that figure.

---

10 In the actual simulation, a small term \( \epsilon q \), with \( \epsilon << 1 \), has been added to the left-hand side of this equation. This term slightly tames the trend of the solution to spread along the \( q \)-axis, and makes the presentation of results easier, without affecting the system’s dynamics too much.
Fig. 9.4. Oscillations in a pendulum with weak damping, $\delta/\omega_0 = 0.1$, driven by a sinusoidal external force with a fixed effective amplitude $f_0/\omega_0^2 = 1$, and several close values of the frequency $\omega$ (listed on the panels). Left panel column: the oscillation waveforms $q(t)$ recorded after certain initial transient intervals. Right column: representations of the same processes on the Poincaré plane of the variables $[q, p]$, with the $q$-axis turned vertically, for the convenience of comparison with the left panels.
So, the transition to chaos in dynamic systems may be at least qualitatively similar to than in 1D maps, with a law similar to Eq. (6) for the critical values of some parameter of the system (in Fig. 4, frequency $\omega$), though with a system-specific value of the coefficient $\delta$. Moreover, we may consider the first two differential equations of the system (10) as a 2D map that relates the vector $\{q_{n+1}, p_{n+1}\}$ of the coordinate and momentum, measured at $\psi = 2\pi(n + 1)$, with the previous value $\{q_n, p_n\}$ of that vector, reached at $\psi = 2\pi n$.

Unfortunately, this similarity also implies that the deterministic chaos in dynamic systems is at least as complex, and is as little understood, as in maps. For example, Fig. 5 shows (a part of) the phase diagram of the externally-driven pendulum, with the red bar marking the route to chaos traced in Fig. 4, and shading/hatching styles marking different oscillation regimes. One can see that the pattern is at least as complex as that shown in Figs. 2 and 3, and, besides a few features, is equally unpredictable from the form of the equation.

Are there any valuable general results concerning the deterministic chaos in dynamic systems? The most important (though an almost evident) result is that this phenomenon is impossible in any system described by one or two first-order differential equations with time-independent right-hand sides. Indeed, let us start with a single equation

$$\dot{q} = f(q),$$

(9.11)

where $f(q)$ is any single-valued function. This equation may be directly integrated to give

$$t = \int \frac{dq'}{f(q')} + \text{const},$$

(9.12)

showing that the relation between $q$ and $t$ is unique and hence does not leave any place for chaos.

---

11 In some cases, it is possible to predict a parameter region where chaos cannot happen, due to the lack of any instability-amplification mechanism. Unfortunately, typically the analytically predicted boundaries of such a region form a rather loose envelope of the actual (numerically simulated) chaotic regions.
Next, let us explore a system of two such equations:

\[
\begin{align*}
\dot{q}_1 &= f_1(q_1, q_2), \\
\dot{q}_2 &= f_2(q_1, q_2).
\end{align*}
\]  

(9.13)

Consider its phase plane shown schematically in Fig. 6. In a “usual” system, the trajectories approach either some fixed point (Fig. 6a) describing static equilibrium, or a limit cycle (Fig. 6b) describing periodic oscillations. (Both notions are united by the term attractor because they “attract” trajectories launched from various initial conditions.) On the other hand, phase plane trajectories of a chaotic system of equations that describe physical variables (which cannot be infinite), should be confined to a limited phase plane area, and simultaneously cannot start repeating each other. (This topology is frequently called the strange attractor.) For that, the 2D trajectories need to cross – see, e.g., point A in Fig. 6c.

![Fig. 9.6. Attractors in dynamical systems: (a) a fixed point, (b) a limit cycle, and (c) a strange attractor.](image)

However, in the case described by Eqs. (13), such a crossing is clearly impossible, because according to these equations, the tangent of a phase plane trajectory is a unique function of the coordinates \(\{q_1, q_2\}\):

\[
\frac{dq_1}{dq_2} = \frac{f_1(q_1, q_2)}{f_2(q_1, q_2)}.
\]  

(9.14)

Thus, in this case the deterministic chaos is impossible.\(^{12}\) It becomes, however, readily possible if the right-hand sides of a system similar to Eq. (13) depend either on other variables of the system or time. For example, if we consider the first two differential equations of the system (10), in the case \(f_0 = 0\) they have the structure of the system (13) and hence the chaos is impossible, even at \(\delta < 0\) when (as we know from Sec. 5.4) the system allows self-excitation of oscillations – leading to a limit-cycle attractor. However, if \(f_0 \neq 0\), this argument does not work any longer, and (as we have already seen) the system may have a strange attractor – which is, for dynamic systems, a synonym for the deterministic chaos.

Thus, chaos is only possible in autonomous dynamic systems described by three or more differential equations of the first order.\(^{13}\)

\(^{12}\) A mathematically strict formulation of this statement is called the Poincaré-Bendixon theorem, which was proved by Ivar Bendixon as early as in 1901.

\(^{13}\) Since a typical dynamic system with one degree of freedom is described by two such equations, the number of first-order equations describing a dynamic system is sometimes called the number of its half-degrees of freedom. This notion is very useful and popular in statistical mechanics – see, e.g., SM Sec. 2.2 and on.
9.3. Chaos in Hamiltonian systems

The last conclusion is of course valid for Hamiltonian systems, which are just a particular type of dynamic systems. However, one may wonder whether these systems, that feature at least one first integral of motion, \( H = \text{const} \), and hence are more “ordered” than the systems discussed above, can exhibit chaos at all. The answer is \( \text{yes} \) because such systems still can have mechanisms for exponential growth of a small initial perturbation.

As the simplest way to show it, let us consider the so-called mathematical billiard, i.e. system with a ballistic particle (a “ball”) moving freely by inertia on a horizontal plane surface (“table”) limited by rigid impenetrable walls. In this idealized model of the usual game of billiards, the ball’s velocity \( \mathbf{v} \) is conserved when it moves on the table, and when it runs into a wall, the ball is elastically reflected from it as from a mirror,\(^{14}\) with the reversal of the sign of the normal velocity \( v_n \), and the conservation of the tangential velocity \( v_\tau \), and hence without any loss of its kinetic (and hence the full) energy

\[
E = H = T = \frac{m}{2} v^2 = \frac{m}{2} \left( v^2_n + v^2_\tau \right).
\] (9.15)

This model, while being a legitimate 2D dynamic system,\(^{15}\) allows geometric analyses for several simple table shapes. The simplest case is a rectangular billiard of area \( a \times b \) (Fig. 7), whose analysis may be readily carried out just by the replacement of each ball reflection event with the mirror reflection of the table in that wall – see the dashed lines on panel (a).

Such analysis (left for the reader’ pleasure :-) shows that if the tangent of the ball launching angle \( \varphi \) is commensurate with the side length ratio:

\[
\tan \varphi = \pm \frac{m b}{n a},
\] (9.16)

where \( n \) and \( m \) are non-negative integers without common integer multipliers, the ball returns exactly to the launch point \( \text{O} \), after bouncing \( m \) times from each wall of length \( a \), and \( n \) times from each wall of length \( b \). (Red lines in Fig. 7a show an example of such a trajectory for \( n = m = 1 \), while blue lines, for \( m = 3, n = 1 \).) The larger is the sum \((m + n)\), the more complex is such closed trajectory – “orbit”.

\(^{14}\) A more scientific-sounding name for such a reflection is specular – from the Latin word “speculum” meaning a metallic mirror.

\(^{15}\) Indeed, it is fully described by the following Lagrangian function: \( L = mv^2/2 - U(\mathbf{p}) \), with \( U(\mathbf{p}) = 0 \) for the 2D radius vectors \( \mathbf{p} \) belonging to the table area, and \( U(\mathbf{p}) = +\infty \) outside the area.
Finally, if \((n + m) \to \infty\), i.e. \(\tan \phi\) and \(b/a\) are incommensurate (meaning that their ratio is an irrational number), the trajectory covers all the table area, and the ball never returns exactly into the launch point. Still, this is not genuine chaos. Indeed, a small shift of the launch point \(O\) shifts all the trajectory fragments by the same displacement. Moreover, at any time \(t\), each of Cartesian components \(v_j(t)\) of the ball’s velocity (with coordinate axes parallel to the table sides) may take only two values, \(\pm v_j(0)\), and hence may vary only as much as the initial velocity is being changed.

In 1963, i.e. well before E. Lorenz’s work, Yakov Sinai showed that the situation changes completely if an additional wall, in the shape of a circle, is inserted into the rectangular billiard (Fig. 8). For most initial conditions, the ball’s trajectory eventually runs into the circle (see the red line on panel (a) as an example), and the further trajectory becomes essentially chaotic. Indeed, let us consider the ball’s reflection from the circle-shaped wall – Fig. 8b. Due to the conservation of the tangential velocity, and the sign change of the normal velocity component, the reflection obeys a simple law: \(\theta_r = \theta_i\). Figure 8b shows that as the result, the magnitude of a small difference \(\delta \phi\) between the angles of two close trajectories (as measured in the lab system), doubles at each reflection from the curved wall. This means that the small deviation grows along the ball trajectory as

\[
|\delta \phi(N)| \sim |\delta \phi(0)| \times 2^N \equiv |\delta \phi(0)| e^{N \ln 2},
\]

where \(N\) is the number of reflections from the convex wall. As we already know, such exponential divergence of trajectories, with a positive Lyapunov exponent, is the main feature of deterministic chaos.

The most important new feature of the dynamic chaos in Hamiltonian systems is its dependence on initial conditions. (In the systems discussed in the previous two previous sections, that lack the integrals of motion, the initial conditions are rapidly “forgotten”, and the chaos is usually characterized after an initial transient period – see, e.g., Fig. 4.) Indeed, even a Sinai billiard allows periodic motion, along closed orbits, at certain initial conditions – see the blue and green lines in Fig. 8a as examples.

---

16 Superficially, Eq. (17) is also valid for a plane wall, but as was discussed above, a billiard with such walls features a full correlation between sequential reflections, so that angle \(\phi\) always returns to its initial value. In a Sinai billiard, such correlation disappears. Concave walls may also make a billiard chaotic; a famous example is the stadium billiard, suggested by Leonid Bunimovich in 1974, with two straight, parallel walls connecting two semi-circular, concave walls. Another example, which allows a straightforward analysis (first carried out by Martin Gutzwiller in the 1980s), is the so-called Hadamard billiard: an infinite (or rectangular) table with a non-horizontal surface of negative curvature.

17 Curved-wall billiards are also a convenient platform for studies of quantum properties of classically chaotic systems (for their conceptual discussion, see QM Sec. 3.5), in particular, the features called “quantum scars” – see, e.g., the spectacular numerical simulation results by E. Heller, Phys. Rev. Lett. 53, 1515 (1984).
Thus the chaos “depth” in such systems may be characterized by the “fraction”\(^{18}\) of the phase space of initial parameters (for a 2D billiard, of the 3D space of initial values of \(x, y,\) and \(\phi\)) resulting in chaotic trajectories.

This conclusion is also valid for Hamiltonian systems that are met in experiment more frequently than the billiards, for example, coupled nonlinear oscillators without damping. Perhaps the earliest and the most popular example is the so-called Hénon-Heiles system,\(^{19}\) which may be described by the following Lagrangian function:

\[
L = \frac{m_1}{2} (\dot{q}_1^2 - \omega_1^2 q_1^2) + \frac{m_2}{2} (\dot{q}_2^2 - \omega_2^2 q_2^2) - \epsilon \left( q_1^2 - \frac{1}{3} q_2^2 \right) q_2.
\]  

(9.18)

It is straightforward to derive the corresponding Lagrange equations of motion,

\[
\begin{align*}
    m_1 \ddot{q}_1 + \omega_1^2 q_1 &= -2 \epsilon q_1 q_2, \\
    m_2 \ddot{q}_2 + \omega_2^2 q_2 &= -\epsilon (q_1^2 - q_2^2),
\end{align*}
\]  

(9.19)

and find their first integral of motion (physically, the energy conservation law):

\[
H = E = \frac{m_1}{2} (\dot{q}_1^2 + \omega_1^2 q_1^2) + \frac{m_2}{2} (\dot{q}_2^2 + \omega_2^2 q_2^2) + \epsilon \left( q_1^2 - \frac{1}{3} q_2^2 \right) q_2 = \text{const}.
\]  

(9.20)

In the context of our discussions in Chapters 5 and 6, Eqs. (19) may be readily interpreted as those describing two oscillators, with small-oscillation frequencies \(\omega_1\) and \(\omega_2\), coupled only as described by the quadratic terms on the right-hand sides of the equations. This means that as the oscillation amplitudes \(A_{1,2}\), and hence the total energy \(E\) of the system, are close to zero, the oscillator subsystems are virtually independent, each performing sinusoidal oscillations at its own frequency. This observation suggests a convenient way to depict the system’s motion.\(^{20}\) Let us consider a Poincaré plane for one of the oscillators (say, with the coordinate \(q_2\)), similar to that discussed in Sec. 2 above, with the only difference is that (because of the absence of an explicit function of time in the system’s equations), the trajectory on the phase plane \([q_2, \dot{q}_2]\) is highlighted at the moments when \(q_1 = 0\).

Let us start from the limit \(A_{1,2} \to 0\), when the oscillations of \(q_2\) are virtually sinusoidal. As we already know (see Fig. 5.9 and its discussion), if the representation point highlighting was perfectly synchronous with frequency \(\omega_2\) of the oscillations, there would be only one point on the Poincaré plane – see, e.g. the right top panel of Fig. 4. However, at the \(q_1\) – initiated highlighting, there is not such synchronism, so that each period, a different point of the elliptical (at the proper scaling of the velocity,

---

\(^{18}\) Actually, quantitative characterization of the fraction is not trivial, because it may have fractal dimensionality. Unfortunately, due to lack of time I have to refer the reader interested in this issue to special literature, e.g., the monograph by B. Mandelbrot (cited above) and references therein.

\(^{19}\) It was first studied in 1964 by Michel Hénon and Carl Heiles as a simple model of star rotation about a galactic center. Most studies of this equation have been carried out for the following particular case: \(m_2 = 2m_1, m_1 \omega_1^2 = m_2 \omega_2^2\). In this case, introducing new variables \(x = \alpha q_1, y = \alpha q_2,\) and \(\tau = \omega_1 t\), it is possible to rewrite Eqs. (18)-(20) in parameter-free forms. All the results shown in Fig. 9 below are for this case.

\(^{20}\) Generally, the system has a trajectory in 4D space, e.g., that of coordinates \(q_{1,2}\) and their time derivatives, although the first integral of motion (20) means that for each fixed energy \(E\), the motion is limited to a 3D subspace. Still, this is one dimension too many for a convenient representation of the motion.
circular) trajectory is highlighted, so that the resulting points, for certain initial conditions, reside on a circle of radius $A_2$. If we now vary the initial conditions, i.e. redistribute the initial energy between the oscillators, but keep the total energy $E$ constant, on the Poincaré plane we get a set of ellipses.

Now, if the initial energy is increased, the nonlinear interaction of the oscillations starts to deform these ellipses, causing also their crossings – see, e.g., the top left panel of Fig. 9. Still, below a certain threshold value of $E$, all Poincaré points belonging to a certain initial condition sit on a single closed contour. Moreover, these contours may be calculated approximately, but with pretty good accuracy, using straightforward generalization of the method discussed in Sec. 5.2.\(^{21}\)

However, starting from some value of energy, certain initial conditions lead to sequences of points scattered over parts of the Poincaré plane, with a nonzero area – see the top right panel of Fig. 9. This means that the corresponding oscillations $q_2(t)$ do not repeat from one (quasi-) period to the next one – cf. Fig. 4 for the dissipative, forced pendulum. This is chaos.\(^{22}\) However, some other initial

\(^{22}\) This fact complies with the necessary condition of chaos, discussed at the end of Sec. 2 because Eqs. (19) may be rewritten as a system of *four* differential equations of the first order.
conditions still lead to closed contours. This feature is similar to that in Sinai billiards, and is typical for Hamiltonian systems. As the energy is increased, larger and larger parts of the Poincaré plane correspond to the chaotic motion, signifying deeper and deeper chaos – see the bottom panel of Fig. 9.

9.4. Chaos and turbulence

This extremely short section consists of essentially just one statement, extending the discussion in Sec. 8.5. The (re-) discovery of the deterministic chaos in systems with just a few degrees of freedom in the 1960s has changed the tone of the debates concerning turbulence origins, very considerably. At first, an extreme point of view that equated the notions of chaos and turbulence, became the debate’s favorite. However, after initial excitement, significant evidence of the Landau-style mechanisms, involving many degrees of freedom, has been rediscovered and could not be ignored any longer. To the best knowledge of this author, who is a very distant albeit interested observer of that field, most experimental and numerical-simulation data carry features of both mechanisms, so that the debate continues. Due to the age difference, most readers of these notes have much better chances than their author to see where will this discussion end.

9.5. Exercise problems

9.1. Generalize the reasoning of Sec. 1 to an arbitrary 1D map \( q_{n+1} = f(q_n) \), with a function \( f(q) \) differentiable at all points of interest. In particular, derive the condition of stability of an \( N \)-point limit cycle \( q^{(1)} \rightarrow q^{(2)} \rightarrow \ldots \rightarrow q^{(N)} \rightarrow q^{(1)} \ldots \)

9.2. Use the stability condition, derived in the previous problem, to analyze the possibility of the deterministic chaos in the so-called tent map, with

\[
f(q) = \begin{cases} 
  rq, & \text{for } 0 \leq q \leq 1/2, \\
  r(1-q), & \text{for } 1/2 \leq q \leq 1,
\end{cases} \quad \text{with } 0 \leq r \leq 2.
\]

9.3. A dynamic system is described by the following system of differential equations:

\[
\dot{q}_1 = -q_1 + a_1 q_2^3, \\
\dot{q}_2 = a_2 q_2 - a_3 q_2^3 + a_4 q_2(1-q_1^2).
\]

Can it exhibit chaos at some set of constant parameters \( a_1-a_4 \)?

9.4. A periodic function of time has been added to the right-hand side of the first equation of the system considered in the previous problem. Is deterministic chaos possible now?

23 An important milestone on that way was the work by S. Newhouse et al., Comm. Math. Phys. 64, 35 (1978), who proved the existence of a strange attractor in a rather abstract model of fluid flow.
25 The reader interested in the deterministic chaos as such may also like to have a look at a very popular book by S. Strogatz, Nonlinear Dynamics and Chaos, Westview, 2001.

Chapter 10. A Bit More of Analytical Mechanics

This concluding chapter reviews two alternative approaches to analytical mechanics, whose major value is a closer parallel to quantum mechanics in general and its quasiclassical (WKB) approximation in particular. One of them, the Hamiltonian formalism, is also convenient for the derivation of an important asymptotic result, the adiabatic invariance, for classical systems with slowly changing parameters.

10.1. Hamilton equations

Throughout this course, we have seen how analytical mechanics, in its Lagrangian form, is invaluable for solving various particular problems of classical mechanics. Now let us discuss several alternative formulations\(^1\) that may not be much more useful for this purpose, but shed additional light on possible extensions of classical mechanics, most importantly to quantum mechanics.

As was already discussed in Sec. 2.3, the partial derivative \(p_j \equiv \partial L/\partial \dot{q}_j\) participating in the Lagrange equation (2.19),

\[
\frac{d}{dt} \frac{\partial L}{\partial \dot{q}_j} - \frac{\partial L}{\partial q_j} = 0,
\]

may be considered as the generalized momentum corresponding to the generalized coordinate \(q_j\), and the full set of these momenta may be used to define the Hamiltonian function (2.32):

\[
H \equiv \sum_j p_j \dot{q}_j - L. \tag{10.2}
\]

Now let us rewrite the full differential of this function\(^2\) in the following form:

\[
dH = \sum_j \left( \sum_j p_j \dot{q}_j - L \right) = \sum_j \left[ d(p_j) \dot{q}_j + p_j d(\dot{q}_j) \right] - dL
\]

\[
= \sum_j \left[ d(p_j) \dot{q}_j + p_j d(\dot{q}_j) \right] - \left[ \frac{\partial L}{\partial t} dt + \sum_j \left( \frac{\partial L}{\partial q_j} d(q_j) + \frac{\partial L}{\partial \dot{q}_j} d(\dot{q}_j) \right) \right]. \tag{10.3}
\]

According to the definition of the generalized momentum, the second terms of each sum over \(j\) in the last expression cancel each other, while according to the Lagrange equation (1), the derivative \(\partial L/\partial q_j\) is equal to \(\dot{p}_j\), so that

\[
dH = -\frac{\partial L}{\partial t} dt + \sum_j \left( \dot{q}_j dp_j - \dot{p}_j dq_j \right). \tag{10.4}
\]

So far, this is just a universal identity. Now comes the main trick of Hamilton’s approach: let us consider \(H\) as a function of the following independent arguments: time \(t\), the generalized coordinates \(q_j\),

---

\(^1\) Due to not only William Rowan Hamilton (1805-1865), but also Carl Gustav Jacob Jacobi (1804-1851).

\(^2\) Actually, this differential was already spelled out (but partly and implicitly) in Sec. 2.3 – see Eqs. (2.33)-(2.35).
and the generalized momenta $p_j$ - rather than generalized velocities $\dot{q}_j$. With this commitment, the general “chain rule” of differentiation of a function of several arguments gives

$$\frac{dH}{dt} = \frac{\partial H}{\partial t} dt + \sum_j \left( \frac{\partial H}{\partial q_j} dq_j + \frac{\partial H}{\partial p_j} dp_j \right),$$

(10.5)

where $dt$, $dq_j$, and $dp_j$ are independent differentials. Since Eq. (5) should be valid for any choice of these argument differentials, it should hold in particular if they correspond to the real law of motion, for which Eq. (4) is valid as well. The comparison of Eqs. (4) and (5) gives us three relations:

$$\frac{\partial H}{\partial t} = -\frac{\partial L}{\partial t},$$

(10.6)

$$\dot{q}_j = \frac{\partial H}{\partial p_j}, \quad p_j = -\frac{\partial H}{\partial q_j}.$$  

(10.7)

Comparing the first of them with Eq. (2.35), we see that

$$\frac{dH}{dt} = \frac{\partial H}{\partial t},$$

(10.8)

meaning that the function $H(t, q_j, p_j)$ can change in time only via its explicit dependence on $t$. Two Eqs. (7) are even more substantial: provided that such function $H(t, q_j, p_j)$ has been calculated, they give us two first-order differential equations (called the Hamilton equations) for the time evolution of the generalized coordinate and generalized momentum of each degree of freedom of the system.3

Let us have a look at these equations for the simplest case of a system with one degree of freedom, with the Lagrangian function (3.3):

$$L = \frac{m_{ef}}{2} \dot{q}^2 - U_{ef}(q, t).$$

(10.9)

In this case, $p \equiv \partial L / \partial \dot{q} = m_{ef} \dot{q}$, and $H \equiv p \dot{q} - L = m_{ef} \dot{q}^2 / 2 + U_{ef}(q, t)$. To honor our new commitment, we need to express the Hamiltonian function explicitly via $t$, $q$, and $p$ (rather than $\dot{q}$). From the above expression for $p$, we immediately have $\dot{q} = p / m_{ef}$; plugging this expression back to Eq. (9), we get

$$H = \frac{p^2}{2m_{ef}} + U_{ef}(q, t).$$

(10.10)

Now we can spell out Eqs. (7) for this particular case:

$$\dot{q} \equiv \frac{\partial H}{\partial p} = \frac{p}{m_{ef}};$$

(10.11)

$$\dot{p} \equiv -\frac{\partial H}{\partial q} = -\frac{\partial U_{ef}}{\partial q}.$$  

(10.12)

---

3 Of course, the right-hand side of each equation (7) may include coordinates and momenta of other degrees of freedom as well, so that the equations of motion for different $j$ are generally coupled.
While the first of these equations just repeats the definition of the generalized momentum corresponding to the coordinate \( q \), the second one gives the equation of momentum’s change. Differentiating Eq. (11) over time, and plugging Eq. (12) into the result, we get:

\[
\dot{q} = \frac{\dot{p}}{m_{ef}} = -\frac{1}{m_{ef}} \frac{\partial U_{ef}}{\partial q}.
\]  

(10.13)

So, we have returned to the same equation (3.4) that had been derived from the Lagrangian approach.\(^4\)

Thus, the Hamiltonian formalism does not give much new for the solution of this problem – and indeed most problems of classical mechanics. (This is why its discussion had been postponed until the very end of this course.) Moreover, since the Hamiltonian function \( H(t, q_j, p_j) \) does not include generalized velocities explicitly, the phenomenological introduction of dissipation in this approach is less straightforward than that in the Lagrangian equations, whose precursor form (2.17) is valid for dissipative forces as well. However, the Hamilton equations (7), which treat the generalized coordinates and momenta in a manifestly symmetric way, are heuristically fruitful – besides being very appealing aesthetically. This is especially true in the cases where these arguments participate in \( H \) in a similar way. For example, in the very important case of a dissipation-free linear (“harmonic”) oscillator, for which \( U_{ef} = \kappa_{ef} q^2 / 2 \), Eq. (10) gives the famous symmetric form

\[
H = \frac{p^2}{2m_{ef}} + \frac{\kappa_{ef} q^2}{2} \equiv \frac{p^2}{2m_{ef}} + \frac{m_{ef} \omega_0^2 q^2}{2}, \quad \text{where } \omega_0^2 = \frac{\kappa_{ef}}{m_{ef}}.
\]

(10.14)

The Hamilton equations (7) for this system preserve that symmetry, especially evident if we introduce the normalized momentum \( \rho \equiv p/m_{ef} \omega_0 \) (already used in Secs. 5.6 and 9.2):

\[
\frac{dq}{dt} = \omega_0 \rho, \quad \frac{d\rho}{dt} = -\omega_0 q.
\]  

(10.15)

More practically, the Hamilton approach gives additional tools for the search for the integrals of motion. To see that, let us consider the full time derivative of an arbitrary function \( f(t, q_j, p_j) \):

\[
\frac{df}{dt} = \frac{\partial f}{\partial t} + \sum_j \left( \frac{\partial f}{\partial q_j} \dot{q}_j + \frac{\partial f}{\partial p_j} \dot{p}_j \right).
\]

(10.16)

Plugging in \( \dot{q}_j \) and \( \dot{p}_j \) from the Hamilton equations (7), we get

\[
\frac{df}{dt} = \frac{\partial f}{\partial t} + \sum_j \left( \frac{\partial f}{\partial q_j} \frac{\partial H}{\partial \dot{q}_j} - \frac{\partial f}{\partial \dot{q}_j} \frac{\partial H}{\partial q_j} \right) \equiv \frac{\partial f}{\partial t} + \{H, f\}.
\]  

(10.17)

The last term on the right-hand side of this expression is the so-called Poisson bracket,\(^5\) and is defined, for two arbitrary functions \( f(t, q_j, p_j) \) and \( g(t, q_j, p_j) \), as

---

\(^4\) The reader is highly encouraged to perform a similar check for a few more problems, for example those listed at the end of the chapter, to get a better feeling of how the Hamiltonian formalism works.

\(^5\) Named after Siméon Denis Poisson (1781-1840), of the Poisson equation and the Poisson statistical distribution fame.
\[ \{ g, f \} \equiv \sum_j \left( \frac{\partial g}{\partial p_j} \frac{\partial f}{\partial q_j} - \frac{\partial f}{\partial p_j} \frac{\partial g}{\partial q_j} \right) \]  
\hspace{1cm} (10.18)

From this definition, one can readily verify that besides evident relations \( \{ f, f \} = 0 \) and \( \{ f, g \} = -\{ g, f \} \), the Poisson brackets obey the following important \textit{Jacobi identity}:

\[ \{ f, \{ g, h \} \} + \{ g, \{ h, f \} \} + \{ h, \{ f, g \} \} = 0. \]  
\hspace{1cm} (10.19)

Now let us use these relations for a search for integrals of motion. First, Eq. (17) shows that if a function \( f \) does not depend on time explicitly, and

\[ \{ H, f \} = 0, \]  
\hspace{1cm} (10.20)

then \( df/dt = 0 \), i.e. that function is an integral of motion. Moreover, it turns out that if we already know two integrals of motion, say \( f \) and \( g \), then the following function,

\[ F \equiv \{ f, g \}, \]  
\hspace{1cm} (10.21)

is also an integral of motion – the so-called \textit{Poisson theorem}. In order to prove it, we may use the Jacobi identity (19) with \( h = H \). Next, using Eq. (17) to express the Poisson brackets \( \{ g, H \} \), \( \{ H, g \} \), and \( \{ H, \{ f, g \} \} = \{ H, F \} \) via the full and partial time derivatives of the functions \( f \), \( g \), and \( F \), we get

\[ \left\{ f, \frac{\partial g}{\partial t} - \frac{dg}{dt} \right\} + \left\{ g, \frac{\partial f}{\partial t} - \frac{df}{dt} \right\} + \frac{dF}{dt} - \frac{\partial F}{\partial t} = 0, \]  
\hspace{1cm} (10.22)

so that if \( f \) and \( g \) are indeed integrals of motion, i.e., \( df/dt = dg/dt = 0 \), then

\[ \frac{dF}{dt} = \frac{\partial F}{\partial t} + \left\{ f, \frac{\partial g}{\partial t} \right\} - \left\{ g, \frac{\partial f}{\partial t} \right\} = \frac{\partial F}{\partial t} - \left[ \{ f, \frac{\partial}{\partial t}, g \} + \{ f, \frac{\partial g}{\partial t} \} \right]. \]  
\hspace{1cm} (10.23)

Plugging Eq. (21) into the first term of the right-hand side of this equation, and differentiating it by parts, we get \( dF/dt = 0 \), i.e. \( F \) is indeed an integral of motion as well.

Finally, one more important role of the Hamilton formalism is that it allows one to trace the close formal connection between classical and quantum mechanics. Indeed, using Eq. (18) to calculate the Poisson brackets of the generalized coordinates and momenta, we readily get

\[ \{ q_j, q'_j \} = 0, \quad \{ p_j, p'_j \} = 0, \quad \{ q_j, p'_j \} = -\delta_{jj}. \]  
\hspace{1cm} (10.24)

In quantum mechanics, the operators of these variables (“observables”) obey commutation relations\(^6\)

\[ [\hat{q}_j, \hat{q}'_j] = 0, \quad [\hat{p}_j, \hat{p}'_j] = 0, \quad [\hat{q}_j, \hat{p}'_j] = i\hbar \delta_{jj}, \]  
\hspace{1cm} (10.25)

where the definition of the commutator, \( [\hat{g}, \hat{f}] \equiv \hat{g} \hat{f} - \hat{f} \hat{g} \), is to a certain extent\(^7\) similar to that (18) of the Poisson bracket. We see that the classical relations (24) are similar to the quantum-mechanical relations (25) if the following parallel has been made:

\(^6\) See, e.g., QM Sec. 2.1.

\(^7\)
This analogy extends well beyond Eqs. (24)-(25). For example, making the replacement \((26)\) in Eq. (17), we get

\[
\frac{d\hat{f}}{dt} = \frac{\partial \hat{f}}{\partial t} + \frac{i}{\hbar} \left[ \hat{H}, \hat{f} \right],
\]

i.e.

\[
\frac{d\hat{f}}{dt} = \frac{i}{\hbar} \left[ \hat{H}, \hat{f} \right],
\]

which is the correct equation of operator evolution in the Heisenberg picture of quantum mechanics.\(^8\)

The parallel \((26)\) may give important clues in the search for the proper quantum-mechanical operator of a given observable – which is not always elementary.

10.2. Adiabatic invariance

One more application of the Hamiltonian formalism in classical mechanics is the solution of the following problem.\(^9\) Earlier in the course, we already studied some effects of time variation of parameters of a single oscillator (Sec. 5.5) and coupled oscillators (Sec. 6.5). However, those discussions were focused on the case when the parameter variation speed is comparable with the own oscillation frequency (or frequencies) of the system. Another practically important case is when some system’s parameter (let us call it \(\lambda\)) is changed much more slowly (adiabatically\(^10\)),

\[
|\frac{\dot{\lambda}}{\lambda}| \ll \frac{1}{\mathcal{T}},
\]

where \(\mathcal{T}\) is a typical period of oscillations in the system. Let us consider a 1D system whose Hamiltonian \(H(q, p, \lambda)\) depends on time only via such a slow evolution of such parameter \(\dot{\lambda} = \dot{\lambda}(t)\), and whose initial energy restricts the system’s motion to a finite coordinate interval – see, e.g., Fig. 3.2c.

Then, as we know from Sec. 3.3, if the parameter \(\lambda\) is constant, the system performs a periodic (though not necessarily sinusoidal) motion back and forth the \(q\)-axis, or, in a different language, along a closed trajectory on the phase plane \([q, p]\) – see Fig. 1.\(^11\) According to Eq. (8), in this case \(H\) is constant along the trajectory. (To distinguish this particular value from the Hamiltonian function as such, I will call it \(E\), implying that this constant coincides with the full mechanical energy \(E\) - as does for the Hamiltonian (10), though this assumption is not necessary for the calculation made below.)

The oscillation period \(\mathcal{T}\) may be calculated as a contour integral along this closed trajectory:

\(^7\) There is, of course, a conceptual difference between the “usual” products of the function derivatives participating in the Poisson brackets, and the operator “products” (meaning their sequential action on a state vector) forming the commutator.

\(^8\) See, e.g., QM Sec. 4.6.

\(^9\) Various aspects of this problem and its quantum-mechanical extensions were first discussed by L. Le Cornu (1895), Lord Rayleigh (1902), H. Lorentz (1911), P. Ehrenfest (1916), and M. Born and V. Fock (1928).

\(^10\) This term is also used in thermodynamics and statistical mechanics, where it implies not only a slow parameter variation (if any) but also thermal insulation of the system – see, e.g., SM Sec. 1.3. Evidently, the latter condition is irrelevant in our current context.

\(^11\) In Sec. 5.6, we discussed this plane for the particular case of sinusoidal oscillations – see Fig. 5.9
\[ \tau = \int_0^\tau dt = \oint \frac{dt}{dq} = \oint \frac{1}{q} dq. \]  

(10.29)

Using the first of the Hamilton equations (7), we may represent this integral as

\[ \tau = \oint \frac{1}{\partial H / \partial p} dq. \]  

(10.30)

At each given point \( q \), \( H = E \) is a function of \( p \) alone, so that we may flip the partial derivative in the denominator just as the full derivative, and rewrite Eq. (30) as

\[ \tau = \oint \frac{\partial p}{\partial E} dq. \]  

(10.31)

For the particular Hamiltonian (10), this relation is immediately reduced to Eq. (3.27), now in the form of a contour integral:

\[ \tau = \left( \frac{m_{\text{eff}}}{2} \right)^{1/2} \oint \frac{1}{[E - U_{\text{eff}}(q)]^{1/2}} dq. \]  

(10.32)

Naively, it may look that these formulas may be also used to find the motion period’s change when the parameter \( \lambda \) is being changed adiabatically, for example, by plugging the given functions \( m_{\text{eff}}(\lambda) \) and \( U_{\text{eff}}(q, \lambda) \) into Eq. (32). However, there is no guarantee that the energy \( E \) in that integral would stay constant as the parameter changes, and indeed we will see below that this is not necessarily the case. Even more interestingly, in the most important case of the harmonic oscillator (\( U_{\text{eff}} = \kappa_{\text{eff}} q^2/2 \)), whose oscillation period \( \tau \) does not depend on \( E \) (see Eq. (3.29) and its discussion), its variation in the adiabatic limit (28) may be readily predicted: \( \tau(\lambda) = 2\pi/\omega_0(\lambda) = 2\pi [m_{\text{eff}}(\lambda)/\kappa_{\text{eff}}(\lambda)]^{1/2} \), but the dependence of the oscillation energy \( E \) (and hence the oscillation amplitude) on \( \lambda \) is not immediately obvious.

In order to address this issue, let us use Eq. (8) (with \( E = H \)) to represent the rate of the energy change with \( \lambda(t) \), i.e. in time, as

\[ \frac{dE}{dt} = \frac{\partial H}{\partial t} = \frac{\partial H}{\partial \lambda} \frac{d\lambda}{dt}. \]  

(10.33)

Since we are interested in a very slow (adiabatic) time evolution of energy, we can average Eq. (33) over fast oscillations in the system, for example over one oscillation period \( \tau \), treating \( d\lambda/dt \) as a constant during this averaging. (This is the most critical point of this argumentation, because at any non-
vanishing rate of parameter change the oscillations are, strictly speaking, non-periodic.\textsuperscript{12)} The averaging yields
\[
\frac{dE}{dt} = -\frac{d\lambda}{dt} \frac{\partial H}{\partial \lambda} = -\frac{d\lambda}{dt} \int \frac{\partial H}{\partial \lambda} \, dt.
\] (10.34)

Transforming this time integral to the contour one, just as we did at the transition from Eq. (29) to Eq. (30), and then using Eq. (31) for \( T \), we get
\[
\frac{dE}{dt} = -\frac{d\lambda}{dt} \int \frac{\partial H}{\partial \lambda} \, dq.
\] (10.35)

At each point \( q \) of the contour, \( H \) is a function of not only \( \lambda \), but also of \( p \), which may be also \( \lambda \)-dependent, so that if \( E \) is fixed, the partial differentiation of the relation \( E = H \) over \( \lambda \) yields
\[
\frac{\partial H}{\partial \lambda} + \frac{\partial H}{\partial p} \frac{\partial p}{\partial \lambda} = 0, \quad \text{i.e.,} \quad \frac{\partial H / \partial \lambda}{\partial H / \partial p} = -\frac{\partial p}{\partial \lambda}.
\] (10.36)

Plugging the last relation to Eq.(35), we get
\[
\frac{dE}{dt} = -\frac{d\lambda}{dt} \int \frac{\partial p}{\partial \lambda} \, dq.
\] (10.37)

Since the left-hand side of Eq. (37) and the derivative \( d\lambda/dt \) do not depend on \( q \), we may move them into the integrals over \( q \) as constants, and rewrite Eq. (37) as
\[
\int \left( \frac{\partial p}{\partial E} \frac{dE}{dt} + \frac{\partial p}{\partial \lambda} \frac{d\lambda}{dt} \right) \, dq = 0.
\] (10.38)

Now let us consider the following integral over the same phase-plane contour,
\[
J = \frac{1}{2\pi} \int p \, dq,
\] (10.39)
called the \textit{action variable}. Just to understand its physical sense, let us calculate \( J \) for a harmonic oscillator (14). As we know very well from Chapter 5, for such an oscillator, \( q = A \cos \psi, \ p = -m_e\omega_0 A \sin \psi \) (with \( \Psi = \omega_0 t + \text{const} \)), so that \( J \) may be easily expressed either via the oscillations’ amplitude \( A \), or via their energy \( E = H = m_e \omega_0^2 A^2/2 \):
\[
J = \frac{1}{2\pi} \int p \, dq = \frac{1}{2\pi} \int_{-\pi}^{\pi} (-m_e \omega_0 A \sin \psi) d(A \cos \psi) = \frac{m_e \omega_0}{2} \frac{A^2}{\omega_0} = \frac{E}{\omega_0}.
\] (10.40)

\textsuperscript{12} Because of the implied nature of this conjecture (which is very close to the assumptions made at the derivation of the reduced equations in Sec. 5.3), new, more strict (but also much more cumbersome) proofs of the final Eq. (42) are still being offered in literature – see, e.g., C. Wells and S. Siklos, \textit{Eur. J. Phys.} 28, 105 (2007) and/or A. Lobo \textit{et al.}, \textit{Eur. J. Phys.} 33, 1063 (2012).
Returning to a general system with adiabatically changed parameter $\lambda$, let us use the definition of $J$, Eq. (39), to calculate its time derivative, again taking into account that at each point $q$ of the trajectory, $p$ is a function of $E$ and $\lambda$:

$$\frac{dJ}{dt} = \frac{1}{2\pi} \oint dq \left[ \frac{dp}{dt} \right] = \frac{1}{2\pi} \oint dq \left( \frac{\partial p}{\partial E} \frac{dE}{dt} + \frac{\partial p}{\partial \lambda} \frac{d\lambda}{dt} \right).$$

(10.41)

Within the accuracy of our approximation, in which the contour integrals (38) and (41) are calculated along a closed trajectory, the factor $dE/dt$ is indistinguishable from its time average, and these integrals coincide so that the result (38) is applicable to Eq. (41) as well. Hence, we have finally arrived at a very important result: at a slow parameter variation, $dJ/dt = 0$, i.e. the action variable remains constant:

$$J = \text{const}.$$  

(10.42)

This is the famous \textit{adiabatic invariance}.\textsuperscript{13} In particular, according to Eq. (40), in a harmonic oscillator, the energy of oscillations changes proportionately to its own (slowly changed) frequency.

Before moving on, let me briefly note that the adiabatic invariance is not the only application of the action variable $J$. Since the initial choice of generalized coordinates and velocities (and hence the generalized momenta) in analytical mechanics is arbitrary (see Sec. 2.1), it is almost evident that $J$ may be taken for a new generalized momentum corresponding to a certain new generalized coordinate $\Theta$,\textsuperscript{14} and that the pair $\{J, \Theta\}$ should satisfy the Hamilton equations (7), in particular,

$$\frac{d\Theta}{dt} = \frac{\partial H}{\partial J}.$$  

(10.43)

Following the commitment of Sec. 1 (made there for the “old” arguments $q_j, p_j$), before the differentiation on the right-hand side of Eq. (43), $H$ should be expressed as a function (besides $t$) of the “new” arguments $J$ and $\Theta$. For time-independent Hamiltonian systems, $H$ is uniquely defined by $J$ – see, e.g., Eq. (40). Hence in this case the right-hand side of Eq. (43) does not depend on either $t$ or $\Theta$, so that according to that equation, $\Theta$ (called the \textit{angle variable}) is a linear function of time:

$$\Theta = \frac{\partial H}{\partial J} t + \text{const}.$$  

(10.44)

For a harmonic oscillator, according to Eq. (40), the derivative $\partial H/\partial J = \partial E/\partial J$ is just $\omega_0 \equiv 2\pi/T$, so that $\Theta = \omega_0 t + \text{const}$, i.e. it is just the full phase $\Psi$ that was repeatedly used in this course – especially in Chapter 5. It may be shown that a more general form of this relation,

$$\frac{\partial H}{\partial J} = \frac{2\pi}{T},$$  

(10.45)

\textsuperscript{13} For certain particular oscillators, e.g., a point pendulum, Eq. (42) may be also proved directly – an exercise highly recommended to the reader.

\textsuperscript{14} This, again, is a plausible argument but not a strict proof. Indeed: though, according to its definition (39), $J$ is nothing more than a sum of several (formally, the infinite number of) values of the momentum $p$, they are not independent, but have to be selected on the same closed trajectory on the phase plane. For more mathematical vigor, the reader is referred to Sec. 45 of \textit{Mechanics} by Landau and Lifshitz (which was repeatedly cited above), which discusses the general rules of the so-called \textit{canonical transformations} from one set of Hamiltonian arguments to another one – say from $\{p, q\}$ to $\{J, \Theta\}$.
is valid for an arbitrary system described by Eq. (10). Thus, Eq. (44) becomes

$$\Theta = 2\pi \frac{t}{T} + \text{const}.$$  

(10.46)

This means that for an arbitrary (nonlinear) 1D oscillator, the angle variable $\Theta$ is a convenient generalization of the full phase $\Psi$. Due to this reason, the variables $J$ and $\Theta$ present a convenient tool for discussion of certain fine points of the dynamics of strongly nonlinear oscillators – for whose discussion I, unfortunately, do not have time/space.\(^{15}\)

10.3. The Hamilton principle

Now let me show that the Lagrange equations of motion, that were derived in Sec. 2.1 from the Newton laws, may be also obtained from the so-called Hamilton principle,\(^{16}\) namely the condition of a minimum (or rather an extremum) of the following integral called action:

$$S \equiv \int_{t_{\text{ini}}}^{t_{\text{fin}}} L dt ,$$  

(10.47)

where $t_{\text{ini}}$ and $t_{\text{fin}}$ are, respectively, the initial and final moments of time, at which all generalized coordinates and velocities are considered fixed (not varied) – see Fig. 2.

The proof of that statement (in the realm of classical mechanics) is rather simple. Considering, similarly to Sec. 2.1, a possible virtual variation of the motion, described by infinitesimal deviations $\{ \delta q_j(t), \delta \dot{q}_j(t) \}$ from the real motion, the necessary condition for $S$ to be minimal is

$$\delta S \equiv \int_{t_{\text{ini}}}^{t_{\text{fin}}} \delta L dt = 0 ,$$  

(10.48)

\(^{15}\) An interested reader may be referred, for example, to Chapter 6 in J. Jose and E. Saletan, Classical Dynamics, Cambridge U. Press, 1998.

\(^{16}\) It is also called the “principle of least action”, or the “principle of stationary action”. (These names may be fairer in the context of a long history of the development of the principle, starting from its simpler particular forms, which includes the names of P. de Fermat, P. Maupertuis, L. Euler, and J.-L. Lagrange.)
where $\delta S$ and $\delta L$ are the variations of the action and the Lagrange function, corresponding to the set \{ $\delta q_j(t)$, $\delta \dot{q}_j(t)$ \}. As has been already discussed in Sec. 2.1, we can use the operation of variation just as the usual differentiation (but at a fixed time, see Fig. 2), swapping these two operations if needed – see Fig. 2.3 and its discussion. Thus, we may write

$$\delta L = \sum_j \left( \frac{\partial L}{\partial q_j} \delta q_j + \frac{\partial L}{\partial \dot{q}_j} \delta \dot{q}_j \right) = \sum_j \left( \frac{\partial L}{\partial q_j} \delta q_j + \sum_j \frac{\partial L}{\partial \dot{q}_j} \frac{d}{dt} \delta q_j \right).$$

(10.49)

After plugging the last expression into Eq. (48), we can integrate the second term by parts:

$$\delta S = \int_{t_{ini}}^{t_{fin}} \sum_j \left[ \frac{\partial L}{\partial q_j} \delta q_j + \delta \dot{q}_j \right] dt = \int_{t_{ini}}^{t_{fin}} \sum_j \frac{\partial L}{\partial q_j} \delta q_j dt + \sum_j \left[ \frac{\partial L}{\partial \dot{q}_j} \delta \dot{q}_j \right]_{t_{ini}}^{t_{fin}} - \int_{t_{ini}}^{t_{fin}} \sum_j \delta q_j \left( \frac{\partial L}{\partial \dot{q}_j} \right) dt = 0.$$  

(10.50)

Since the generalized coordinates in the initial and final points are considered fixed (not affected by the variation), all $\delta q_j(t_{ini})$ and $\delta q_j(t_{fin})$ vanish, so that the second term in the last form of Eq. (50) vanishes as well. Now multiplying and dividing the last term of that expression by $dt$, we finally get

$$\delta S = \int_{t_{ini}}^{t_{fin}} \sum_j \frac{\partial L}{\partial q_j} \delta q_j dt - \sum_j \int_{t_{ini}}^{t_{fin}} \delta q_j \left( \frac{d}{dt} \frac{\partial L}{\partial \dot{q}_j} \right) dt = - \int_{t_{ini}}^{t_{fin}} \sum_j \left[ \frac{d}{dt} \left( \frac{\partial L}{\partial \dot{q}_j} \right) - \frac{\partial L}{\partial \dot{q}_j} \right] \delta q_j dt = 0.$$  

(10.51)

This relation should hold for an arbitrary set of functions $\delta q_j(t)$, and for any time interval, and this is only possible if the expressions in the square brackets equal zero for all $j$, giving us the set of the Lagrange equations (2.19). So, the Hamilton principle indeed gives the Lagrange equations of motion.

It is fascinating to see how does the Hamilton principle work for particular cases. As a very simple example, let us consider the usual 1D linear oscillator, with the Lagrangian function used so many times before in this course:

$$L = \frac{m}{2} q^2 - \frac{m \omega_0^2}{2} q^2.$$  

(10.52)

As we know very well, the Lagrange equations of motion for this $L$ are exactly satisfied by any sinusoidal function with the frequency $\omega_0$, in particular by a symmetric function of time

$$q_e(t) = A \cos \omega_0 t, \quad \text{so that } \dot{q}_e(t) = -A \omega_0 \sin \omega_0 t.$$  

(10.53)

On a limited time interval, say $0 \leq \omega_0 t \leq +\pi/2$, this function is rather smooth and may be well approximated by another simple, reasonably selected functions of time, for example

$$q_a(t) = A \left( 1 - \lambda t^2 \right), \quad \text{so that } \dot{q}_a(t) = -2A \lambda t,$$  

(10.54)

provided that the parameter $\lambda$ is also selected in a reasonable way. Let us take $\lambda = (\pi/2 \omega_0)^2$, so that the approximate function $q_a(t)$ coincides with the exact function $q_e(t)$ at both ends of our time interval (Fig.3):
and check which of them the Hamilton principle “prefers”, i.e. which function gives the least action.

\[
q_a(t_{\text{ini}}) = q_c(t_{\text{ini}}) = A, \quad q_a(t_{\text{fin}}) = q_c(t_{\text{fin}}) = 0, \quad \text{where } t_{\text{ini}} \equiv 0, \quad t_{\text{fin}} \equiv \frac{\pi}{2\omega_0},
\]

(10.55)

An elementary calculation of the action (47), corresponding to these two functions, yields

\[
S_e = \left( \frac{\pi}{8} - \frac{\pi}{8} \right) m\omega_0 A^2 = 0, \quad S_a = \left( \frac{4}{3\pi} - \frac{2\pi}{15} \right) m\omega_0 A^2 \approx (0.4244 - 0.4189) m\omega_0 A^2 > 0,
\]

(10.56)

with the first terms in all the parentheses coming from the time integrals of the kinetic energy, and the second terms, from those of the potential energy.

This result shows, first, that the exact function of time, for which these two contributions exactly cancel,\(^{17}\) is indeed “preferable” for minimizing the action. Second, for the approximate function, the two contributions to the action are rather close to the exact ones, and hence almost cancel each other, signaling that this approximation is very reasonable. It is evident that in some cases when the exact analytical solution of the equations of motion cannot be found, the minimization of \(S\) by adjusting one or more free parameters, incorporated into a guessed “trial” function, may be used to find a reasonable approximation for the actual law of motion.\(^{18}\)

It is also very useful to make the notion of action \(S\), defined by Eq. (47), more transparent by calculating it for the simple case of a single particle moving in a potential field that conserves its energy \(E = T + U\). In this case, the Lagrangian function \(L = T - U\) may be represented as

\[
L = T - U = 2T - (T + U) = 2T - E = mv^2 - E,
\]

(10.57)

with a time-independent \(E\), so that

\[
S = \int Ldt = \int mv^2 dt - Et + \text{const.}
\]

(10.58)

\(^{17}\) Such cancellation, i.e. the equality \(S = 0\), is of course not the general requirement; it is specific only for this particular example.

\(^{18}\) This is essentially a classical analog of the variational method of quantum mechanics – see, e.g., QM Sec. 2.9.
Representing the expression under the remaining integral as \( mv \cdot dt = p \cdot (dr/dt) dt = p \cdot dr \), we finally get
\[
S = \int p \cdot dr - Et + \text{const} = S_0 - Et + \text{const},
\]
where the time-independent integral
\[
S_0 = \int p \cdot dr
\]
is frequently called the *abbreviated action*.

This expression may be used to establish one more important connection between classical and quantum mechanics – now in its Schrödinger picture. Indeed, in the quasiclassical (WKB) approximation of that picture\(^{19}\) a particle of fixed energy is described by a de Broglie wave
\[
\Psi(r,t) \propto \exp \left\{ i \left[ \int k \cdot dr - \omega t + \text{const} \right] \right\},
\]
where the wave vector \( k \) is proportional to the particle’s momentum, and the frequency \( \omega \), to its energy:
\[
k = \frac{p}{\hbar}, \quad \omega = \frac{E}{\hbar}.
\]
Plugging these expressions into Eq. (61) and comparing the result with Eq. (59), we see that the WKB wavefunction may be represented as
\[
\Psi \propto \exp \left\{ i S / \hbar \right\}.
\]

Hence Hamilton’s principle (48) means that the total phase of the quasiclassical wavefunction should be minimal along the particle’s real trajectory. But this is exactly the so-called *eikonal minimum principle* well known from the optics (though valid for any other waves as well), where it serves to define the ray paths in the geometric optics limit – similar to the WKB approximation condition. Thus, the ratio \( S/\hbar \) may be considered just as the eikonal, i.e. the total phase accumulation, of the de Broglie waves.\(^{20}\)

Now, comparing Eq. (60) with Eq. (39), we see that the action variable \( J \) is just the change of the abbreviated action \( S_0 \) along a single phase-plane contour (divided by \( 2\pi \)). This means, in particular, that in the WKB approximation, \( J \) is the number of de Broglie waves along the classical trajectory of a particle, i.e. an integer value of the corresponding quantum number. If the system’s parameters are changed slowly, the quantum number has to stay integer, and hence \( J \) cannot change, giving a quantum-mechanical interpretation of the adiabatic invariance. This is really fascinating: a fact of classical mechanics may be “derived” (or at least understood) more easily from the quantum mechanics’ standpoint.\(^{21}\)

\(^{19}\) See, e.g., QM Sec. 3.1.

\(^{20}\) Indeed, Eq. (63) was the starting point for R. Feynman’s development of his path-integral formulation of quantum mechanics – see, e.g., QM Sec. 5.3.

\(^{21}\) As a reminder, we have run into a similarly pleasant surprise at our discussion of the non-degenerate parametric excitation in Sec. 6.7.
10.4. The Hamilton-Jacobi equation

The action $S$, defined by Eq. (47), may be used for one more analytical formulation of classical mechanics. For that, we need to make one more, different commitment: $S$ has to be considered a function of the following independent arguments: the final time point $t_{\text{fin}}$ (which I will, for brevity, denote as $t$ in this section), and the set of generalized coordinates (but not of the generalized velocities!) at that point:

$$S \equiv \int_{t_{\text{ini}}}^{t} L dt = S[t, q_j(t)].$$  \hspace{1cm} (10.64)

Let us calculate the variation of this (from the variational point of view, new!) function, resulting from an arbitrary combination of variations of the final values $q_j(t)$ of the coordinates while keeping $t$ fixed. Formally this may be done by repeating the variational calculations described by Eqs. (49)-(51), besides that now the variations $\delta q_j$ at the finite point ($t$) do not necessarily equal zero. As a result, we get

$$\delta S = \sum_j \left( \frac{\partial L}{\partial q_j} \delta q_j \right)_{t_{\text{ini}}} - \int_{t_{\text{ini}}}^{t} \sum_j \left[ \frac{d}{dt} \left( \frac{\partial L}{\partial \dot{q}_j} \right) - \frac{\partial L}{\partial q_j} \right] \delta q_j dt.$$  \hspace{1cm} (10.65)

For the motion along the real trajectory, i.e. satisfying the Lagrange equations, the second term of this expression equals zero. Hence Eq. (65) shows that, for (any) fixed time $t$,

$$\frac{\partial S}{\partial q_j} = \frac{\partial L}{\partial \dot{q}_j}.$$  \hspace{1cm} (10.66)

But the last derivative is nothing else than the generalized momentum $p_j$ – see Eq. (2.31), so that

$$\frac{\partial S}{\partial q_j} = p_j.$$  \hspace{1cm} (10.67)

(As a reminder, both parts of this relation refer to the final moment $t$ of the trajectory.) As a result, the full derivative of the action $S[t, q_j(t)]$ over time takes the form

$$\frac{dS}{dt} = \frac{\partial S}{\partial t} + \sum_j \frac{\partial S}{\partial q_j} \dot{q}_j = \frac{\partial S}{\partial t} + \sum_j p_j \dot{q}_j.$$  \hspace{1cm} (10.68)

Now, by the very definition (64), the full derivative $dS/dt$ is nothing more than the function $L$, so that Eq. (67) yields

$$\frac{\partial S}{\partial t} = L - \sum_j p_j \dot{q}_j.$$  \hspace{1cm} (10.69)

However, according to the definition (2) of the Hamiltonian function $H$, the right-hand side of Eq. (69) is just $-H$, so that we get an extremely simply-looking Hamilton-Jacobi equation

$$\frac{\partial S}{\partial t} = -H.$$  \hspace{1cm} (10.70)

This simplicity is, however, rather deceiving, because in order to use this equation for the calculation of the function $S(t, q_j)$ for any particular problem, the Hamiltonian function has to be first expressed as a function of time $t$, generalized coordinates $q_j$, and the generalized momenta $p_j$ (which
may be, according to Eq. (67), represented just as derivatives $\frac{\partial S}{\partial q_j}$. Let us see how does this procedure work for the simplest case of a 1D system with the Hamiltonian function given by Eq. (10). In this case, the only generalized momentum is $p = \frac{\partial S}{\partial q}$, so that

$$H = \frac{p^2}{2m_{ef}} + U_{ef}(q,t) = \frac{1}{2m_{ef}} \left( \frac{\partial S}{\partial q} \right)^2 + U_{ef}(q,t),$$

and Eq. (70) is reduced to a partial differential equation,

$$\frac{\partial S}{\partial t} + \frac{1}{2m_{ef}} \left( \frac{\partial S}{\partial q} \right)^2 + U_{ef}(q,t) = 0.$$  

(10.72)

Its solution may be readily found in the easiest case of time-independent potential energy $U_{ef} = U_{ef}(q)$. In this case, Eq. (72) is evidently satisfied by the following variable-separated solution:

$$S(t,q) = S_0(q) + \text{const} \times t.$$  

(10.73)

Plugging this solution into Eq. (72), we see that since the sum of the two last terms on the left-hand side of that equation represents the full mechanical energy $E$, the constant in Eq. (73) is nothing but $-E$. Thus for the function $S_0(q)$ we get an ordinary differential equation

$$-E + \frac{1}{2m_{ef}} \left( \frac{dS_0}{dq} \right)^2 + U_{ef}(q) = 0.$$  

(10.74)

Integrating it, we get

$$S_0 = \int \left[ 2m_{ef} \left( E - U_{ef}(q) \right) \right]^{1/2} dq + \text{const},$$  

(10.75)

so that, finally, the action is equal to

$$S = \int \left[ 2m_{ef} \left( E - U_{ef}(q) \right) \right]^{1/2} dq - Et + \text{const}.$$  

(10.76)

For the case of 1D motion of a single 1D particle, i.e. for $q = x$, $m_{ef} = m$, $U_{ef}(q) = U(x)$, this solution is just the 1D case of the more general Eqs. (59)-(60), which were obtained above by a much more simple way. (In particular, $S_0$ is just the abbreviated action.)

This particular case illustrates that the Hamilton-Jacobi equation is not the most efficient way for the solution of most practical problems of classical mechanics. However, it may be rather useful for studies of certain mathematical aspects of dynamics. Moreover, in the early 1950s this approach was extended to a completely different field – the optimal control theory, in which the role of action $S$ is played by the so-called cost function – a certain functional of a system (understood in a very general sense of this term), that should be minimized by an optimal choice of a control signal – a function of time that affects the system’s evolution in time. From the point of view of this mathematical theory, Eq. (70) is a particular case of a more general Hamilton-Jacobi-Bellman equation.23

23 See, e.g., T. Bertsekas, Dynamic Programming and Optimal Control, vols. 1 and 2, Aetna Scientific, 2005 and 2007. The reader should not be intimidated by the very unnatural term “dynamic programming”, which was invented by the founding father of this field, Richard Ernest Bellman, to lure government bureaucrats into funding his research, deemed too theoretical at that time. (Presently, it has a broad range of important applications.)
10.5. Exercise problems

In each of Problems 10.1-10.3, for the given system:

(i) derive the Hamilton equations of motion, and
(ii) check whether the equations are equivalent to those derived from the Lagrangian formalism.

10.1. Our “testbed” system: a bead on a ring, being rotated with a fixed angular velocity $\omega$ about its vertical diameter – see Fig. 2.1, reproduced on the right.

10.2. The system considered in Problem 2.3: a pendulum hanging from a horizontal support whose motion law $x_0(t)$ is fixed – see the figure on the right. (No vertical plane constraint.)

10.3. The system considered in Problem 2.8: a block of mass $m$ that can slide, without friction, along the inclined surface of a heavy wedge of mass $m'$. The wedge is free to move, also without friction, along a horizontal surface – see the figure on the right. (Both motions are within the vertical plane containing the steepest slope line.)

10.4. Find and solve the equations of motion of a particle with the following Hamiltonian function:
$$H = \frac{1}{2m}(p + ar)^2,$$
where $a$ is a constant scalar.

10.5. Let $L$ be the Lagrangian function, and $H$ the Hamiltonian function, of the same system. What three of the following four statements,
$$\begin{align*}
(i) \quad \frac{dL}{dt} &= 0, \\
(ii) \quad \frac{\partial L}{\partial t} &= 0, \\
(iii) \quad \frac{dH}{dt} &= 0, \\
(iv) \quad \frac{\partial H}{\partial t} &= 0,
\end{align*}$$
are equivalent? Give an example when those three equalities hold, but the fourth one does not.

10.6. Calculate the Poisson brackets of a Cartesian component of the angular momentum $\mathbf{L}$ of a particle moving in a central force field and its Hamiltonian function $H$, and discuss the most evident implication of the result.
10.7. After small oscillations had been initiated in the point pendulum shown in Fig. on the right, the string is being pulled up slowly, so that the pendulum’s length $l$ is being reduced. Neglecting dissipation,

(i) prove by a direct calculation that the oscillation energy is indeed changing proportionately to the oscillation frequency, as it follows from the constancy of the corresponding adiabatic invariant (40); and

(ii) find the $l$-dependence of the amplitudes of the angular and linear deviations from the equilibrium.

10.8. The mass $m$ of a small body that performs 1D oscillations in the potential well $U(x) = ax^{2n}$, with $n > 0$, is being changed slowly. Calculate the oscillation energy $E$ as a function of $m$.

10.9. A stiff ball is bouncing vertically from the floor of an elevator whose upward acceleration changes very slowly. Neglecting the energy dissipation, calculate how much does the bounce height $h$ change during the acceleration’s increase from 0 to $g$. Is your result valid for an equal but abrupt increase of the elevator’s acceleration?

Chapter 1. Electric Charge Interaction

This brief chapter describes the basics of electrostatics – the study of interactions between static (or slowly moving) electric charges. Much of this material should be known to the reader from their undergraduate studies; because of that, the explanations are very brief.\(^1\)

1.1. The Coulomb law

A quantitative discussion of classical electrodynamics, starting from the electrostatics, requires a common agreement on the meaning of the following notions:\(^2\)

- electric charges \(q_k\), as revealed, most explicitly, by observation of electrostatic interaction between the charged particles;

- electric charge conservation – the fact that the algebraic sum of \(q_k\) of all particles inside any closed volume is conserved, unless the charged particles cross the volume’s border; and

- point charges – the charged particles so small that their position in space, for the given problem, may be completely described (in a given reference frame) by their radius-vectors \(r_k\).

I will assume that these notions are well known to the reader – though my strong advice is to give some thought to their vital importance. Using these notions, the Coulomb law\(^3\) for the interaction of two point, stationary charges may be formulated as follows:

\[
F_{kk'} = \kappa q_k q_{k'} \frac{r_k - r_{k'}}{|r_k - r_{k'}|^3} \equiv \kappa q_k q_{k'} \frac{n_{kk'}}{R_{kk'}},
\]

\[
\text{with } R_{kk'} \equiv |r_k - r_{k'}|, \quad n_{kk'} \equiv \frac{R_{kk'}}{R_{kk'}}, \quad R_{kk'} \equiv |R_{kk'}|.
\]

where \(F_{kk'}\) denotes the electrostatic (“Coulomb”) force exerted on charge number \(k\) by charge number \(k'\), separated from it by distance \(R_{kk'}\) – see Fig. 1.

---

\(^1\) For remedial reading, I can recommend, for example, D. Griffiths, *Introduction to Electrodynamics*, 4\(^{th}\) ed., Pearson, 2015.

\(^2\) On top of the more general notions of the classical Newtonian space, point particles and forces, as used in classical mechanics – see, e.g., CM Sec. 1.1.

\(^3\) Formulated in 1785 by Charles-Augustin de Coulomb, on basis of his earlier experiments, in turn rooting in previous studies of electrostatic phenomena, with notable contributions by William Gilbert, Otto von Guericke, Charles François de Cisternay Du Fay, and Benjamin Franklin.
I am confident that this law is very familiar to the reader, but a few comments may still be due:

(i) Flipping the indices \( k \) and \( k' \), we see that Eq. (1) complies with the 3rd Newton law: the reciprocal force is equal in magnitude but opposite in direction: \( \mathbf{F}_{kk'} = -\mathbf{F}_{k'k} \).

(ii) Since the vector \( \mathbf{R}_{kk'} = \mathbf{r}_k - \mathbf{r}_{k'} \), by its definition, is directed from the point \( \mathbf{r}_k \) toward the point \( \mathbf{r}_{k'} \) (Fig. 1), Eq. (1) correctly describes the experimental fact that charges of the same sign (i.e. with \( q_k q_{k'} > 0 \)) repulse, while those with opposite signs (\( q_k q_{k'} < 0 \)) attract each other.

(iii) In some textbooks, the Coulomb law (1) is given with the qualifier “in free space” or “in vacuum”. However, actually Eq. (1) remains valid even in the presence of any other charges, or example, of internal charges in quasi-continuous media that may surround the two charges (number \( k \) and \( k' \)) under consideration. The confusion stems from the fact (to be discussed in detail in Chapter 3 below) that in some cases it is convenient to formally represent the effect of the other charges as an effective modification of the Coulomb law.

(iv) The constant \( \kappa \) in Eq. (1) depends on the system of units we use. In the Gaussian units, \( \kappa \) is set to 1, for the price of introducing a special unit of charge (the statcoulomb) that would make experimental data compatible with Eq. (1), for forces \( \mathbf{F}_{k'k} \) measured in the Gaussian units (dynes). On the other hand, in the International System (“SI”) of units, the charge unit is one coulomb (abbreviated C), and \( \kappa \) is different from unity:

\[
\kappa|_\text{SI} = \frac{1}{4\pi\varepsilon_0}, \quad (1.2)
\]

where \( \varepsilon_0 \approx 8.854 \times 10^{-12} \) is called the electric constant.

Unfortunately, the continuing struggle between zealot proponents of these two systems bears all not-so-nice features of a religious war, with a similarly slim chance for any side to win it in any foreseeable future. In my humble view, each of these systems has its advantages and handicaps (to be noted below on several occasions), and every educated physicist should have no problem with using any of them. Following insisting recommendations of international scientific unions, I am using SI units through my series. However, for the readers’ convenience, in this course (where the difference between the Gaussian and SI systems is especially significant) I will write the most important formulas with the constant (2) clearly displayed – for example, Eq. (1) as

\[
\mathbf{F}_{k'k} = \frac{q_k q_{k'}}{4\pi\varepsilon_0} \frac{\mathbf{r}_k - \mathbf{r}_{k'}}{|\mathbf{r}_k - \mathbf{r}_{k'}|^3}, \quad (1.3)
\]

so that the transfer to the Gaussian units may be performed just by the formal replacement \( 4\pi\varepsilon_0 \rightarrow 1 \). (In the cases when the transfer is not obvious, I will duplicate such formulas in the Gaussian units.)

Besides Eq. (3), another key experimental law of electrostatics is the linear superposition principle: the electrostatic forces exerted on some point charge (say, \( q_k \)) by other charges add up as vectors to form the net force

\[\text{---}
\]

4 Since 2018, one coulomb is defined, in the “legal” metrology, as a certain, exactly fixed number of the fundamental electric charges \( e \), and the “legal” SI value of \( \varepsilon_0 \) is not more exactly equal to \( 10^{7/4}\pi^2 \) (where \( c \) is the speed of light) as it was before that, but remains extremely close to that fraction, with the relative difference of the order of \( 10^{-10} \) – see appendix CA: Selected Physical Constants.
\[ \mathbf{F}_k = \sum_{k \neq k'} \mathbf{F}_{kk'} , \]

where the summation is extended over all charges but \( q_k \), and the partial force \( \mathbf{F}_{kk'} \) is described by Eq. (3). The fact that the sum is restricted to \( k' \neq k \) means that a point charge, in statics, does not interact with itself. This fact may look trivial from Eq. (3), whose right-hand side diverges at \( \mathbf{r}_k \rightarrow \mathbf{r}_k \), but becomes less evident (though still true) in quantum mechanics where the charge of even an elementary particle is effectively spread around some volume, together with particle’s wavefunction.\(^5\)

Now we may combine Eqs. (3) and (4) to get the following expression for the net force \( \mathbf{F} \) acting on charge \( q \) located at point \( \mathbf{r} \):

\[ \mathbf{F}(\mathbf{r}) = q \frac{1}{4\pi \varepsilon_0} \sum_{r_k \neq \mathbf{r}} q_{k'} \frac{\mathbf{r} - \mathbf{r}_{k'}}{|\mathbf{r} - \mathbf{r}_{k'}|^3}. \]

This equality implies that it makes sense to introduce the notion of the **electric field** at point \( \mathbf{r} \) (as an entity independent of the probe charge \( q \)), characterized by the following vector:

\[ \mathbf{E}(\mathbf{r}) \equiv \frac{\mathbf{F}(\mathbf{r})}{q} , \]

formally called the **electric field strength** – but much more frequently, just the “electric field”. In these terms, Eq. (5) becomes

\[ \mathbf{E}(\mathbf{r}) = \frac{1}{4\pi \varepsilon_0} \sum_{r_k \neq \mathbf{r}} q_{k'} \frac{\mathbf{r} - \mathbf{r}_{k'}}{|\mathbf{r} - \mathbf{r}_{k'}|^3} . \]

The notion of the field is just convenient in electrostatics, but becomes virtually unavoidable for the description of time-dependent phenomena (such as electromagnetic waves, see Chapter 7 and on), where the electromagnetic field shows up as a specific form of matter, with zero rest mass, and hence different from the usual “material” particles.

Many real-world problems involve multiple point charges located so closely that it is possible to approximate them with a continuous charge distribution. Indeed, let us consider a group of many \((dN \gg 1)\) close charges, located at points \( \mathbf{r}_k \), all within an elementary volume \( d^3 r' \). For relatively distant field observation points, with \( |\mathbf{r} - \mathbf{r}_{k'}| \gg dr' \), the geometrical factor in the corresponding terms of Eq. (7) is essentially the same. As a result, these charges may be treated as a single elementary charge \( dQ(\mathbf{r}') \). Since at \( dN \gg 1 \), this elementary charge is proportional to the elementary volume \( d^3 r' \), we can define the local 3D **charge density** \( \rho(\mathbf{r}') \) by the relation

\[ \rho(\mathbf{r}') d^3 r' \equiv dQ(\mathbf{r}') \equiv \sum_{r_k \in d^3 r'} q_{k'} , \]

and rewrite Eq. (7) as an integral (over the volume containing all essential charges):

\[ \mathbf{E}(\mathbf{r}) = \frac{1}{4\pi \varepsilon_0} \int \rho(\mathbf{r}') \frac{\mathbf{r} - \mathbf{r}'}{|\mathbf{r} - \mathbf{r}'|^3} d^3 r' . \]

\(^5\) Note that some widely used approximations, e.g., the density functional theory (DFT) of multi-particle systems, which essentially violate this law, thus limiting their accuracy and applicability – see, e.g., QM Sec. 8.4.
Note that for a continuous, smooth charge density \( \rho(r') \), the integral in Eq. (9) does not diverge at \( R \equiv r - r' \to 0 \), because in this limit the fraction under the integral increases as \( R^{-2} \), i.e. slower than the decrease of the elementary volume \( d^3 r' \), proportional to \( R^3 \).

Let me emphasize the dual role of Eq. (9). In the case when \( \rho(r) \) is a continuous function representing the average charge, defined by Eq. (8), Eq. (9) is not valid at distances \( \mid r - r_k \mid \) of the order of the distance between the adjacent point charges, i.e. does not describe rapid variations of the electric field at these distances. Such approximate, smoothly changing field \( E(r) \), is called macroscopic; we will repeatedly return to this notion in the following chapters. On the other hand, Eq. (9) may be also used for the description of the exact (frequently called microscopic) field of discrete point charges, by employing the notion of the Dirac \( \delta \)-function, which is the mathematical approximation for a very sharp function equal to zero everywhere but one point, and still having a finite integral (equal to 1). Indeed, in this formalism, a set of point charges \( q_k \) located in points \( r_k \) may be represented by pseudo-continuous density

\[
\rho(r') = \sum_k q_k \delta(r' - r_k).
\]  

(1.10)

Plugging this expression into Eq. (9), we return to its exact, discrete version (7). In this sense, Eq. (9) is exact, and we may use it as the general expression for the electric field.

1.2. The Gauss law

Due to the extension of Eq. (9) to point (“discrete”) charges, it may seem that we do not need anything else for solving any problem of electrostatics. In practice, however, this is not quite true – first of all, because the direct use of Eq. (9) frequently leads to complex calculations. Indeed, let us try to solve a very simple problem: finding the electric field induced by a spherically-symmetric charge distribution with density \( \rho(r') \). We may immediately use the problem symmetry to argue that the electric field should be also spherically-symmetric, with only one component in the spherical coordinates: \( E(r) = E(r)n_r \), where \( n_r \equiv r/r \) is the unit vector in the direction of the field observation point \( r \) (Fig. 2).

![Fig. 1.2. One of the simplest problems of electrostatics: electric field produced by a spherically-symmetric charge distribution.](image)

Taking this direction for the polar axis of a spherical coordinate system, we can use the evident axial symmetry of the system to reduce Eq. (9) to

6 See, e.g., MA Sec. 14. The 2D (areal) charge density \( \sigma \) and the 1D (linear) density \( \lambda \) may be defined absolutely similarly to the 3D (volumic) density \( \rho \) : \( dQ = \sigma d^2 r, dQ = \lambda dr \). Note that the approximations in that either \( \sigma \neq 0 \) or \( \lambda \neq 0 \) imply that \( \rho \) is formally infinite at the charge location; for example, the model in that a plane \( z = 0 \) is charged with areal density \( \sigma \neq 0 \), means that \( \rho = \sigma \delta(z) \), where \( \delta(z) \) is the Dirac delta-function.
where \( \theta \) and \( R \) are the geometrical parameters marked in Fig. 2. Since they all may be readily expressed via \( r' \) and \( \theta' \), using the auxiliary parameters \( a \) and \( h \),

\[
\cos \theta = \frac{r-a}{R}, \quad R^2 = h^2 + (r-r'\cos \theta)^2, \quad \text{where } a \equiv r'\cos \theta', \quad h \equiv r'\sin \theta',
\]

Eq. (11) may be eventually reduced to an explicit integral over \( r' \) and \( \theta' \), and worked out analytically, but that would require some effort.

For other problems, the integral (9) may be much more complicated, defying an analytical solution. One could argue that with the present-day abundance of computers and numerical algorithm libraries, one can always resort to numerical integration. This argument may be enhanced by the fact that numerical integration is based on the replacement of the required integral by a discrete sum, and the summation is much more robust to the (unavoidable) discretization and rounding errors than the finite-difference schemes typical for the numerical solution of differential equations. These arguments, however, are only partly justified, since in many cases the numerical approach runs into a problem sometimes called the curse of dimensionality – the exponential dependence of the number of needed calculations on the number of independent parameters of the problem. Therefore, despite the proliferation of numerical methods in physics, analytical results have an ever-lasting value, and we should try to get them whenever we can. For our current problem of finding the electric field generated by a fixed set of electric charges, large help may come from the so-called Gauss law.

Let us consider a single point charge \( q \) inside a smooth, closed surface \( S \) (Fig. 3), and calculate product \( E_n d^2 r \), where \( d^2 r \) is an elementary area of the surface (which may be well approximated with a plane fragment of that area), and \( E_n \equiv E \cdot n \) is the component of the electric field at that point, normal to the plane.

![Diagram of Gauss Law](image)

Fig. 1.3. Deriving the Gauss law: a point charge \( q \) (a) inside volume \( V \), and (b) outside of that volume.

This component may be calculated as \( E \cos \theta \), where \( \theta \) is the angle between the vector \( E \) and the unit vector \( n \) normal to the surface. Now let us notice that the product \( \cos \theta d^2 r \) is nothing more than the

---

7 For a more detailed discussion of this problem, see, e.g., CM Sec. 5.8.
area $d^2r'$ of the projection of $d^2r$ onto the plane perpendicular to vector $\mathbf{r}$ connecting the charge $q$ with this point of the surface (Fig. 3), because the angle between the planes $d^2r'$ and $d^2r$ is also equal to $\theta$. Using the Coulomb law for $\mathbf{E}$, we get

$$E_n d^2r = E \cos \theta d^2r = \frac{1}{4\pi\epsilon_0} \frac{q}{r^2} d^2r'. \quad (1.13)$$

But the ratio $d^2r'/r^2$ is nothing more than the elementary solid angle $d\Omega$ under which the areas $d^2r'$ and $d^2r$ are seen from the charge point, so that $E_n d^2r$ may be represented as just a product of $d\Omega$ by a constant $(q/4\pi\epsilon_0)$. Summing these products over the whole surface, we get

$$\oint_S E_n d^2r = \frac{q}{4\pi\epsilon_0} \oint_S d\Omega = \frac{q}{\epsilon_0}, \quad (1.14)$$

since the full solid angle equals $4\pi$. (The integral on the left-hand side of this relation is called the flux of electric field through surface $S$.)

The relation (14) expresses the Gauss law for one point charge. However, it is only valid if the charge is located inside the volume $V$ limited by the surface $S$. In order to find the flux created by a charge outside of the volume, we still can use Eq. (13), but have to be careful with the signs of the elementary contributions $E_n dA$. Let us use the common convention to direct the unit vector $\mathbf{n}$ out of the closed volume we are considering (the so-called outer normal), so that the elementary product $E_n d^2r = (\mathbf{E} \cdot \mathbf{n}) d^2r$ and hence $d\Omega = E_n d^2r'/r^2$ is positive if the vector $\mathbf{E}$ is pointing out of the volume (like in the example shown in Fig. 3a and the upper-right area in Fig. 3b), and negative in the opposite case (for example, in the lower-left area in Fig. 3b). As the latter figure shows, if the charge is located outside of the volume, for each positive contribution $d\Omega$ there is always an equal and opposite contribution to the integral. As a result, at the integration over the solid angle the positive and negative contributions cancel exactly, so that

$$\oint_S E_n d^2r = 0. \quad (1.15)$$

The real power of the Gauss law is revealed by its generalization to the case of many charges within volume $V$. Since the calculation of flux is a linear operation, the linear superposition principle (4) means that the flux created by several charges is equal to the (algebraic) sum of individual fluxes from each charge, for which either Eq. (14) or Eq. (15) are valid, depending on the charge position (in or out of the volume). As the result, for the total flux we get:

$$\oint_S E_n d^2r = \frac{Q_V}{\epsilon_0} \equiv \frac{1}{\epsilon_0} \sum_{j \in V} q_j \equiv \frac{1}{\epsilon_0} \int_{r'} \rho(r') d^3r', \quad (1.16)$$

where $Q_V$ is the net charge inside volume $V$. This is the full version of the Gauss law.8

In order to appreciate the problem-solving power of the law, let us return to the problem illustrated by Fig. 2, i.e. a spherical charge distribution. Due to its symmetry, which had already been discussed above, if we apply Eq. (16) to a sphere of radius $r$, the electric field should be normal to the

---

8 Named after the famed Carl Gauss (1777-1855), even though it was first formulated earlier (in 1773) by Joseph-Louis Lagrange, who was also the father-founder of analytical mechanics – see, e.g., CM Chapter 2.)
sphere at each its point (i.e., \( E_n = E \)), and its magnitude the same at all points: \( E_n = E = E(r) \). As a result, the flux calculation is elementary:

\[
\int E_n d^2r = 4\pi r^2 E(r).
\]  \hspace{1cm} (1.17)

Now, applying the Gauss law (16), we get:

\[
4\pi r^2 E(r) = \frac{1}{\varepsilon_0} \int \rho(r') d^3r' = \frac{4\pi}{\varepsilon_0} \int_0^r r'^2 \rho(r') dr',
\]  \hspace{1cm} (1.18)

so that, finally,

\[
E(r) = \frac{1}{r^2 \varepsilon_0} \int_0^r r'^2 \rho(r') dr' = \frac{1}{4\pi \varepsilon_0} \frac{Q(r)}{r^2},
\]  \hspace{1cm} (1.19)

where \( Q(r) \) is the full charge inside the sphere of radius \( r \):

\[
Q(r) = \int_{r<r'} \rho(r') d^3r' = 4\pi \int_0^r \rho(r') r'^2 dr'.
\]  \hspace{1cm} (1.20)

In particular, this formula shows that the field outside of a sphere of a finite radius \( R \) is exactly the same as if all its charge \( Q = Q(R) \) was concentrated in the sphere’s center. (Note that this important result is only valid for a spherically-symmetric charge distribution.) For the field inside the sphere, finding the electric field still requires explicit integration (20), but this 1D integral is much simpler than the 2D integral (11), and in some important cases may be readily worked out analytically. For example, if the charge \( Q \) is uniformly distributed inside a sphere of radius \( R \),

\[
\rho(r') = \rho = \frac{Q}{V} = \frac{Q}{(4\pi/3)R^3},
\]  \hspace{1cm} (1.21)

the integration is elementary:

\[
E(r) = \frac{\rho}{r^2 \varepsilon_0} \int_0^r r'^2 dr' = \frac{\rho r}{3\varepsilon_0} = \frac{1}{4\pi \varepsilon_0} \frac{Qr}{R^3}.
\]  \hspace{1cm} (1.22)

We see that in this case, the field is growing linearly from the center to the sphere’s surface, and only at \( r > R \) starts to decrease in agreement with Eq. (19) with constant \( Q(r) = \dot{Q} \). Note that the electric field is continuous for all \( r \) (including \( r = R \)), as for all systems with finite volumic density,

In order to underline the importance of the last condition, let us consider one more elementary but very important example of the Gauss law’s application. Let a thin plane sheet (Fig. 4) be charged uniformly, with an areal density \( \sigma = \text{const.} \). In this case, it is fruitful to use the Gauss volume in the form of a planar “pillbox” of thickness 2\( z \) (where \( z \) is the Cartesian coordinate perpendicular to the charged plane) and certain area \( A \) – see the dashed lines in Fig. 4. Due to the symmetry of the problem, it is evident that the electric field should be: (i) directed along the \( z \)-axis, (ii) constant on each of the upper and bottom sides of the pillbox, (iii) equal and opposite on these sides, and (iv) parallel to the side surfaces of the box. As a result, the full electric field flux through the pillbox’ surface is just \( 2AE(z) \), so that the Gauss law (16) yields \( 2AE(z) = Q_A/\varepsilon_0 = \sigma A/\varepsilon_0 \), and we get a very simple but important formula

\[
E(z) = \frac{\sigma}{2\varepsilon_0} = \text{const.}
\]  \hspace{1cm} (1.23)
Notice that, somewhat counter-intuitively, the field magnitude does not depend on the distance from the charged plane. From the point of view of the Coulomb law (5), this result may be explained as follows: the farther the observation point from the plane, the weaker the effect of each elementary charge, \( dQ = \sigma d^2 r \), but the more such elementary charges give contributions to the vertical component of vector \( \mathbf{E} \).

Note also that though the magnitude \( E \equiv |\mathbf{E}| \) of the electric field is constant, its component \( E_n \) normal to the plane (for our coordinate choice, \( E_z \) changes its sign at the plane, experiencing a discontinuity (jump) equal to

\[
\Delta E_n = \frac{\sigma}{\varepsilon_0}.
\]  

This jump disappears if the surface is not charged. Returning for a split second to our charged sphere problem, in it we consider the volumic charge density \( \rho \) to be finite everywhere, including the sphere’s surface, so that on it \( \sigma = 0 \), and the electric field should indeed be continuous – as it is.

Admittedly, the integral form (16) of the Gauss law is immediately useful only for highly symmetrical geometries, such as in the two problems discussed above. However, it may be recast into an alternate, differential form whose field of useful applications is much wider. This form may be obtained from Eq. (16) using the divergence theorem that, according to the vector algebra, is valid for any space-differentiable vector, in particular \( \mathbf{E} \), and for the volume \( V \) limited by any closed surface \( S \):

\[
\int_S E_n d^2 r = \int_V (\nabla \cdot \mathbf{E}) d^3 r,
\]  

where \( \nabla \) is the del (or “nabla”) operator of spatial differentiation.\(^{10}\) Combining Eq. (25) with the Gauss law (16), we get

\[
\int_V \left( \nabla \cdot \mathbf{E} - \frac{\rho}{\varepsilon_0} \right) d^3 r = 0.
\]  

For a given spatial distribution of electric charge (and hence of the electric field), this equation should be valid for any choice of the volume \( V \). This can hold only if the function under the integral vanishes at each point, i.e. if\(^{11}\)

\[^9\] See, e.g., MA Eq. (12.2). Note also that the scalar product under the volumic integral in Eq. (25) is nothing else than the divergence of the vector \( \mathbf{E} \) – see, e.g., MA Eq. (8.4).

\[^{10}\] See, e.g., MA Secs. 8-10.

\[^{11}\] In the Gaussian units, just as in the initial Eq. (6), \( \varepsilon_0 \) has to be replaced with \( 1/4\pi \), so that the Maxwell equation (27) looks like \( \nabla \cdot \mathbf{E} = 4\pi \rho \), while Eq. (28) stays the same.
Note that in sharp contrast with the integral form (16), Eq. (27) is **local**: it relates the electric field divergence to the charge density at the same point. This equation, being the differential form of the Gauss law, is frequently called one of the *Maxwell equations*\(^\text{12}\) – to be discussed again and again later in this course.

In the mathematical terminology, Eq. (27) is **inhomogeneous**, because it has a right-hand side independent (at least explicitly) from the field \(E\) that it describes. Another, **homogeneous** Maxwell equation’s “embryo” (valid for the stationary case only!) may be obtained by noticing that the curl of the point charge’s field, and hence that of any system of charges, equals zero:\(^\text{13}\)

\[
\nabla \times E = 0.
\]

(We will arrive at two other Maxwell equations, for the magnetic field, in Chapter 5, and then generalize all the equations to their full, time-dependent form in the end of Chapter 6. However, Eq. (27) would stay the same.)

Just to get a better gut feeling of Eq. (27), let us apply it to the same example of a uniformly charged sphere (Fig. 2). Vector algebra tells us that the divergence of a spherically symmetric vector function \(E(r) = E(r)n\), may be simply expressed in spherical coordinates:\(^\text{14}\)

\[
\nabla \cdot E = \frac{1}{r^2} \frac{d}{dr} \left( r^2 E \right) = \begin{cases} \frac{\rho}{\varepsilon_0}, & \text{for } r \leq R, \\ 0, & \text{for } r \geq R, \end{cases}
\]

which may be readily integrated on each of these segments:

\[
E(r) = \frac{1}{\varepsilon_0} \frac{1}{r^2} \times \left\{ \rho \int_{c_1}^{r^2} dr = \frac{\rho r^3}{3} + c_1, \quad \text{for } r \leq R, \\ c_2, \quad \text{for } r \geq R. \right. \]

In order to determine the integration constant \(c_1\), we can use the following boundary condition: \(E(0) = 0\). (It follows from the problem’s spherical symmetry: in the center of the sphere, the electric field has to vanish, because otherwise, where would it be directed?) This requirement gives \(c_1 = 0\). The second constant, \(c_2\), may be found from the continuity condition \(E(R - 0) = E(R + 0)\), which has already been discussed above, giving \(c_2 = \rho R^3 / 3 \equiv Q/4\pi\). As a result, we arrive at our previous results (19) and (22).

We can see that in this particular, highly symmetric case, using the differential form of the Gauss law is more complex than its integral form. (For our second example, shown in Fig. 4, it would be even less natural.) However, Eq. (27) and its generalizations are more convenient for asymmetric charge

---

\(\text{12}\) Named after the genius of classical electrodynamics and statistical physics, James Clerk Maxwell (1831-1879).

\(\text{13}\) This follows, for example, from the direct application of MA Eq. (10.11) to any spherically-symmetric vector function of the type \(f(r) = f(r)n\), (in particular, to the electric field of a point charge placed at the origin), giving \(f_\theta = f_\phi = 0\) and \(\partial f_\theta / \partial \theta = \partial f_\phi / \partial \phi = 0\), so that all components of the vector \(\nabla \times f\) vanish. Since nothing prevents us from placing the reference frame’s origin at the point charge’s location, this result remains valid for any position of the charge.

\(\text{14}\) See, e.g., MA Eq. (10.10) for this particular case when \(\partial / \partial \theta = \partial / \partial \phi = 0\).
distributions, and are invaluable in the cases where the charge distribution \( \rho(\mathbf{r}) \) is not known \textit{a priori} and has to be found in a self-consistent way. (We will start discussing such cases in the next chapter.)

### 1.3. Scalar potential and electric field energy

One more help for solving electrostatics (and more complex) problems may be obtained from the notion of the \textit{electrostatic potential}, which is just the electrostatic potential energy \( U \) of a probe point particle with charge \( q \) placed into the field in question, normalized by its charge:

\[
\phi \equiv \frac{U}{q}. \tag{1.31}
\]

As we know from classical mechanics,\(^{15}\) the notion of \( U \) (and hence \( \phi \)) makes the most sense for the case of \textit{potential forces}, for example those depending just on the particle's position. Eqs. (6) and (9) show that, in static situations, the electric field clearly falls into this category. For such a field, the potential energy may be defined as a scalar function \( U(\mathbf{r}) \) that allows the force to be calculated as its gradient (with the opposite sign):

\[
\mathbf{F} = -\nabla U. \tag{1.32}
\]

Dividing both sides of this equation by the probe charge, and using Eqs. (6) and (31), we get\(^{16}\)

\[
\mathbf{E} = -\nabla \phi. \tag{1.33}
\]

To calculate the scalar potential, let us start from the simplest case of a single point charge \( q \) placed at the origin. For it, Eq. (7) takes the simple form

\[
\mathbf{E} = \frac{1}{4\pi \varepsilon_0} \frac{q}{r^3} \mathbf{r} = \frac{1}{4\pi \varepsilon_0} \frac{q}{r^2} \mathbf{n}. \tag{1.34}
\]

It is straightforward to verify that the last fraction in the last form of Eq. (34) is equal to \(-\nabla(1/r)\).\(^{17}\) Hence, according to the definition (33), for this particular case

\[
\phi = \frac{1}{4\pi \varepsilon_0} \frac{q}{r}. \tag{1.35}
\]

(In the Gaussian units, this result is spectacularly simple: \( \phi = q/r \).) Note that we could add an arbitrary constant to this potential (and indeed to \textit{any} other distribution of \( \phi \) discussed below) without changing the force, but it is convenient to define the potential energy to approach zero at infinity.

In order to justify the introduction and the following exploration of \( U \) and \( \phi \), let me demonstrate (I hope, unnecessarily :-) how useful the notions are, on a very simple example. Let two similar charges \( q \) be launched from afar, with the same initial speed \( v_0 \ll c \) each, straight toward each other (i.e. with the zero impact parameter) – see Fig. 5. Since, according to the Coulomb law, the charges repel each

\(^{15}\) See, e.g., CM Sec. 1.4.

\(^{16}\) Eq. (28) could be also derived from this relation, because according to vector algebra, any gradient field has vanishing curl – see, e.g., MA Eq. (11.1).

\(^{17}\) This may be done either by Cartesian components or using the well-known expression \( \nabla f = (df/dr) \mathbf{n} \), valid for any spherically-symmetric scalar function \( f(\mathbf{r}) \) – see, e.g., MA Eq. (10.8) for the particular case \( \partial/r/\partial \theta = \partial/\partial \phi = 0 \).
other with increasing force, they will stop at some minimum distance \( r_{\text{min}} \) from each other, and than fly back. We could of course find \( r_{\text{min}} \) directly from the Coulomb law. However, for that we would need to write the 2\textsuperscript{nd} Newton law for each particle (actually, due to the problem symmetry, they would be similar), then integrate them over time to find the particle velocity \( v \) as a function of distance, and then recover \( r_{\text{min}} \) from the requirement \( v = 0 \).

\[ \text{Fig. 1.5. A simple problem of charged particle motion.} \]

The notion of potential allows this problem to be solved in one line. Indeed, in the field of potential forces the system’s total energy \( \mathcal{E} = T + U = T + q\phi \) is conserved. In our non-relativistic case \( v \ll c \), the kinetic energy \( T \) is just \( \frac{1}{2}mv^2 \). Hence, equating the total energy of two particles at the points \( r = \infty \) and \( r = r_{\text{min}} \), and using Eq. (35) for \( \phi \), we get

\[
2 \frac{mv_0^2}{2} + 0 = 0 + \frac{1}{4\pi\varepsilon_0} \frac{q^2}{r_{\text{min}}},
\]

immediately giving us the final answer: \( r_{\text{min}} = \frac{q^2}{4\pi\varepsilon_0 mv_0^2} \). So, the notion of the scalar potential is indeed very useful.

With this motivation, let us calculate \( \phi \) for an arbitrary configuration of charges. For a single charge in an arbitrary position (say, \( r_k \)), \( r \equiv |r| \) in Eq. (35) should be evidently replaced with \( |r - r_k| \). Now, the linear superposition principle (3) allows for an easy generalization of this formula to the case of an arbitrary set of discrete charges,

\[
\phi(r) = \frac{1}{4\pi\varepsilon_0} \sum_{r_k \neq r} \frac{q_{r_k}}{|r - r_k|}.
\]

Finally, using the same arguments as in Sec. 1, we can use this result to argue that in the case of an arbitrary continuous charge distribution

\[
\phi(r) = \frac{1}{4\pi\varepsilon_0} \int \frac{\rho(r')}{|r - r'|} d^3r'.
\]

Again, Dirac’s delta-function allows to use the last equation to recover Eq. (37) for discrete charges as well, so that Eq. (38) may be considered the general expression for the electrostatic potential.

For most practical calculations, using this expression and then applying Eq. (33) to the result, is preferable to using Eq. (9), because \( \phi \) is a scalar, while \( E \) is a 3D vector, mathematically equivalent to 3 scalars. Still, this approach still may lead to technical problems similar to those discussed in Sec. 2. For example, applying it to the spherically-symmetric distribution of charge (Fig. 2), we get the integral

\[
\phi = \frac{1}{4\pi\varepsilon_0} 2\pi \int_0^\pi \sin \theta' d\theta' \int_0^\infty r'^2 dr' \frac{\rho(r')}{R} \cos \theta',
\]

which is not much simpler than Eq. (11).
The situation may be much improved by recasting Eq. (38) into a differential form. For that, it is sufficient to plug the definition of $\phi$, Eq. (33), into Eq. (27):

$$\nabla \cdot (-\nabla \phi) = \frac{\rho}{\varepsilon_0}. \quad (1.40)$$

The left-hand side of this equation is nothing else than the Laplace operator of $\phi$ (with the minus sign), so that we get the famous Poisson equation\textsuperscript{18} for the electrostatic potential:

$$\nabla^2 \phi = -\frac{\rho}{\varepsilon_0}. \quad (1.41)$$

(In the Gaussian units, the Poisson equation is $\nabla^2 \phi = -4\pi \rho$.) This differential equation is so convenient for applications that even its particular case for $\rho = 0$,

$$\nabla^2 \phi = 0, \quad (1.42)$$

has earned a special name – the Laplace equation\textsuperscript{19}.

In order to get a feeling of the Poisson equation’s value as a problem-solving tool, let us return to the spherically-symmetric charge distribution (Fig. 2) with a constant charge density $\rho$. Using the symmetry, we can represent the potential as $\phi(r)$, and hence use the following simple expression for its Laplace operator:\textsuperscript{20}

$$\nabla^2 \phi = \frac{1}{r^2} \frac{d}{dr} \left( r^2 \frac{d\phi}{dr} \right), \quad (1.43)$$

so that for the points inside the charged sphere ($r \leq R$) the Poisson equation yields

$$\frac{1}{r^2} \frac{d}{dr} \left( r^2 \frac{d\phi}{dr} \right) = -\frac{\rho}{\varepsilon_0}, \quad \text{i.e.} \quad \frac{d}{dr} \left( r^2 \frac{d\phi}{dr} \right) = -\frac{\rho}{\varepsilon_0} r^2. \quad (1.44)$$

Integrating the last form of the equation over $r$ once, with the natural boundary condition $d\phi/dr \big|_{r=0} = 0$ (because of the condition $E(0) = 0$, which has been discussed above), we get

$$\frac{d\phi}{dr} (r) = -\frac{\rho}{r^2 \varepsilon_0} \int_0^r r'^2 \, dr' = -\frac{\rho r}{3 \varepsilon_0} = -\frac{1}{4\pi \varepsilon_0} \frac{Qr}{R^3}. \quad (1.45)$$

Since this derivative is nothing more than $-E(r)$, in this formula we can readily recognize our previous result (22). Now we may like to carry out the second integration to calculate the potential itself:

$$\phi(r) = -\frac{Q}{4\pi \varepsilon_0 R^3} \int_0^r r' \, d'r' + c_1 = -\frac{Qr^2}{8\pi \varepsilon_0 R^3} + c_1. \quad (1.46)$$

\textsuperscript{18} Named after Siméon Denis Poisson (1781-1840), also famous for the Poisson distribution – one of the central results of the probability theory – see, e.g., SM Sec. 5.2.

\textsuperscript{19} After the famous mathematician (and astronomer) Pierre-Simon Laplace (1749-1827) who, together with Alexis Clairault, is credited for the development of the very concept of potential.

\textsuperscript{20} See, e.g., MA Eq. (10.8) for $\partial \partial \theta = \partial \partial \phi = 0$. 
Before making any judgment on the integration constant \( c_1 \), let us solve the Poisson equation (in this case, just the Laplace equation) for the range outside the sphere \((r > R)\):

\[
\frac{1}{r^2} \frac{d}{dr} \left( r^2 \frac{d\phi}{dr} \right) = 0.
\]  
(1.47)

Its first integral,

\[
\frac{d\phi}{dr} (r) = \frac{c_2}{r^2},
\]  
(1.48)

also gives the electric field (with the minus sign). Now using Eq. (45) and requiring the field to be continuous at \( r = R \), we get

\[
\frac{c_2}{R^2} = -\frac{Q}{4\pi\varepsilon_0 R^2}, \quad \text{i.e.,} \quad \frac{d\phi}{dr} (r) = -\frac{Q}{4\pi\varepsilon_0 r^2},
\]  
(1.49)

in an evident agreement with Eq. (19). Integrating this result again,

\[
\phi(r) = -\frac{Q}{4\pi\varepsilon_0} \int \frac{dr}{r^2} = \frac{Q}{4\pi\varepsilon_0 r} + c_3, \quad \text{for } r > R,
\]  
(1.50)

we can select \( c_3 = 0 \), so that \( \phi(\infty) = 0 \), in accordance with the usual (though not compulsory) convention. Now we can finally determine the constant \( c_1 \) in Eq. (46) by requiring that this equation and Eq. (50) give the same value of \( \phi \) at the boundary \( r = R \). (According to Eq. (33), if the potential had a jump, the electric field at that point would be infinite.) The final answer may be represented as

\[
\phi(r) = \frac{Q}{4\pi\varepsilon_0} \left( \frac{R^2 - r^2}{2R^2} + 1 \right), \quad \text{for } r \leq R.
\]  
(1.51)

We see that using the Poisson equation to find the electrostatic potential distribution for highly symmetric problems may be more cumbersome than directly finding the electric field—say, from the Gauss law. However, we will repeatedly see below that if the electric charge distribution is not fixed in advance, using Eq. (41) may be the only practicable way to proceed.

Returning now to the general theory of electrostatic phenomena, let us calculate the potential energy \( U \) of an arbitrary system of point electric charges \( q_k \). Despite the apparently simple relation (31) between \( U \) and \( \phi \), the result is not that straightforward. Indeed, let us assume that the charge distribution has a finite spatial extent, so that at large distances from it (formally, at \( r = \infty \)) the electric field tends to zero, so that the electrostatic potential tends to a constant. Selecting this constant, for convenience, to equal zero, we may calculate \( U \) as a sum of the energy increments \( \Delta U_k \) created by bringing the charges, one by one, from infinity to their final positions \( \mathbf{r}_k \) — see Fig. 6.21 According to the integral form of Eq. (32), such a contribution is

\[
\Delta U_k = -\int_{\infty}^{\mathbf{r}_k} \mathbf{F}(r) \cdot d\mathbf{r} = -q_k \int_{\infty}^{\mathbf{r}_k} \mathbf{E}(r) \cdot d\mathbf{r} \equiv q_k \phi(\mathbf{r}_k),
\]  
(1.52)

21 Indeed, by the very definition of the potential energy of a system, it should not depend on the way we are arriving at its final configuration.
where $\mathbf{E}(\mathbf{r})$ is the total electric field, and $\phi(\mathbf{r})$ is the total electrostatic potential during this process, besides the field created by the very charge $q_k$ that is being moved.

This expression shows that the increment $\Delta U_k$, and hence the total potential energy $U$, depend on the source of the electric field $\mathbf{E}$. If the field is dominated by an external field $\mathbf{E}_{\text{ext}}$, induced by some external charges, not being a part of the charge configuration under our analysis (whose energy we are calculating, see Fig. 6), the spatial distribution $\phi(\mathbf{r})$ is determined by this field, i.e. does not depend on how many charges we have already brought in, so that Eq. (52) is reduced to

$$
\Delta U_k = q_k \phi_{\text{ext}}(\mathbf{r}_k), \quad \text{where} \quad \phi_{\text{ext}}(\mathbf{r}) \equiv -\int_{\infty}^{\mathbf{r}} \mathbf{E}_{\text{ext}}(\mathbf{r}') \cdot d\mathbf{r}'.
$$

(1.53)

Summing up these contributions, we get what is called the charge system’s energy in the external field:22

$$
U_{\text{ext}} \equiv \sum_k \Delta U_k = \sum_k q_k \phi_{\text{ext}}(\mathbf{r}_k).
$$

(1.54)

Now repeating the argumentation that has led us to Eq. (9), we see that for a continuously distributed charge, this sum turns into an integral:

$$
U_{\text{ext}} = \int \rho(\mathbf{r}) \phi_{\text{ext}}(\mathbf{r}) d^3 r.
$$

(1.55)

(As was discussed above, using the delta-functional representation of point charges, we may always return from here to Eq. (54), so that Eq. (55) may be considered as a final, universal result.)

The result is different in the opposite limit, when the electric field $\mathbf{E}(\mathbf{r})$ is created only by the very charges whose energy we are calculating. In this case, $\phi(\mathbf{r})$ in Eq. (52) is the potential created only by the charges with numbers $k' = 1, 2, \ldots, (k - 1)$ already in place when the $k^{\text{th}}$ charge is moved in (in Fig. 6, the charges inside the dashed boundary), and we may use the linear superposition principle to write

$$
\Delta U_k = q_k \sum_{k' < k} \phi_{k'}(\mathbf{r}_k), \quad \text{so that} \quad U = \sum_k \Delta U_k = \sum_{k' < k} q_k \phi_{k'}(\mathbf{r}_k).
$$

(1.56)

This result is so important that is worthy of rewriting it in several other forms. First, we may use Eq. (35) to represent Eq. (56) in a more symmetric form:

\[22\] An alternative, perhaps more accurate term for $U_{\text{ext}}$ is the energy of the system’s interaction with the external field.
The expression under this sum is evidently symmetric with respect to the index swap, so that it may be extended into a different form,

\[
U = \frac{1}{4\pi\varepsilon_0} \sum_{k \neq k'} \frac{q_k q_{k'}}{|\mathbf{r}_k - \mathbf{r}_{k'}|}.
\]  
(1.57)

where the interaction between each couple of charges is described by two, equal terms under the sum, and the front coefficient \( \frac{1}{2} \) is used to compensate this double-counting. The convenience of the last form is that it may be readily generalized to the continuous case:

\[
U = \frac{1}{4\pi\varepsilon_0} \frac{1}{2} \int d^3r \int d^3r' \frac{\rho(r)\rho(r')}{|\mathbf{r} - \mathbf{r}'|}.
\]  
(1.58)

(As before, in this case the restriction expressed in the discrete charge case as \( k \neq k' \) is not important, because if the charge density is a continuous function, the integral (59) does not diverge at point \( r = r' \).)

To represent this result in one more form, let us notice that according to Eq. (38), the inner integral over \( r' \) in Eq. (59), divided by \( 4\pi\varepsilon_0 \), is just the full electrostatic potential at point \( r \), and hence

\[
U = \frac{1}{2} \int \rho(r)\phi(r) d^3r.
\]  
(1.60)

For the discrete charge case, this result is

\[
U = \frac{1}{2} \sum_k q_k\phi(r_k),
\]  
(1.61)

but here it is important to remember that here the “full” potential’s value \( \phi(r_k) \) should exclude the (infinite) contribution from the point charge \( k \) itself. Comparing the last two formulas with Eqs. (54) and (55), we see that the electrostatic energy of charge interaction within the system, as expressed via the charge-by-potential product, is twice less than that of the energy of charge interaction with a fixed (“external”) field. This is evidently the result of the fact that in the case of mutual interaction of the charges, the electric field \( \mathbf{E} \) in the basic Eq. (52) is proportional to the charge magnitude, rather than constant.\(^{23}\)

Now we are ready to address an important conceptual question: can we locate this interaction energy in space? Eqs. (58)-(61) seem to imply that non-zero contributions to \( U \) come only from the regions where the electric charges are located. However, one of the most beautiful features of physics is that sometimes completely different interpretations of the same mathematical result are possible. In order to get an alternative view at our current result, let us write Eq. (60) for a volume \( V \) so large that the electric field on the limiting surface \( S \) is negligible, and plug into it the charge density expressed from the Poisson equation (41):

\(^{23}\) The nature of this additional factor \( \frac{1}{2} \) is absolutely the same as in the well-known formula \( U = (\frac{1}{2})kx^2 \) for the potential energy of an elastic spring providing the returning force \( F = -kx \), proportional to its displacement \( x \) from the equilibrium position.
This expression may be integrated by parts as

\[ U = -\frac{\varepsilon_0}{2} \int \phi \nabla^2 \phi \, d^3 r. \]  

(1.62)

According to our condition of negligible field \( E = -\nabla \phi \) at the surface, the first integral vanishes, and we get a very important formula

\[ U = \frac{\varepsilon_0}{2} \int (\nabla \phi)^2 \, d^3 r = \frac{\varepsilon_0}{2} \int E^2 \, d^3 r. \]  

(1.64)

This result, represented in the following equivalent form:

\[ U = \int u(r) \, d^3 r, \quad \text{with} \quad u(r) = \frac{\varepsilon_0}{2} E^2(r), \]  

(1.65)

certainly invites an interpretation very much different than Eq. (60): it is natural to interpret \( u(r) \) as the spatial density of the electric field energy, which is continuously distributed over all the space where the field exists – rather than just its part where the charges are located.

Let us have a look at how these two alternative pictures work for our testbed problem, a uniformly charged sphere. If we start with Eq. (60), we may limit the integration by the sphere volume \((0 \leq r \leq R)\) where \( \rho \neq 0 \). Using Eq. (51), and the spherical symmetry of the problem \((d^3 r = 4\pi r^2 dr)\), we get

\[ U = \frac{1}{2} \int_0^R \rho \phi r^2 \, dr = \frac{1}{2} \frac{4\pi \rho Q}{4\pi \varepsilon_0} \int_0^R \left( \frac{R^2 - r^2}{2R^2} + 1 \right) r^2 \, dr = \frac{6}{5} \frac{1}{4\pi \varepsilon_0 R^2} \frac{Q^2}{2}. \]  

(1.66)

On the other hand, if we use Eq. (65), we need to integrate the energy density everywhere, i.e. both inside and outside of the sphere:

\[ U = \frac{\varepsilon_0}{2} 4\pi \left[ \int_0^R E^2 r^2 \, dr + \int_R^\infty E^2 r^2 \, dr \right]. \]  

(1.67)

Using Eqs. (19) and (22) for, respectively, the external and internal regions, we get

\[ U = \frac{\varepsilon_0}{2} 4\pi \left[ \int_0^R \left( \frac{Qr}{4\pi \varepsilon_0} \right)^2 r^2 \, dr + \int_R^\infty \left( \frac{Q}{4\pi \varepsilon_0 r^2} \right)^2 r^2 \, dr \right] = \left( \frac{1}{5} + 1 \right) \frac{1}{4\pi \varepsilon_0 R^2} \frac{Q^2}{2}. \]  

(1.68)

This is (fortunately :-) the same answer as given by Eq. (66), but to some extent Eq. (68) is more informative, because it shows how exactly the electric field’s energy is distributed between the interior and exterior of the charged sphere.

---

24 This transformation follows from the divergence theorem MA (12.2) applied to the vector function \( \mathbf{f} = \phi \nabla \phi \), taking into account the differentiation rule MA Eq. (11.4a): \( \nabla \cdot (\phi \nabla \phi) = (\nabla \phi) \cdot (\nabla \phi) + \phi \nabla \cdot (\nabla \phi) = (\nabla \phi)^2 + \phi \nabla^2 \phi \).

25 In the Gaussian units, the standard replacement \( \varepsilon_0 \rightarrow 1/4\pi \) turns the last of Eqs. (65) into \( u(r) = E^2/8\pi \).

26 Note that \( U \rightarrow \infty \) at \( R \rightarrow 0 \). Such divergence appears at the application of Eq. (65) to any point charge. Since it does not affect the force acting on the charge, the divergence does not create any technical difficulty for analysis.
We see that, as we could expect, within the realm of *electrostatics*, Eqs. (60) and (65) are equivalent. However, when we examine *electrodynamics* (in Chapter 6 and beyond), we will see that the latter equation is more general, and that it is more adequate to associate the electric energy with the field itself rather than its sources – in our current case, the electric charges.

Finally, let us calculate the potential energy of a system of charges in the general case when both the internal interaction of the charges, and their interaction with an external field are important. One might fancy that such a calculation should be very hard since, in both ultimate limits, when one of these interaction dominates, we have got different results. However, once again we get help from the almighty linear superposition principle: in the general case, for the total electric field we may write

$$
\mathbf{E}(\mathbf{r}) = \mathbf{E}_{\text{int}}(\mathbf{r}) + \mathbf{E}_{\text{ext}}(\mathbf{r}), \quad \phi(\mathbf{r}) = \phi_{\text{int}}(\mathbf{r}) + \phi_{\text{ext}}(\mathbf{r}),
$$

(1.69)

where the index “int” now marks the field induced by the charge system under analysis, i.e. the variables participating (without indices) in Eqs. (56)-(68). Now let us imagine that our system is being built up in the following way: first, the charges are brought together at $\mathbf{E}_{\text{ext}} = 0$, giving the potential energy $U_{\text{int}}$ expressed by Eq. (60), and then $\mathbf{E}_{\text{ext}}$ is slowly increased. Evidently, the energy contribution from the latter process cannot depend on the internal interaction of the charges, and hence may be expressed in the form (55). As the result, the total potential energy\(^{27}\) is the sum of these two components:

$$
U = U_{\text{int}} + U_{\text{ext}} = \frac{1}{2} \int \rho(\mathbf{r}) \phi_{\text{int}}(\mathbf{r}) d^3r + \int \rho(\mathbf{r}) \phi_{\text{ext}}(\mathbf{r}) d^3r.
$$

(1.70)

Now making, in the first integral, the transition from the potentials to the fields, absolutely similar to that performed in Eqs. (62)-(65), we may rewrite this expression as

$$
U = \int u(\mathbf{r}) d^3r, \quad \text{with} \quad u(\mathbf{r}) \equiv \frac{\varepsilon_0}{2} \left[ E_{\text{int}}^2(\mathbf{r}) + 2 \mathbf{E}_{\text{int}}(\mathbf{r}) \cdot \mathbf{E}_{\text{ext}}(\mathbf{r}) \right].
$$

(1.71)

One might think that this result, more general than Eq. (65) and perhaps less familiar to the reader, is something entirely new; however, it is not. Indeed, let us add to, and subtract $E_{\text{ext}}^2(\mathbf{r})$ from the sum in the brackets, and use Eq. (69) for the total electric field $\mathbf{E}(\mathbf{r})$; then Eq. (71) takes the form

$$
U = \frac{\varepsilon_0}{2} \int E^2(\mathbf{r}) d^3r - \frac{\varepsilon_0}{2} \int E_{\text{ext}}^2(\mathbf{r}) d^3r.
$$

(1.72)

Hence, in the most important case when we are using the potential energy to analyze the statics and dynamics of a system of charges in a fixed external field, i.e. when the second term in Eq. (72) may be considered as a constant, we may still use for $U$ an expression similar to the familiar Eq. (65), but with the field $\mathbf{E}(\mathbf{r})$ being the sum (69) of the internal and external fields.

Let us see how does this work in a very simple problem. A uniform external electric field $\mathbf{E}_{\text{ext}}$ is applied normally to a very broad, plane layer that contains a very large and equal number of free electric charges of both signs – see Fig. 7. What is the equilibrium distribution of the charges over the layer?

\(^{27}\) This total $U$ (or rather its part dependent on our system of charges) is sometimes called the *Gibbs potential energy* of the system. (I will discuss this notion in detail in Sec. 3.5.)
Since the equilibrium distribution should minimize the total potential energy of the system, Eq. (72) immediately gives the answer: the distribution should provide \( \mathbf{E} = \mathbf{E}_{\text{int}} + \mathbf{E}_{\text{ext}} = 0 \) inside the whole layer\(^{28}\) – the effect called the electric field screening. The only way to ensure this equality is to have enough free charges of opposite signs residing on the layer’s surfaces to induce a uniform field \( \mathbf{E}_{\text{int}} = -\mathbf{E}_{\text{ext}} \), exactly compensating the external field at each point inside the layer – see Fig. 7. According to Eq. (24), the areal density of these surface charges should equal \( \pm \sigma \), with \( \sigma = E_{\text{ext}}/\varepsilon_0 \). This is a rudimentary but reasonable model of the conductor’s polarization – to be discussed in detail in the next chapter.

### 1.4. Exercise problems

1.1. Calculate the electric field created by a thin, long, straight filament, electrically charged with a constant linear density \( \lambda \), using two approaches:

   (i) directly from the Coulomb law, and

   (ii) using the Gauss law.

1.2. Two thin, straight parallel filaments, separated by distance \( \rho \), carry equal and opposite uniformly distributed charges with linear density \( \lambda \) – see the figure on the right. Calculate the force (per unit length) of the Coulomb interaction of the wires. Compare its dependence on \( \rho \) with the Coulomb law for the force between two point charges.

1.3. A sphere of radius \( R \), whose volume had been charged with a constant density \( \rho \), is split with a very narrow, planar gap passing through its center. Calculate the force of the mutual electrostatic repulsion of the resulting two hemispheres.

1.4. A thin spherical shell of radius \( R \), that had been charged with a constant areal density \( \sigma \), is split into two equal halves by a very narrow, planar cut passing through the sphere’s center. Calculate the force of electrostatic repulsion between the resulting hemispheric shell, and compare the result with that of the previous problem.

1.5. Calculate the distribution of the electrostatic potential created by a straight, thin filament of a finite length \( 2l \), charged with a constant linear density \( \lambda \), and explore the result in the limits of very small and very large distances from the filament.

---

\(^{28}\) Note that the area-uniform distribution of the charge inside the layer does not affect the field (and hence its energy) outside it.
1.6. A thin plane sheet, perhaps of an irregular shape, carries electric charge with a constant areal density $\sigma$.

(i) Express the electric field’s component normal to the plane, at a certain distance from it, via the solid angle $\Omega$ at which the sheet is visible from the observation point.

(ii) Use the result to calculate the field in the center of a cube, with one face charged with a constant density $\sigma$.

1.7. Can one create, in an extended region of space, electrostatic fields with the Cartesian components proportional to the following products of Cartesian coordinates $\{x, y, z\}$:

(i) $\{yz, xz, xy\}$,

(ii) $\{xy, xy, yz\}$?

1.8. Distant sources have been used to create different electric fields on two sides of a wide and thin metallic membrane, with a round hole of radius $R$ in it – see the figure on the right. Besides the local perturbation created by the hole, the fields are uniform:

$$E(r)_{r>R} = n_z \times \begin{cases} E_1, \quad &\text{at } z < 0, \\ E_2, \quad &\text{at } z > 0. \end{cases}$$

Prove that the system may serve as an electrostatic lens for charged particles flying along the $z$-axis, at distances $\rho << R$ from it, and calculate the focal distance $f$ of the lens. Spell out the conditions of validity of your result.

1.9. Eight equal point charges $q$ are located at the corners of a cube of side $a$. Calculate all Cartesian components $E_j$ of the electric field, and their spatial derivatives $\partial E_j/\partial r_j$, at the cube’s center, where $r_j$ are the Cartesian coordinates oriented along the cube’s sides – see the figure on the right. Are all your results valid for the center of a plane square, with four equal charges in its corners?

1.10. By a direct calculation, find the average electric potential of the spherical surface of radius $R$, created by a point charge $q$ located at a distance $r > R$ from the sphere’s center. Use the result to prove the following general mean value theorem: the electric potential at any point is always equal to its average value on any spherical surface with the center at that point, and containing no electric charges inside it.

1.11. Two similar thin, circular, coaxial disks of radius $R$, separated by distance $2d$, are uniformly charged with equal and opposite areal densities $\pm \sigma$ – see the figure on the right. Calculate and sketch the distribution of the electrostatic potential and the electric field of the disks along their common axis.
1.12. In a certain reference frame, the electrostatic potential, created by some electric charge distribution, is

\[
\phi(\mathbf{r}) = C \left( \frac{1}{r} + \frac{1}{2r_0} \right) \exp\left\{ -\frac{r}{r_0} \right\},
\]

where \( C \) and \( r_0 \) are constants, and \( r \equiv |\mathbf{r}| \) is the distance from the origin. Calculate the charge distribution in space.

1.13. A thin flat sheet, cut in the form of a rectangle of size \( a \times b \), is electrically charged with a constant areal density \( \sigma \). Without an explicit calculation of the spatial distribution \( \phi(\mathbf{r}) \) of the electrostatic potential induced by this charge, find the ratio of its values at the center and at the corners of the rectangle.

**Hint:** Consider partitioning the rectangle into several similar parts and using the linear superposition principle.

1.14. Calculate the electrostatic energy per unit area of the system of two thin, parallel planes with equal and opposite charges of a constant areal density \( \sigma \), separated by distance \( d \).

1.15. The system analyzed in the previous problem (two thin, parallel, oppositely charged planes) is now placed into an external, uniform, normal electric field \( E_{\text{ext}} = \sigma/\epsilon_0 \) – see the figure on the right. Find the force (per unit area) acting on each plane, by two methods:

(i) directly from the electric field distribution, and
(ii) from the potential energy of the system.

1.16. Explore the relation between the Laplace equation (42) and the condition of the minimum of the electrostatic field energy (65).

1.17. Prove the following reciprocity theorem of electrostatics: if two spatially-confined charge distributions \( \rho_1(\mathbf{r}) \) and \( \rho_2(\mathbf{r}) \) create respective distributions \( \phi_1(\mathbf{r}) \) and \( \phi_2(\mathbf{r}) \) of the electrostatic potential, then

\[
\int \rho_1(\mathbf{r})\phi_2(\mathbf{r})d^3r = \int \rho_2(\mathbf{r})\phi_1(\mathbf{r})d^3r.
\]

**Hint:** Consider integral \( \int \mathbf{E}_1 \cdot \mathbf{E}_2 d^3r \).

1.18. Calculate the energy of electrostatic interaction of two spheres, of radii \( R_1 \) and \( R_2 \), each with a spherically-symmetric charge distribution, separated by distance \( d > R_1 + R_2 \).

1.19. Calculate the electrostatic energy \( U \) of a (generally, thick) spherical shell, with a charge \( Q \) uniformly distributed through its volume – see the figure on the right. Analyze and interpret the dependence of \( U \) on the inner cavity’s radius \( R_1 \), at fixed \( Q \) and \( R_2 \).

---

[29] This is only the simplest one of several reciprocity theorems in electromagnetism – see, e.g., Sec. 6.8 below.
Chapter 2. Charges and Conductors

This chapter will start a discussion of the very common situations when the electric charge distribution in space is not known a priori, but rather should be calculated in a self-consistent way together with the electric field it creates. The simplest situations of this kind involve conductors, and lead to the so-called boundary problems in which partial differential equations describing the field distribution have to be solved with appropriate boundary conditions. Such problems are also broadly used in other parts of electrodynamics (and indeed in other fields of physics as well), so that following tradition, I will use this chapter’s material as a playground for a discussion of various methods of boundary problem solution, and the special functions most frequently encountered in the process.

2.1. Polarization and screening

The basic principles of electrostatics outlined in Chapter 1 present the conceptually full solution to the problem of finding the electrostatic field (and hence Coulomb forces) induced by electric charges distributed over space with density \( \rho(\mathbf{r}) \). However, in most practical situations, this function is not known but should be found self-consistently with the field. For example, if a volume of relatively dense material is placed into an external electric field, it is typically polarized, i.e. acquires some local charges of its own, which contribute to the total electric field \( \mathbf{E}(\mathbf{r}) \) inside, and even outside it – see Fig. 1a.

The full solution of such problems should satisfy not only the fundamental Eq. (1.7), but also the so-called constitutive relations between various macroscopic variables describing the body’s material. Due to the atomic character of real materials, such relations may very involved. In this part of my series, I will have time to address these relations, for various materials, only rather superficially, focusing on their simple approximations. Fortunately, in most practical cases such approximations work very well.

In particular, for the polarization of good conductors, a very reasonable approximation is given by the so-called macroscopic model, in which the free charges in the conductor are is treated as a charged continuum that is free to move under the effect of the force \( \mathbf{F} = q\mathbf{E} \) exerted by the macroscopic electric field \( \mathbf{E} \), i.e. the field averaged over the atomic scale – see also the discussion at the end of Sec. 1.1. In electrostatics (which excludes the case dc currents, to be discussed in Chapter 4 below), there

---

1 A more detailed discussion of the electrostatic field screening may be found, e.g., in SM Sec. 6.4. (Alternatively, see either Sec. 13.5 of J. Hook and H. Hall, Solid State Physics, 2nd ed., Wiley, 1991; or Chapter 17 of N. Ashcroft and N. Mermin, Solid State Physics, Brooks Cole, 1976.)

© K. Likharev
should be no such motion, so that everywhere inside the conductor the macroscopic electric field should vanish:

$$E = 0.$$  \hspace{1cm} (2.1a)

This is the electric field screening\(^2\) effect, meaning, in particular, that the conductor’s polarization in an external electric field has the extreme form shown (rather schematically) in Fig. 1a, with the field of the induced surface charges completely compensating the external field in the conductor’s bulk. (Eq. (1a) may be rewritten in another, frequently more convenient form:

$$\phi = \text{const},$$  \hspace{1cm} (2.1b)

where \(\phi\) is the macroscopic electrostatic potential, related to the macroscopic electric field by Eq. (1.33). Note, however, that if a problem includes several unconnected conductors, the constant in Eq. (1b) may be specific for each of them.)

Now let us examine what we can say about the electric field just outside a conductor, within the same macroscopic model. At close proximity, any smooth surface (in our current case, that of a conductor) looks planar. Let us integrate Eq. (1.28) over a narrow \((d \ll l)\) rectangular loop \(C\) encircling a part of such plane conductor’s surface (see the dashed line in Fig. 2a), and apply to the electric field vector \(E\) the well-known vector algebra equality – the Stokes theorem\(^3\)

$$\oint_S (\nabla \times E)\, d^2r = \int_C E \cdot dr,$$  \hspace{1cm} (2.2)

where \(S\) is any surface limited by the contour \(C\).

In our current, case the contour is dominated by two straight lines of length \(l\), so that if \(l\) is much smaller that the characteristic scale of field change, but much larger that the inter-atomic distances, the right-hand side of Eq. (2) may be approximated as \([E_{\tau}^\text{in} - E_{\tau}^\text{out}] l\), where \(E_{\tau}\) is the tangential component of the corresponding macroscopic field, parallel to the surface. On the other hand, according to Eq. (1.28), the left-hand side of Eq. (2) equals zero. Hence, the macroscopic field’s component \(E_{\tau}\) should be continuous at the surface, and to satisfy Eq. (1a) inside the conductor, the component has to vanish immediately outside it: \([E_{\tau}]^\text{out} = 0\). This means that the electrostatic potential immediately outside of a conducting surface does not change along it. In other words, the equipotential surfaces outside a

\(^2\) This term, used for the electric field, should not be confused with shielding – the word used for the description of the magnetic field reduction by magnetic materials – see Chapter 5 below.

\(^3\) See, e.g., MA Eq. (12.1).
conductor should “lean” to the conductor’s surface, with their potential values approaching the constant potential – see Fig. 2b.

So, the electrostatic field just outside the conductor has to be normal to its surface. In order to find this normal field, we may use the universal relation (1.24). Since in our current case $E_n = 0$ inside the conductor, we get

$$\sigma = \varepsilon_0 (E_n)_{\text{out}} = -\varepsilon_0 (\nabla \phi)_n \equiv -\varepsilon_0 \frac{\partial \phi}{\partial n},$$

where $\sigma$ is the areal density of the conductor’s surface charge. Note that deriving this universal relation between the normal component of the field and the surface charge density, we have not used any cause-vs-effect arguments, so that Eq. (3) is valid regardless whether the surface charge is induced by an externally applied field (the case of conductor’s polarization, shown in Fig. 1a), or the electric field is induced by the electric charge placed on the conductor and then self-redistributed over its surface (Fig. 1b), or it is some mixture of both effects.

Before starting to use the macroscopic model for the solution of particular problems of electrostatics, let me use the balance of this section to briefly discuss its limitations. (The reader in a rush may skip this discussion and proceed to Sec. 2; however, I believe that every educated physicist has to understand when does the model work, and when it does not.)

Since the argumentation which has led to Eq. (1.24) and hence Eq. (3) is valid for any thickness $d$ of the Gauss pillbox, within the macroscopic model, the whole surface charge is located within an infinitely thin surface layer. This is of course impossible physically: for one, this would require an infinite volumic density $\rho$ of the charge. In reality, the charged layer (and hence the region of electric field’s crossover from the finite value (3) to zero) has a nonzero thickness $\lambda$. At least three effects contribute to $\lambda$.

(i) **Atomic structure of matter.** Within each atom, and frequently between the adjacent atoms as well, the genuine (“microscopic”) electric field is highly non-uniform. Thus, as was already stated above, Eq. (1) is valid only for the macroscopic field in a conductor, averaged over distances of the order of the atomic size scale $a_0 \sim 10^{-10}$ m, and cannot be applied to the field changes on that scale. As a result, the surface layer of charges cannot be much thinner than $a_0$.

(ii) **Thermal excitation.** In the conductor’s bulk, the number of protons of atomic nuclei ($n$) and electrons ($n_e$) per unit volume are balanced, so that the net charge density, $\rho = e(n - n_e)$, vanishes. However, if an external electric field penetrates a conductor, free electrons can shift in or out of its affected part, depending on the field’s contribution to their potential energy, $\Delta U = q_e \phi = -e \phi$. (Here the arbitrary constant in $\phi$ is chosen to give $\phi = 0$ well inside the conductor.) In the classical statistics, this change is described by the Boltzmann distribution:

$$n_e(r) = n \exp \left\{ -\frac{U(r)}{k_B T} \right\},$$

---

4 This scale originates from the quantum-mechanical effects of electron motion, characterized by the Bohr radius $r_B = h^2/m_e(e^2/4\pi\varepsilon_0) \approx 0.53 \times 10^{-10}$ m – see, e.g., QM Eq. (1.10). It also defines the scale $E_B = e/4\pi\varepsilon_0 r_B^2 \approx 10^{12}$ SI units (V/m) of the microscopic electric fields inside the atoms. (Please note how large these fields are.)

5 In this series, $e$ denotes the fundamental charge, $e \approx 1.6 \times 10^{-19}$ C > 0, so that the electron’s charge equals ($-e$).

6 See, e.g., SM Sec. 3.1.
where \( T \) is the absolute temperature in kelvins (K), and \( k_B \approx 1.38 \times 10^{-23} \) J/K is the Boltzmann constant. As a result, the net charge density is

\[
\rho(r) = en \left[ 1 - \exp \left( \frac{e\phi(r)}{k_B T} \right) \right].
\] (2.5)

The penetrating electric field polarizes the atoms as well. As will be discussed in the next chapter, such polarization results in the reduction of the electric field by a material-specific dimensionless factor \( \kappa \) (larger, but typically not too much larger than 1), called the dielectric constant. As a result, the Poisson equation (1.41) takes the form,

\[
\frac{d^2 \phi}{dz^2} = -\frac{\rho}{\kappa \varepsilon_0},
\] (2.6)

where we have taken advantage of the 1D geometry of the system to simplify the Laplace operator, with the \( z \)-axis normal to the surface.

Even with this simplification, Eq. (6) is a nonlinear differential equation allowing an analytical but rather bulky solution. Since our current goal is just to estimate of the field penetration depth \( \lambda \), let us simplify the equation further by considering the low-field limit: \( |\phi| \sim |E| \lambda \ll k_B T \). In this limit we may extend the exponent into the Taylor series, and keep only two leading terms (of which the first one cancels with the following unity). As a result, Eq. (6) becomes linear,

\[
\frac{d^2 \phi}{dz^2} = \frac{en}{\kappa \varepsilon_0 k_B T} \phi, \quad \text{i.e.,} \quad \frac{d^2 \phi}{dz^2} = \frac{1}{\lambda^2} \phi,
\] (2.7)

where the constant \( \lambda \), in this case, is called the Debye screening length \( \lambda_D \):

\[
\lambda_D^2 = \frac{\kappa \varepsilon_0 k_B T}{e^2 n}.
\] (2.8)

As the reader certainly knows, Eq. (7) describes an exponential decrease of the electric potential, with the characteristic length \( \lambda_D \): \( \phi \propto \exp\{-z/\lambda_D\} \), where the \( z \)-axis is directed inside the conductor. Plugging in the fundamental constants, we get the following estimate: \( \lambda_D [m] \approx 7 \times (\kappa \times T [K]/n [m^{-3}])^{1/2} \). According to this formula, in semiconductors at room temperature, the Debye length may be rather substantial. For example, in silicon (\( \kappa \approx 12 \)) doped to the free charge carrier concentration \( n = 3 \times 10^{18} \) cm\(^{-3}\) (the value typical for modern integrated circuits), \( \lambda_D \approx 2 \) nm, still well above the atomic size scale \( a_0 \). However, for typical good metals (\( n \sim 10^{29} \) m\(^{-3}\), \( \kappa \sim 10 \)) the same formula gives \( \lambda_D \sim 10^{-11} \) m, less than \( a_0 \). In this case Eq. (8) should not be taken literally, because it is based on the assumption of a continuous charge distribution.

\[\text{Debye screening length}\]

---

7 This equation and/or its straightforward generalization to the case of charged particles (ions) of several kinds is frequently (especially in the theories of electrolytes and plasmas) called the Debye-Hückel equation.

8 There is a good reason for making an estimate of \( \lambda_D \) for this case: the electric field created by the gate electrode of a field-effect transistor, penetrating into doped silicon by a depth \( \sim \lambda_D \), controls the electric current in this most important electronic device – on whose back all our information technology rides. Because of that, \( \lambda_D \) establishes the possible scale of semiconductor circuit shrinking, which is the basis of the well-known Moore’s law. (Practically, the scale is determined by integrated circuit patterning techniques, and Eq. (8) may be used to find the proper charge carrier density \( n \) and hence the necessary level of silicon doping – see, e.g., SM Sec. 6.4.)
(iii) Quantum statistics. Actually, the last estimate is not valid for good metals (and highly doped semiconductors) for one more reason: their free electrons obey the quantum (Fermi-Dirac) statistics rather than the Boltzmann distribution (4). As a result, at all realistic temperatures the electrons form a degenerate quantum gas, occupying all available energy states below certain energy level $E_F > k_B T$, called the Fermi energy. In these conditions, the screening of relatively low electric field may be described by replacing Eq. (5) with

$$\rho = e(n - n_e) = -eg(\hat{e}_F)(-U) = -e^2 g(\hat{e}_F)\phi,$$

where $g(\hat{e})$ is the density of quantum states (per unit volume per unit energy) at electron’s energy $\hat{e}$. At the Fermi surface, the density is of the order of $n/E_F$. As a result, we again get the second of Eqs. (7), but with a different characteristic scale $\lambda$, defined by the following relation:

$$\lambda_{TF}^2 = \frac{k e_0}{e^2 g(\hat{e}_F)} \sim \frac{k e_0 E_F}{e^2 n},$$

and called the Thomas-Fermi screening length. Since for most good metals, $n$ is of the order of $10^{29}$ m$^{-3}$, and $E_F$ is of the order of 10 eV, Eq. (10) typically gives $\lambda_{TF}$ close to a few $a_0$, and makes the Thomas-Fermi screening theory valid at least semi-quantitatively.

To summarize, the electric field penetration into good conductors is limited to a depth $\lambda$ ranging from a fraction of a nanometer to a few nanometers, so that for problems with the characteristic size much larger than that scale, the macroscopic model (1) gives very good accuracy, and we will use them in the rest of this chapter. However, the reader should remember that in many situations involving semiconductors, as well as at some nanoscale experiments with metals, the electric field penetration should be taken into account.

Another important condition of the macroscopic model’s validity is imposed on the electric field’s magnitude, which is especially significant for semiconductors. Indeed, as Eq. (6) shows, Eq. (7) is only valid if $e |\phi| << k_B T$, so that $|E| \sim |\phi| / \lambda_D$ should be much lower than $k_B T/e\lambda_D$. In the example given above ($\lambda_D \approx 2$ nm, $T = 300$ K), this means $|E| << E \sim 10^7$ V/m = $10^5$ V/cm – the value readily reachable in the lab. At larger fields, the field penetration becomes nonlinear, leading to the very important effect of carrier depletion; it will be discussed in SM Sec. 6.4. For typical metals, such linearity limit, $E \sim E_F/e\lambda_{TF}$ is much higher, $\sim 10^{11}$ V/m, but the model may be violated at lower fields by other effects, such as the impact-ionization leading to electric breakdown, which may start at $\sim 10^7$ V/m.

## 2.2. Capacitance

Let us start using the macroscopic model from systems consisting of charged conductors only, with no stand-alone charges in the space outside them. Our goal here is calculating the distributions of the electric field $E$ and potential $\phi$ in space, and the distribution of the surface charge density $\sigma$ over the conductor surfaces. However, before doing that for particular situations, let us see if there are any integral measures of these distributions, that should be our primary focus.

---

9 See, e.g., SM Sec. 2.8. For a more detailed derivation of Eq. (10), see SM Chapter 3.

10 See, e.g., SM Sec. 3.3.
The simplest case is of course a single conductor in the otherwise free space. According to Eq. (1b), all its volume should have a constant electrostatic potential $\phi$, evidently providing one convenient global measure of the situation. Another integral measure is provided by the total charge

$$Q \equiv \int_{V} \rho \, d^3 r \equiv \int_{S} \sigma \, d^2 r,$$

(2.11)

where the latter integral is extended over the whole surface $S$ of the conductor. In the general case, what we can tell about the relation between $Q$ and $\phi$? At $Q = 0$, there is no electric field in the system, and it is natural (though not necessary) to select the arbitrary constant in the electrostatic potential to have $\phi = 0$ everywhere. Then, if the conductor is charged with a non-zero $Q$, according to the linear Eq. (1.7), the electric field in any point of space has to be proportional to that charge. Hence the electrostatic potential at all points, including its value $\phi$ on the conductor, is also proportional to $Q$:

$$\phi = p Q. \quad (2.12)$$

The proportionality coefficient $p$, which depends on the conductor’s size and shape, but neither on $\phi$ nor on $Q$, is called the reciprocal capacitance (or, not too often, “electric elastance”). Usually, Eq. (12) is rewritten in a different form,

$$Q = C \phi, \quad \text{with} \quad C \equiv \frac{1}{p},$$

(2.13)

where $C$ is called self-capacitance. (Frequently, $C$ is called just capacitance, but as we will see very soon, for more complex situations the latter term may be ambiguous.)

Before calculating $C$ for particular geometries, let us have a look at the electrostatic energy $U$ of a single conductor. To calculate it, of the several relations discussed in Chapter 1, Eq. (1.61) is most convenient, because all elementary charges $q_k$ are now parts of the conductor’s surface charge, and hence reside at the same potential $\phi$ – see Eq. (1b) again. As a result, the equation becomes very simple:

$$U = \frac{1}{2} \phi \sum_{k} q_k = \frac{1}{2} \phi Q. \quad (2.14)$$

Moreover, using the linear relation (13), the same result may be re-written in two more forms:

$$U = \frac{Q^2}{2C} = \frac{C}{2} \phi^2. \quad (2.15)$$

We will discuss several ways to calculate $C$ in the next sections, and right now will have a quick look at just the simplest example for which we have calculated everything necessary in the previous chapter: a conducting sphere of radius $R$. Indeed, we already know the electric field distribution: according to Eq. (1), $E = 0$ inside the sphere, while Eq. (1.19), with $Q(r) = Q$, describes the field distribution outside it, because of the evident spherical symmetry of the surface charge distribution. Moreover, since the latter formula is exactly the same as for the point charge placed in the sphere’s center, the potential distribution in space can be obtained from Eq. (1.35) by replacing $q$ with the sphere’s full charge $Q$. Hence, on the surface of the sphere (and, according to Eq. (1b), through its interior),
\[ \phi = \frac{1}{4\pi \varepsilon_0} \frac{Q}{R}. \]  

(2.16)

Comparing this result with the definition (13), for the self-capacitance we obtain a very simple formula

\[ C = 4\pi \varepsilon_0 R. \]  

(2.17)

This formula, which should be well familiar to the reader,\(^{11}\) is convenient to get some feeling of how large the SI unit of capacitance (1 farad, abbreviated as F) is: the self-capacitance of Earth \( (R_E \approx 6.34 \times 10^6 \text{ m}) \) is below 1 mF! Another important note is that while Eq. (17) is not exactly valid for a conductor of arbitrary shape, it implies an important general estimate

\[ C \sim 2\pi \varepsilon_0 a \]  

(2.18)

where \( a \) is the scale of the linear size of any conductor.\(^{12}\)

Now proceeding to a system of two arbitrary conductors, we immediately see why we should be careful with the capacitance definition: one constant \( C \) is insufficient to describe such a system. Indeed, here we have two, generally different conductor potentials, \( \phi_1 \) and \( \phi_2 \), that may depend on both conductor charges, \( Q_1 \) and \( Q_2 \). Using the same arguments as for the single-conductor case, we may conclude that the dependence is always linear:

\[ \phi_1 = \rho_{11} Q_1 + \rho_{12} Q_2, \]
\[ \phi_2 = \rho_{21} Q_1 + \rho_{22} Q_2, \]  

(2.19)

but now has to be described by more than one coefficient. Actually, it turns out that there are three rather than four different coefficients in these relations, because

\[ \rho_{12} = \rho_{21}. \]  

(2.20)

This equality may be proved in several ways, for example, using the general reciprocity theorem of electrostatics (whose proof was the subject of Problem 1.17):

\[ \int \rho_1(\mathbf{r}) \phi^{(2)}(\mathbf{r}) d^3 r = \int \rho_2(\mathbf{r}) \phi^{(1)}(\mathbf{r}) d^3 r, \]  

(2.21)

where \( \phi^{(1)}(\mathbf{r}) \) and \( \phi^{(2)}(\mathbf{r}) \) are the potential distributions induced, respectively, by two electric charge distributions, \( \rho_1(\mathbf{r}) \) and \( \rho_2(\mathbf{r}) \). In our current case, each of these integrals is limited to the volume (or, more exactly, the surface) of the corresponding conductor, where each potential is constant and may be taken out of the integral. As a result, Eq. (21) is reduced to

\[ Q_1 \phi^{(2)}(\mathbf{r}_1) = Q_2 \phi^{(1)}(\mathbf{r}_2). \]  

(2.22)

\(^{11}\) In the Gaussian units, using the standard replacement \( 4 \pi \varepsilon_0 \rightarrow 1 \), this relation takes an even simpler form: \( C = R \), very easy to remember. Generally, in the Gaussian units (but not in the SI system!) the capacitance has the dimensionality of length, i.e. is measured in centimeters. Note also that a fractional SI unit, 1 picofarad \( (10^{-12} \text{ F}) \), is very close to the Gaussian unit: \( 1 \text{ pF} = (1 \times 10^{-12})/(4 \pi \varepsilon_0 \times 10^{-2}) \text{ cm} \approx 0.8998 \text{ cm} \). So, this unit is rather close to the capacitance of a metallic ball with a 1-cm radius, making it very convenient for human-scale systems.

\(^{12}\) These arguments are somewhat insufficient to say which size should be used for \( a \) in the case of narrow, extended conductors, e.g., a thin, long wire. Very soon we will see that in such cases the electrostatic energy, and hence \( C \), depends mostly on the larger size of the conductor.
In terms of Eq. (19), \( \phi^{(2)}(r_1) \) is just \( p_{12}Q_2 \), while \( \phi^{(1)}(r_2) \) equals \( p_{21}Q_1 \). Plugging these expressions into Eq. (22), and canceling the products \( Q_1Q_2 \), we arrive at Eq. (20).

Hence the 2×2 matrix of coefficients \( p_{jj'} \) (called the \textit{reciprocal capacitance matrix}) is always symmetric, and using the natural notation \( p_{11} \equiv p_1, p_{22} \equiv p_2, p_{12} = p_{21} \equiv p, \) we may rewrite it in a simpler form:

\[
\begin{pmatrix}
p_1 & p \\
p & p_2
\end{pmatrix}.
\] (2.23)

Plugging the relation (19), in this new notation, into Eq. (1.61), we see that the full electrostatic energy of the system may be expressed by a quadratic form:

\[
U = \frac{p_1}{2} Q_1^2 + pQ_1Q_2 + \frac{p_2}{2} Q_2^2.
\] (2.24)

It is evident that the middle term on the right-hand side of this equation describes the electrostatic coupling of the conductors. (Without it, the energy would be just a sum of two independent electrostatic energies of conductors 1 and 2.)\(^{13}\) Still, even with this simplification, Eqs. (19) and (20) show that in the general case of arbitrary charges \( Q_1 \) and \( Q_2 \), the system of two conductors should be characterized by three, rather than just one coefficient (“the capacitance”). This is why we may attribute a certain single capacitance to the system only in some particular cases.

For practice, the most important of them is when the system as the whole is electrically neutral: \( Q_1 = -Q_2 \equiv Q \). In this case, the most important function of \( Q \) is the difference of the conductors’ potentials, called the \textit{voltage}:\(^{14}\)

\[ V \equiv \phi_1 - \phi_2, \] (2.25)

For that function, the subtraction of two Eqs. (19) gives

\[ V = \frac{Q}{C}, \quad \text{with} \quad C \equiv \frac{1}{p_1 + p_2 - 2p}, \] (2.26)

where the coefficient \( C \) is called the \textit{mutual capacitance} between the conductors – or, again, just “capacitance”, if the term’s meaning is absolutely clear from the context. The same coefficient describes the electrostatic energy of the system. Indeed, plugging Eqs. (19) and (20) into Eq. (24), we see that both forms of Eq. (15) are reproduced if \( \phi \) is replaced with \( V \), \( Q_1 \) with \( Q \), and with \( C \) meaning the mutual capacitance:

\[
U = \frac{Q^2}{2C} = \frac{C}{2} V^2.
\] (2.27)

\(^{13}\) This is why systems with \( p \ll p_1, p_2 \) are called \textit{weakly coupled}, and may be analyzed using approximate methods – see, e.g., Fig. 4 and its discussion below.

\(^{14}\) A word of caution: in condensed matter physics and electrical engineering, voltage is frequently defined as the difference of \textit{electrochemical} rather than \textit{electrostatic} potentials. These two notions coincide if the conductors have equal \textit{workfunctions} – for example if they are made of the same material. In this course, this condition will be implied, and the difference between the two voltages ignored – to be discussed in detail in SM Sec. 6.3.
The best known system for which the mutual capacitance \( C \) may be readily calculated is the *plane* (or “parallel-plate”) *capacitor*, a system of two conductors separated with a narrow plane gap of a constant thickness \( d \) and an area \( A \sim a^2 \gg d^2 \) — see Fig. 3.

![Fig. 2.3. Plane capacitor](image)

Since the surface charges, that contribute to the opposite charges \( \pm Q \) of the conductors of this system, attract each other, in the limit \( d \ll a \) they sit entirely on the opposite surfaces limiting the gap, so there is virtually no electric field outside of the gap, while (according to the discussion in Sec. 1) inside the gap it is normal to the surfaces. According to Eq. (3), the magnitude of this field is \( E = \sigma / \varepsilon_0 \). Integrating this field across thickness \( d \) of the narrow gap, we get \( V = \phi_1 - \phi_2 = Ed = \sigma d / \varepsilon_0 \), so that \( \sigma = \varepsilon_0 V / d \). But due to the constancy of the potential of each electrode, \( V \) should not depend on the position in the gap area. As a result, \( \sigma \) should be also constant over all the gap area \( A \), regardless of the external geometry of the conductors (see Fig. 3 again), and hence \( Q = \sigma A = \varepsilon_0 V / d \). Thus we may write \( V = Q / C \), with

\[
C = \frac{\varepsilon_0 A}{d}.
\]  

(2.28)

Let me offer a few comments on this well-known formula. First, it is valid even if the gap is not quite planar – for example, if it gently curves on a scale much larger than \( d \), but retain its thickness. Second, Eq. (28), valid if \( A \sim a^2 \) is much larger than \( d^2 \), ignores the electric field deviations from uniformity\(^{15} \) at distances \( \sim d \) near the gap edges. Finally, the same condition \( (A \gg d^2) \) assures that \( C \) is much larger than the self-capacitance \( C_j \sim \varepsilon_0 a \) of each conductor – see Eq. (18). The opportunities open by this fact for electronic engineering and experimental physics practice are rather astonishing. For example, a very realistic 3-nm layer of high-quality aluminum oxide (which may provide a nearly perfect electric insulation between two thin conducting films) with an area of 0.1 m\(^2\) (which is a typical area of silicon wafers used in the semiconductor industry) provides \( C \sim 1 \text{ mF} \),\(^{16} \) larger than the self-capacitance of the whole planet Earth!

In the case shown in Fig. 3, the electrostatic coupling of the two conductors is evidently strong. As an opposite example of a weakly coupled system, let us consider two conducting spheres of the same radius \( R \), separated by a much larger distance \( d \) (Fig. 4).

![Fig. 2.4. A system of two far separated, similar conducting spheres.](image)

\(^{15} \) Such “fringe” fields result in an additional “stray” capacitance \( C' \sim \varepsilon_0 a \ll C \sim \varepsilon_0 a \times (a / d) \).

\(^{16} \) Just as in Sec. 1, in order for the estimate to be realistic, I took into account the additional factor \( \kappa \) (for aluminum oxide, close to 10) which should be included into the numerator of Eq. (28) to make it applicable to dielectrics – see Chapter 3 below.
In this case, the diagonal components of the matrix (23) may be approximately found from Eq. (16), i.e. by neglecting the coupling altogether:

\[
p_1 = p_2 \approx \frac{1}{4\pi \varepsilon_0 R}.
\] (2.29)

Now, if we had just one sphere (say, number 1), the electric potential at distance \(d\) from its center would be given by Eq. (16):

\[
\phi = \frac{Q_1}{4\pi \varepsilon_0 d}.
\]

If we move into this point a small \((R \ll d)\) sphere without its own charge, we may expect that its potential should not be too far from this result, so that \(\phi_2 \approx \frac{Q_1}{4\pi \varepsilon_0 d}\). Comparing this expression with the second of Eqs. (19) (taken for \(Q_2 = 0\)), we get

\[
p \approx \frac{1}{4\pi \varepsilon_0 d} \ll p_{1,2}.
\] (2.30)

From here and Eq. (26), the mutual capacitance

\[
C \approx \frac{1}{p_1 + p_2} \approx \frac{1}{2\pi \varepsilon_0 R}.
\] (2.31)

We see that (somewhat counter-intuitively), in this limit \(C\) does not depend substantially on the distance between the spheres, i.e. does not describe their electrostatic coupling. The off-diagonal coefficients of the reciprocal capacitance matrix (20) play this role much better – see Eq. (30).

Now let us consider the case when only one conductor of the two is charged, for example \(Q_1 \equiv Q\), while \(Q_2 = 0\). Then Eqs. (19)-(20) yield

\[
\phi_1 = \frac{Q}{p_1}.
\] (2.32)

Now, we may follow Eq. (13) and define \(C_1 \equiv 1/p_1\) (and \(C_2 \equiv 1/p_2\)), just to see that such partial capacitances of the conductors of the system differ from its mutual capacitance \(C\) – cf. Eq. (26). For example, in the case shown in Fig. 4, \(C_1 = C_2 \approx 4\pi \varepsilon_0 R \approx 2C\).

Finally, let us consider one more frequent case when one of the conductors carries a certain charge (say, \(Q_1 = Q\)), but the potential of its counterpart is sustained constant, say \(\phi_2 = 0\).\(^{17}\) (This condition is especially easy to implement if the second conductor is much larger than the first one. Indeed, as the estimate (18) shows, in this case it would take a much larger charge \(Q_2\) to make the potential \(\phi_2\) comparable with \(\phi_1\).) In this case the second of Eqs. (19), with the account of Eq. (20), yields \(Q_2 = -\frac{p_1}{p_2}Q_1\). Plugging this relation into the first of those equations, we get

\[
Q_1 = C_1^{\text{eff}} \phi_1, \quad \text{with} \quad C_1^{\text{eff}} \equiv \left( p_1 - \frac{p_2}{p_1} \right)^{-1} \equiv \frac{p_2}{p_1 p_2 - p_1^2}.
\] (2.33)

Thus, this effective capacitance of the first conductor is generally different both from both its partial capacitance \(C_1\) and the mutual capacitance \(C\) of the system, emphasizing again how accurate one should be using this term.

\(^{17}\) In electrical engineering, such constant-potential conductor is called the ground. This term stems from the fact that in many cases the Earth surface may be considered a good electric ground, because its potential is unaffected by laboratory-scale electric charges.
Note also that none of these capacitances is equal to any element of the matrix reciprocal to the matrix (23):

$$\begin{pmatrix} p_1 & p \\ p & p_2 \end{pmatrix}^{-1} = \frac{1}{p^2 - p_1 p_2} \begin{pmatrix} -p_2 & p \\ p & -p_1 \end{pmatrix}. \quad (2.34)$$

Because of this reason, the last matrix (sometimes called the physical capacitance matrix), which expresses the vector of conductor charges via the vector of their potentials, is less convenient for most applications than the reciprocal capacitance matrix (23). The same conclusion is valid for multi-conductor systems, which are most conveniently characterized by an evident generalization of Eq. (19). Indeed, in this case even the mutual capacitance between two selected conductors may depend on the electrostatic conditions of other components of the system.

Logically, at this point I would need to discuss the particular, but practically very important case when the regions, where the electric field between each pair of conductors is most significant, do not overlap – such as in the example shown in Fig. 5a. In this case the system’s properties may be discussed using the equivalent-circuit language, representing each such region as a lumped (localized) capacitor, with a certain mutual capacitance $C$, and the whole system as some connection of these capacitors by conducting “wires”, whose length and geometry are not important – see Fig. 5b.

Since the analysis such equivalent circuits is covered in typical introductory physics courses, I will save time by skipping their discussion. However, since such circuits are very frequently met in the physical experiment and electrical engineering practice, I would urge the reader to self-test their understanding of this topic by solving a couple of problems offered in the end of this chapter,\(^{18}\) and if their solution presents any difficulty, review the corresponding section in an undergraduate textbook.

### 2.3. The simplest boundary problems

In the general case when the electric field distribution in the free space between the conductors cannot be easily found from the Gauss law or by any other special methods, the best approach is to try to solve the differential Laplace equation (1.42), with boundary conditions (1b):

$$\nabla^2 \phi = 0, \quad \phi \bigg|_{S_k} = \phi_k, \quad (2.35)$$

\(^{18}\) These problems have been selected to emphasize the fact that not every circuit may be reduced to the simplest connections of the capacitors in parallel and/or in series.
where $S_k$ is the surface of the $k^{th}$ conductor of the system. After such boundary problem has been solved, i.e. the spatial distribution $\phi(r)$ has been found in all points outside the conductors, it is straightforward to use Eq. (3) to find the surface charge density, and finally the total charge

$$Q_k = \oint_{S_k} \sigma d^2 r$$

(2.36)

of each conductor, and hence any component of the reciprocal capacitance matrix. As an illustration, let us implement this program for three very simple problems.

(i) Plane capacitor (Fig. 3). In this case, the easiest way to solve the Laplace equation is to use the linear (Cartesian) coordinates with one coordinate axis (say, $z$), normal to the conductor surfaces – see Fig. 6.

In these coordinates, the Laplace operator is just the sum of three second derivatives.\(^{19}\) It is evident that due to problem’s translational symmetry in the $[x, y]$ plane, deep inside the gap (i.e. at the lateral distance from the edges much larger than $d$) the electrostatic potential may only depend on the coordinate perpendicular to the gap surfaces: $\phi(r) = \phi(z)$. For such a function, the derivatives over $x$ and $y$ vanish, and the boundary problem (35) is reduced to a very simple ordinary differential equation

$$\frac{d^2 \phi}{dz^2}(z) = 0,$$

(2.37)

with boundary conditions

$$\phi(0) = 0, \quad \phi(d) = V.$$  

(2.38)

(For the sake of notation simplicity, I have used the discretion of adding a constant to the potential to make one of the potentials vanish, and also the definition (25) of the voltage $V$.) The general solution of Eq. (37) is a linear function: $\phi(z) = c_1 z + c_2$, whose constant coefficients $c_{1,2}$ may be readily found from the boundary conditions (38). The final solution is

$$\phi = V \frac{z}{d},$$

(2.39)

From here the only nonzero component of the electric field is

$$E_z = -\frac{d\phi}{dz} = -\frac{V}{d},$$

(2.40)

and the surface charge of the capacitor plates

\(^{19}\) See, e.g. MA Eq. (9.1).
\[
\sigma = \varepsilon_0 E_x = \pm \varepsilon_0 E_z = \pm \varepsilon_0 \frac{V}{d},
\]

where the upper and lower sign correspond to the upper and lower plate, respectively. Since \(\sigma\) does not depend on \(x\) and \(y\), we can get the full charges \(Q_1 = -Q_2 \equiv Q\) of the surfaces by its multiplication by the gap area \(A\), giving us again the already known result (28) for the mutual capacitance \(C \equiv Q/V\). I believe that this calculation, though very easy, may serve as a good introduction to the boundary problem solution philosophy, which will be used below for more complex cases.

(ii) Coaxial-cable capacitor. The coaxial cable is a system of two round cylindrical, coaxial conductors, with the cross-section shown in Fig. 7.

![Fig. 2.7. The cross-section of a coaxial capacitor.](image)

Evidently, in this case the cylindrical coordinates \(\{\rho, \varphi, z\}\), with the \(z\)-axis coinciding with the common axis of the cylinders, are most convenient. Due to the axial symmetry of the problem, in these coordinates \(\mathbf{E}(\mathbf{r}) = n \rho \mathbf{E}(\rho), \ \phi(\mathbf{r}) = \phi(\rho), \) so that in the general expression for the Laplace operator\(^{20}\) we can take \(\partial/\partial \varphi = \partial/\partial z = 0\). As a result, only the first (radial) term of the operator survives, and the boundary problem (35) takes the form

\[
\frac{1}{\rho} \frac{d}{d\rho} \left( \rho \frac{d\phi}{d\rho} \right) = 0, \quad \phi(a) = V, \quad \phi(b) = 0.
\]

The sequential integration of this ordinary differential equation is elementary (and similar to that of the Poisson equation in spherical coordinates, carried out in Sec. 1.3), giving

\[
\rho \frac{d\phi}{d\rho} = c_1, \quad \phi(\rho) = c_1 \int_a^\rho \frac{d\rho}{\rho} + c_2 = c_1 \ln \frac{\rho}{a} + c_2.
\]

The constants \(c_{1,2}\) may be found using boundary conditions (42):

\[
V = c_2, \quad 0 = c_1 \ln \frac{b}{a} + c_2,
\]

giving \(c_1 = -V/\ln(b/a)\), so that solution (43) takes the following form:

\[
\phi(\rho) = V \left( 1 - \frac{\ln(\rho/a)}{\ln(b/a)} \right).
\]

\(^{20}\) See, e.g., MA Eq. (10.3).
Next, for our axial symmetry, the general expression for the gradient of a function is reduced to its radial derivative, so that

\[ E(\rho) = -\frac{d\phi(\rho)}{d\rho} = \frac{V}{\rho \ln(b/a)}. \]  

(2.46)

This expression, plugged into Eq. (2), allows us to find the density of conductors’ surface charge. For example, for the inner electrode

\[ \sigma_a = \varepsilon_0 E_a = \frac{\varepsilon_0 V}{a \ln(b/a)}, \]  

(2.47)

so that its full charge (per unit length of the system) is

\[ \frac{Q}{l} = 2\pi a \sigma_a = \frac{2\pi \varepsilon_0 V}{\ln(b/a)}. \]  

(2.48)

(It is straightforward to check that the charge of the outer electrode is equal and opposite.) Hence, by the definition of the mutual capacitance, its value per unit length is

\[ \frac{C}{l} = \frac{Q}{lV} = \frac{2\pi \varepsilon_0}{\ln(b/a)}. \]  

(2.49)

This expression shows that the total capacitance \( C \) is proportional to the systems length \( l \) (if \( l >> a, b \)), while being only logarithmically dependent on is the dimensions of its cross-section. Since the logarithm of a very large argument is an extremely slow function (sometimes called a \textit{quasi-constant}), if the external conductor is made large (\( b >> a \)), the capacitance diverges, but very weakly. Such a logarithmic divergence may be cut by any minuscule additional effect, for example by the finite length \( l \) of the system. This allows one to get a very useful estimate of the self-capacitance of a \textit{single} round wire of radius \( a \):

\[ C \approx \frac{2\pi \varepsilon_0 l}{\ln(l/a)}, \quad \text{for} \ l >> a. \]  

(2.50)

On the other hand, if the gap between the conductors is very narrow: \( b = a + d \), with \( d << a \), then \( \ln(b/a) = \ln(1 + d/a) \) may be approximated as \( d/a \), and Eq. (49) is reduced to \( C \approx 2\pi \varepsilon_0 aL/d \), i.e. to Eq. (28) for the plane capacitor, of the appropriate area \( A = 2\pi aL \).

(iii) \textbf{Spherical capacitor}. This is a system of two conductors, with the \textit{central} cross-section similar to that of the coaxial cable (Fig. 7), but now with the spherical rather than axial symmetry. This symmetry implies that we would be better off using spherical coordinates, so that potential \( \phi \) depends only on one of them, the distance \( r \) from the common center of the conductors: \( \phi(r) = \phi(r) \). As we already know from Sec. 1.3, in this case the general expression for the Laplace operator is reduced to its first (radial) term, so that the Laplace equation takes the simple form (1.47). Moreover, we have already found the general solution to this equation – see Eq. (1.50):

\[ \phi(r) = \frac{c_1}{r} + c_2, \]  

(2.51)

Now acting exactly as above, i.e. determining the constant \( c_1 \) from the boundary conditions \( \phi(a) = V, \phi(b) = 0 \), we get
\begin{equation}
V = c_1 \left( \frac{1}{a} - \frac{1}{b} \right), \quad \text{so that} \quad \phi(r) = \frac{V}{r} \left( \frac{1}{a} - \frac{1}{b} \right)^{-1} + c_2.
\end{equation}

Next, we can use the spherical symmetry to find the electric field, \( E(r) = n \cdot E(r) \), with

\begin{equation}
E(r) = -\frac{d\phi}{dr} = \frac{V}{r^2} \left( \frac{1}{a} - \frac{1}{b} \right)^{-1},
\end{equation}

and hence its values on conductors’ surfaces, and then the surface charge density \( \sigma \) from Eq. (3). For example, for the inner conductor’s surface,

\begin{equation}
\sigma_a = \varepsilon_0 E(a) = \varepsilon_0 \frac{V}{a^2} \left( \frac{1}{a} - \frac{1}{b} \right)^{-1},
\end{equation}

so that, finally, for the full charge of that conductor we get the following result:

\begin{equation}
Q = 4\pi a^2 \sigma = 4\pi \varepsilon_0 \left( \frac{1}{a} - \frac{1}{b} \right)^{-1} V.
\end{equation}

(Again, the charge of the outer conductor is equal and opposite.) Now we can use the definition (26) of the mutual capacitance to get the final result

\begin{equation}
C \equiv \frac{Q}{V} = 4\pi \varepsilon_0 \left( \frac{1}{a} - \frac{1}{b} \right)^{-1} = 4\pi \varepsilon_0 \frac{ab}{b-a}.
\end{equation}

For \( b \gg a \), this result coincides with Eq. (17) for the self-capacitance of the inner conductor. On the other hand, if the gap between two conductors is narrow, \( d \equiv b - a \ll a \),

\begin{equation}
C_m = 4\pi \varepsilon_0 \frac{a(a + d)}{d} \approx 4\pi \varepsilon_0 \frac{a^2}{d},
\end{equation}

i.e. the capacitance approaches that of the planar capacitor of area \( A = 4\pi a^2 \) – as it should.

All this seems (and is) very straightforward, but let us contemplate what was the reason for such easy successes. In each of the cases (i)-(iii) we have managed to find such coordinates that both the Laplace equation and the boundary conditions involve only one of them. The necessary condition for the former fact is that the coordinates are \textit{orthogonal}. This means that three vector components of the local differential \( dr \), due to small variations of the new coordinates (say, \( d\theta \) and \( d\phi \) for the spherical coordinates), are mutually perpendicular.

2.4. Using other orthogonal coordinates

Since the cylindrical and spherical coordinates used above are only the simplest examples of the \textit{curvilinear orthogonal} (or just “orthogonal”) coordinates, this methodology may be extended to other coordinate systems of this type. As an example, let us calculate the self-capacitance of a thin, round conducting disk. The cylindrical or spherical coordinates would not give too much help here, because while they have the appropriate axial symmetry about axis \( z \), they would make the boundary condition on the disk too complicated – involving two coordinates, either \( \rho \) and \( z \), or \( r \) and \( \theta \). The help comes from noting that the flat disk, i.e. the area \( z = 0, r < R \), may be thought of as the limiting case of an \textit{axially-}
symmetric ellipsoid – the result of the rotation of the usual ellipse about one of its axes – in our case, the symmetry axis of the conducting disk (in Fig. 8, the axis $z$).\(^{21}\)

![Figure 2.8. Solving the disk’s capacitance problem. (The cross-section of the system by the vertical plane $y = 0$.)](image)

Analytically, such an ellipsoid may be described by the following equation:

$$\frac{x^2 + y^2}{a^2} + \frac{z^2}{b^2} = 1,$$

where $a$ and $b$ are the so-called major semi-axes, whose ratio determines the ellipse eccentricity (the degree of squeezing). For our problem, we will only need oblate ellipsoids with $a \geq b$; according to Eq. (58), they may be represented as surfaces of constant $\alpha$ in the degenerate ellipsoidal (or “spheroidal”) coordinates $\{\alpha, \beta, \varphi\}$, which are related to the Cartesian coordinates as follows:

$$\begin{align*}
x &= R \cosh \alpha \sin \beta \cos \varphi, \\
y &= R \cosh \alpha \sin \beta \sin \varphi, \\
z &= R \sinh \alpha \cos \beta.
\end{align*}$$

(2.59)

Such ellipsoidal coordinates are an evident generalization of the spherical coordinates, which correspond to the limit $\alpha \gg 1$ (i.e. $r \gg R$). In the opposite limit, the surface of constant $\alpha = 0$ describes our thin disk of radius $R$, with the coordinate $\beta$ describing the distance $\rho \equiv (x^2 + y^2)^{1/2} = R \sin \beta$ of its point from the axis $z$. It is almost evident (and easy to prove) that the curvilinear coordinates (59) are also orthogonal, so that the Laplace operator may be expressed as a sum of three independent terms:

$$\nabla^2 = \frac{1}{R^2 (\cosh^2 \alpha - \sin^2 \beta)} \left[ \frac{1}{\cosh \alpha} \frac{\partial}{\partial \alpha} \left( \cosh \alpha \frac{\partial}{\partial \alpha} \right) + \frac{1}{\sin \beta} \frac{\partial}{\partial \beta} \left( \sin \beta \frac{\partial}{\partial \beta} \right) + \left( \frac{1}{\sin^2 \beta} - \frac{1}{\cosh^2 \alpha} \right) \frac{\partial^2}{\partial \varphi^2} \right].$$

(2.60)

Though this expression may look a bit intimidating, let us notice that in our current problem, the boundary conditions depend only on coordinate $\alpha$:\(^{22}\)

$$\phi \Big|_{\alpha=0} = V, \quad \phi \Big|_{\alpha=\alpha_0} = 0.$$  

(2.61)

Hence there is every reason to believe that the electrostatic potential in all space is a function of $\alpha$ alone; in other words, that all ellipsoids $\alpha = \text{const}$ are the equipotential surfaces. Indeed, acting on such a

---

\(^{21}\) Alternative names for this surface are the “degenerate ellipsoid”, “ellipsoid of rotation”, and “spheroid”.

\(^{22}\) I have called disk’s potential $V$, to distinguish it from the potential $\phi$ at an arbitrary point of space.
function $\phi(\alpha)$ by the Laplace operator (60), we see that the two last terms in the square brackets vanish, and the Laplace equation (35) is reduced to a simple ordinary differential equation

$$\frac{d}{d\alpha} \left[ \cosh \alpha \frac{d\phi}{d\alpha} \right] = 0. \quad (2.62)$$

Integrating it twice, just as we did in the previous problems, we get

$$\phi(\alpha) = c_1 \int \frac{d\alpha}{\cosh \alpha}. \quad (2.63)$$

This integral may be readily worked out, using the substitution $\xi = \sinh \alpha$ (giving $d\xi = \cosh \alpha \, d\alpha$, $\cosh^2 \alpha = 1 + \sinh^2 \alpha = 1 + \xi^2$):

$$\phi(\alpha) = c_1 \int_0^{\sinh \alpha} \frac{d\xi}{1 + \xi^2} + c_2 = c_1 \tan^{-1} (\sinh \alpha) + c_2. \quad (2.64)$$

The integration constants $c_{1,2}$ are again simply found from boundary conditions, in this case Eqs. (61), and we arrive at the following final expression for the electrostatic potential:

$$\phi(\alpha) = V \left[ 1 - \frac{2}{\pi} \tan^{-1} (\sinh \alpha) \right]. \quad (2.65)$$

This solution satisfies both the Laplace equation and the boundary conditions. Mathematicians tell us that the solution of any boundary problem of the type (35) is unique, so we do not need to look any further.

Now we may use Eq. (3) to find the surface density of electric charge, but in the case of a thin disk, it is more natural to add up such densities on its top and bottom surfaces at the same distance $\rho = (x^2 + y^2)^{1/2}$ from the disk’s center (which are evidently equal, due to the problem symmetry about the plane $z = 0$): $\sigma = 2\alpha_0 E_0|_{z = 0}$. According to Eq. (65), the electric field on the upper surface is

$$E_n|_{\alpha = 0} = -\frac{\partial \phi(\alpha)}{\partial \xi} \bigg|_{\xi = 0} = -\frac{\partial \phi(\alpha)}{\partial (R \sinh \alpha \cos \beta)} \bigg|_{\alpha = 0} = \frac{2}{\pi} V \frac{1}{R \cos \beta} = \frac{2}{\pi} \frac{1}{V} \left( \frac{1}{R^2} - \frac{1}{\rho^2} \right)^{1/2}, \quad (2.66)$$

and we see that the charge is distributed over the disk very non-uniformly:

$$\sigma = \frac{4}{\pi} \varepsilon_0 V \frac{1}{(R^2 - \rho^2)^{1/2}}, \quad (2.67)$$

with a singularity at the disk edge. Below we will see that such singularities are very typical for sharp edges of conductors.\(^{23}\) Fortunately, in our current case the divergence is integrable, giving a finite disk charge:

$$Q = \int_{\text{disk surface}} \sigma \, d^2 \rho = \int_0^R \sigma(\rho) 2\pi \rho \, d\rho = \frac{4}{\pi} \varepsilon_0 V 2\pi R \int_0^R \frac{\rho \, d\rho}{(R^2 - \rho^2)^{1/2}} = 4\varepsilon_0 V R \int_0^1 \frac{d\xi}{(1 - \xi^2)^{1/2}} = 8\varepsilon_0 RV. \quad (2.68)$$

---

\(^{23}\) If you seriously worry about the formal infinity of the charge density at $\rho \to R$, please remember that this mathematical artifact disappears with the account of any nonzero disk thickness.
Thus, for the disk’s self-capacitance we get a very simple result,

\[ C = 8\varepsilon_0 R \equiv \frac{2}{\pi} 4\pi\varepsilon_0 R, \]  

(2.69)
a factor of \(2/\pi \approx 0.64\) lower than that for the conducting sphere of the same radius, but still complying with the general estimate (18).

Can we always find such a “good” system of orthogonal coordinates? Unfortunately, the answer is no, even for highly symmetric geometries. This is why the practical value of this approach is limited, and other, more general methods of boundary problem solution are clearly needed. Before proceeding to their discussion, however, let me note that in the case of 2D problems (i.e. cylindrical geometries\(^{24}\)), the orthogonal coordinate method gets much help from the following conformal mapping approach.

Let us consider a pair of Cartesian coordinates \(\{x, y\}\) of the cross-section plane as a complex variable \(z = x + iy\),\(^{25}\) where \(i\) is the imaginary unit \((i^2 = -1)\), and let \(\omega(z) = u + iv\) be an analytic complex function of \(z\).\(^{26}\) For our current purposes, the most important property of an analytic function is that its real and imaginary parts obey the following Cauchy-Riemann relations:\(^{27}\)

\[ \frac{\partial u}{\partial x} = \frac{\partial v}{\partial y}, \quad \frac{\partial v}{\partial x} = -\frac{\partial u}{\partial y}, \]  

(2.70)
For example, for the function

\[ \omega = z^2 = (x + iy)^2 = (x^2 - y^2) + 2ixy, \]  

(2.71)
whose real and imaginary parts are

\[ u = \text{Re}\, \omega = x^2 - y^2, \quad v = \text{Im}\, \omega = 2xy, \]  

(2.72)
we immediately see that \(\partial u/\partial x = 2x = \partial v/\partial y\), and \(\partial v/\partial x = 2y = -\partial u/\partial y\), in accordance with Eq. (70).

Let us differentiate the first of Eqs. (70) over \(x\) again, then change the order of differentiation, and after that use the latter of those equations:

\[ \frac{\partial^2 u}{\partial x^2} = \frac{\partial}{\partial x}\frac{\partial u}{\partial x} = \frac{\partial}{\partial x}\frac{\partial v}{\partial y} = \frac{\partial}{\partial y}\frac{\partial v}{\partial x} = -\frac{\partial}{\partial y}\frac{\partial u}{\partial x} = -\frac{\partial^2 u}{\partial y^2}, \]  

(2.73)
and similarly for \(v\). This means that the sum of second-order partial derivatives of each of real functions \(u(x,y)\) and \(v(x,y)\) is zero, i.e. that the both functions obey the 2D Laplace equation. This mathematical fact opens a nice way of solving problems of electrostatics for (relatively simple) 2D geometries.

---

\(^{24}\) Let me remind the reader that the term cylindrical describes any surface formed by a translation, along a straight line, of an arbitrary curve, and hence more general than the usual circular cylinder. (In this terminology, for example, a prism is also a cylinder of a particular type, formed by a translation of a polygon.)

\(^{25}\) The complex variable \(z\) should not be confused with the (real) \(3^{\text{rd}}\) spatial coordinate \(z\)! We are considering 2D problems now, with the potential independent of \(z\).

\(^{26}\) The analytic (or “holomorphic”) function may be defined as the one that may be expanded into the complex Taylor series, i.e. is infinitely differentiable in the given point. (Almost all “regular” functions, such as \(x^n, x^{1/n}, \exp x, \ln x\), etc. and their combinations are analytic at all \(z\), maybe besides certain special points.) If the reader needs to brush up their background on this subject, I can recommend a popular (and very inexpensive :-) textbook by M. Spiegel et al., Complex Variables, 2\(^{\text{nd}}\) ed., McGraw-Hill, 2009.

\(^{27}\) These relations may be used, in particular, to prove the Cauchy integral formula – see, e.g., MA Eq. (15.1).
Imagine that for a particular boundary problem we have found a function \( w(z) \) for which either \( u(x, y) \) or \( v(x, y) \) is constant on all electrode surfaces. Then all lines of constant \( u \) (or \( v \)) represent equipotential surfaces, i.e. the problem of the potential distribution has been essentially solved.

As a simple example, consider a practically important problem: the *quadrupole electrostatic lens* – a system of four cylindrical electrodes with hyperbolic cross-sections, whose boundaries obey the following relations:

\[
x^2 - y^2 = \begin{cases} +a^2, & \text{for the left and right electrodes,} \\ -a^2, & \text{for the top and bottom electrodes,} \end{cases}
\]  

(2.74)

voltage-biased as shown in Fig. 9a.

![Fig. 2.9. (a) The quadrupole electrostatic lens’ cross-section and (b) its conformal mapping.](image)

Comparing these relations with Eqs. (72), we see that each electrode surface corresponds to a constant value of the function \( u(x, y) \): \( u = \pm a^2 \). Moreover, the potentials of both surfaces with \( u = +a^2 \) are equal to \( +V/2 \), while those with \( u = -a^2 \) are equal to \( -V/2 \). Hence we may conjecture that the electrostatic potential at each point is a function of \( u \) alone; moreover, a simple linear function,

\[
\phi = c_1 u + c_2 = c_1 (x^2 - y^2) + c_2,
\]  

(2.75)

is a valid (and hence the unique) solution of our boundary problem. Indeed, it does satisfy the Laplace equation, while the constants \( c_{1,2} \) may be readily selected in a way to satisfy all the boundary conditions shown in Fig. 9a:

\[
\phi = \frac{V}{2} \frac{x^2 - y^2}{a^2}.
\]  

(2.76)

so that the boundary problem has been solved.

According to Eq. (76), all equipotential surfaces are hyperbolic cylinders, similar to those of the electrode surfaces. What remains is to find the electric field at an arbitrary point inside the system:

\[
E_x = -\frac{\partial \phi}{\partial x} = -\frac{V}{a^2} x, \quad E_y = -\frac{\partial \phi}{\partial y} = V \frac{y}{a^2}.
\]  

(2.77)

These formulas show, in particular, that if charged particles (e.g., electrons in an electron optics system) are launched to fly ballistically through such a lens, along axis \( z \), they experience a force pushing them toward the symmetry axis and proportional to particle’s deviation from the axis (and thus equivalent in
action to an optical lens with a positive refraction power) in one direction, and a force pushing them out (negative refractive power) in the perpendicular direction. One can show that letting charged particles fly through several such lenses, with alternating voltage polarities, in series, enables beam focusing.28

Hence, we have reduced the 2D Laplace boundary problem to that of finding the proper analytic function \( w(z) \). This task may be also understood as that of finding a conformal map, i.e. a correspondence between components of any point pair, \( \{x, y\} \) and \( \{u, v\} \), residing, respectively, on the initial Cartesian plane \( z \) and the plane \( w \) of the new variables. For example, Eq. (71) maps the real electrode configuration onto a plane capacitor of an infinite area (Fig. 9b), and the simplicity of Eq. (75) is due to the fact that for the latter system the equipotential surfaces are just parallel planes.

For more complex geometries, the suitable analytic function \( w(z) \) may be hard to find. However, for conductors with piece-linear cross-section boundaries, substantial help may be obtained from the following Schwarz-Christoffel integral

\[
\omega(z) = \text{const} \times \int \frac{dz}{(z-x_1)^{k_1}(z-x_2)^{k_2}... (z-x_{N-1})^{k_{N-1}}}.
\]  

(2.78)

that provides the conformal mapping of the interior of an arbitrary \( N \)-sided polygon on the plane \( w = u + iv \), onto the upper-half \( (y > 0) \) of the plane \( z = x + iy \). In Eq. (78), \( x_j \) (\( j = 1, 2, N - 1 \)) are the points of axis \( y = 0 \) (i.e., of the boundary of the mapped region on plane \( z \)) to which the corresponding polygon vertices are mapped, while \( k_j \) are the exterior angles at the polygon vertices, measured in the units of \( \pi \), with \(-1 \leq k_j \leq +1\) — see Fig. 10.29 Of the points \( x_j \), two may be selected arbitrarily (because their effects may be compensated by the multiplicative constant in Eq. (78), and the additive constant of integration), while all the others have to be adjusted to provide the correct mapping.

![Schwartz-Christoffel mapping](image)

Fig. 2.10. The Schwartz-Christoffel mapping of a polygon’s interior onto the upper half-plane.

---

29 The integral (78) includes only \((N - 1)\) rather than \(N\) poles, because a polygon’s shape is completely determined by \((N - 1)\) positions \( \omega_i \) of its vertices and \((N - 1)\) angles \( \pi k_j \). In particular, since the algebraic sum of all external angles of a polygon equals \( \pi \), the last angle parameter \( k_j = k_N \) is uniquely determined by the set of the previous ones.
In the general case, the complex integral (78) may be hard to tackle. However, in some important cases, in particular those with right angles ($k_j = \pm \frac{1}{2}$) and/or with some points $w_j$ at infinity, the integrals may be readily worked out, giving explicit analytical expressions for the mapping functions $w(z)$. For example, let us consider a semi-infinite strip, defined by restrictions $-1 \leq u \leq +1$ and $0 \leq v$, on the plane $w$ – see the left panel of Fig. 11.

![Fig. 2.11. A semi-infinite strip mapped onto the upper half-plane.](image)

The strip may be considered as a polygon, with one vertex at the infinitely distant vertical point $w_3 = 0 + i\infty$. Let us map the polygon on the upper half of plane $z$, shown on the right panel of Fig. 11, with the vertex $w_1 = -1 + i0$ mapped onto the point $z_1 = -1 + i0$, and the vertex $w_2 = +1 + i0$ mapped onto the point $z_2 = +1 + i0$. Since the external angles at both these vertices are equal to $+\pi/2$, and hence $k_1 = k_2 = +\frac{1}{2}$, Eq. (78) is reduced to

$$w(z) = \text{const} \times \int \frac{dz}{(z+1)^{1/2}(z-1)^{1/2}} \equiv \text{const} \times \int \frac{dz}{(z^2-1)^{1/2}} \equiv \text{const} \times i \int \frac{dz}{(1-z^2)^{1/2}}. \quad (2.79)$$

This complex integral may be worked out, just as for real $z$, by the substitution $z = \sin \xi$, giving

$$w(z) = \text{const}' \times \int d\xi = c_1 \sin^{-1} z + c_2. \quad (2.80)$$

Determining the constants $c_{1,2}$ from the required mapping, i.e. from the conditions $w(-1+i0) = -1 + i0$ and $w(+1+i0) = +1 + i0$ (see the arrows in Fig. 11), we finally get

$$w(z) = \frac{2}{\pi} \sin^{-1} z, \quad \text{i.e.} \quad z = \sin \frac{\pi w}{2}. \quad (2.81a)$$

Using the well-known expression for the sine of a complex argument,\(^{30}\) we may rewrite this elegant result in either of the following two forms for the real and imaginary components of $z$ and $w$:

$$u = \frac{2}{\pi} \sin^{-1} \left\{ \frac{2x}{\left[ (x+1)^2 + y^2 \right]^{1/2} + \left[ (x-1)^2 + y^2 \right]^{1/2}} \right\}, \quad v = \frac{2}{\pi} \cosh^{-1} \left[ \frac{\left[ (x+1)^2 + y^2 \right]^{1/2} + \left[ (x-1)^2 + y^2 \right]^{1/2}}{2} \right],$$

$$x = \sin \frac{\pi u}{2} \cosh \frac{\pi v}{2}, \quad y = \cos \frac{\pi u}{2} \sinh \frac{\pi v}{2}. \quad (2.81b)$$

---

\(^{30}\) See, e.g., MA Eq. (3.5).
It is amazing how perfectly does the last formula manage to keep \( y \equiv 0 \) at the different borders of our \( w \)-region (Fig. 11): at its side borders \((u = \pm 1, 0 \leq v < \infty)\), this is performed by the first multiplier, while at the bottom border \((-1 \leq u \leq +1, v = 0)\), the equality is enforced by the second multiplier.

This mapping may be used to solve several electrostatics problems with the geometry shown in Fig. 11a; probably the most surprising of them is the following one. A straight gap of width \( 2t \) is cut in a very thin conducting plane, and voltage \( V \) is applied between the resulting half-planes – see the bold straight lines in Fig. 12.

Selecting a Cartesian coordinate system with the \( z \)-axis directed along the cut, the \( y \)-axis perpendicular to the plane, and the origin in the middle of the cut (Fig. 12), we can write the boundary conditions of this Laplace problem as

\[
\begin{align*}
\phi &= +\frac{V}{2}, \quad \text{at } x > t, \ y = 0, \\
\phi &= -\frac{V}{2}, \quad \text{at } x < -t, \ y = 0.
\end{align*}
\] (Due to problem’s symmetry, we may expect that in the middle of the gap, i.e. at \(-t < x < +t\) and \(y = 0\), the electric field is parallel to the plane and hence \(\phi_y = 0\).) The comparison of Figs. 11 and 12 shows that if we normalize our coordinates \(\{x, y\}\) to \(t\), Eqs. (81) provide the conformal mapping of our system on the plane \(z\) to the plane capacitor on the plane \(w\), with the voltage \(V\) between two planes \(u = \pm 1\). Since we already know that in that case \(\phi = (V/2)u\), we may immediately use the first of Eqs. (81b) to write the final solution of the problem:

\[
\begin{align*}
\phi &= \frac{V}{2} u = \frac{V}{\pi} \sin^{-1} \left( \frac{2x}{(x+t)^2 + y^2} \right)^{1/2} + \left( (x-t)^2 + y^2 \right)^{1/2}.
\end{align*}
\] (2.83)

The thin lines in Fig. 12 show the corresponding equipotential surfaces;\(^3\) it is evident that the electric field concentrates at the gap edges, just as it did at the edge of the thin disk (Fig. 8). Let me

---

\(^{31}\) This result may be also obtained using the so-called \textit{elliptical} (not ellipsoidal!) coordinates, and by the Green’s function method, to be discussed in Sec. 10 below.

\(^{32}\) Another graphical representation of the electric field distribution, by \textit{field lines}, is much less convenient. (It is more useful for the magnetic field, so there is no surprise that the field lines were introduced only by Michael Faraday in the 1830s.) As a reminder, the field lines are defined as the curves to whom the field vectors are tangential at each point. By this definition, the electric field lines are always normal to the equipotential surfaces,
leave the remaining calculation of the surface charge distribution and the mutual capacitance between
the half-planes (per unit length) for the reader’s exercise.

2.5. Variable separation – Cartesian coordinates

The general approach of the methods discussed in the last two sections was to satisfy the Laplace
equation by a function of a single variable that also satisfies the boundary conditions. Unfortunately, in
many cases this cannot be done (at least, using practicably simple functions). In this case, a very
powerful method, called the variable separation,\(^{33}\) may work, typically producing “semi-analytical”
results in the form of series (infinite sums) of either elementary or well-studied special functions. Its
main idea is to express the solution of the general boundary problem (35) as the sum of partial solutions,

\[
\phi = \sum_k c_k \phi_k ,
\]  

(2.84)

where each function \(\phi_k\) satisfies the Laplace equation, and then select the set of coefficients \(c_k\) to satisfy
the boundary conditions. More specifically, in the variable separation method the partial solutions \(\phi_k\) are
looked for in the form of a product of functions, each depending of just one spatial coordinate.

Let us discuss this approach on the classical example of a rectangular box with conducting walls
(Fig. 13), with the same potential (that I will take for zero) at all its side walls and the lower lid, but a
different potential \(V\) at the top lid \((z = c)\). Moreover, in order to demonstrate the power of the variable
separation method, let us carry out all the calculations for a more general case when the top lid’s
potential is an arbitrary 2D function \(V(x, y)\).\(^{34}\)

For this geometry, it is natural to use the Cartesian coordinates \(\{x, y, z\}\) and represent each of the
partial solutions in Eq. (84) as a product

\[
\phi_k = X(x)Y(y)Z(z).
\]  

(2.85)

so that it is always straightforward to sketch them, if desirable, from the equipotential surface pattern – as the one
shown in Fig. 12.

\(^{33}\) Again, this method was already discussed in CM Sec. 6.5, and then used also in Secs. 6.6 and 8.4 of that
course. However, the method is so important that I need to repeat its discussion in this part of my series, for the
benefit of the readers who have skipped my Classical Mechanics course for any reason.

\(^{34}\) Such distributions may be implemented in practice using the so-called mosaic electrodes consisting of many
electrically-insulated and individually-biased panels.
Plugging it into the Laplace equation expressed in the Cartesian coordinates,
\[ \frac{\partial^2 \phi_k}{\partial x^2} + \frac{\partial^2 \phi_k}{\partial y^2} + \frac{\partial^2 \phi_k}{\partial z^2} = 0, \]  
and dividing the result by the product $XYZ$, we get
\[ \frac{1}{X} \frac{d^2 X}{dx^2} + \frac{1}{Y} \frac{d^2 Y}{dy^2} + \frac{1}{Z} \frac{d^2 Z}{dz^2} = 0. \]  

Here comes the punch line of the variable separation method: since the first term of this sum may depend only on $x$, the second one only of $y$, etc., Eq. (87) may be satisfied everywhere in the volume only if each of these terms equals a constant. In a minute we will see that for our current problem (Fig. 13), these constant $x$- and $y$-terms have to be negative; hence let us denote these variable separation constants as $(-\alpha^2)$ and $(-\beta^2)$, respectively. Now Eq. (87) shows that the constant $z$-term has to be positive; if we denote it as $\gamma^2$, we get the following relation:
\[ \alpha^2 + \beta^2 = \gamma^2. \]  

Now the variables are separated in the sense that for the functions $X(x)$, $Y(y)$, and $Z(z)$ we have got separate ordinary differential equations,
\[ \frac{d^2 X}{dx^2} + \alpha^2 X = 0, \quad \frac{d^2 Y}{dy^2} + \beta^2 Y = 0, \quad \frac{d^2 Z}{dz^2} - \gamma^2 Z = 0, \]  
which are related only by Eq. (88) for their constant parameters.

Let us start from the equation for the function $X(x)$. Its general solution is the sum of functions $\sin \alpha x$ and $\cos \alpha x$, multiplied by arbitrary coefficients. Let us select these coefficients to satisfy our boundary conditions. First, since $\phi \propto X$ should vanish at the back vertical wall of the box (i.e., with the coordinate origin choice shown in Fig. 13, at $x = 0$ for any $y$ and $z$), the coefficient at $\cos \alpha x$ should be zero. The remaining coefficient (at $\sin \alpha x$) may be included into the general factor $c_k$ in Eq. (84), so that we may take $X$ in the form
\[ X = \sin \alpha x. \]  

This solution satisfies the boundary condition at the opposite wall ($x = a$) only if its argument $\alpha a$ is a multiple of $\pi$, i.e. if $\alpha$ is equal to any of the following numbers (commonly called eigenvalues):\[\alpha_n = \frac{\pi}{a} n, \quad \text{with } n = 1, 2, ...\]  
(Terms with negative values of $n$ would not be linearly-independent from those with positive $n$, and may be dropped from the sum (84). The value $n = 0$ is formally possible, but would give $X = 0$, i.e. $\phi_k = 0$, at any $x$, i.e. no contribution to sum (84), so it may be dropped as well.) Now we see that we indeed had to

---

35 Note that according to Eqs. (91)-(92), as the spatial dimensions $a$ and $b$ of the system are increased, the distances between the adjacent eigenvalues tend to zero. This fact implies that for spatially-infinite, non-periodic systems, the eigenvalue spectra are continuous, so that the sums of the type (84) become integrals. A few problems of this type are provided in Sec. 9 for the reader’s exercise.
take $\alpha$ real, (i.e. $\alpha^2$ positive); otherwise, instead of the oscillating function (90) we would have a sum of two exponential functions, which cannot equal zero at two independent points of the $x$-axis.

Since the equation (89) for function $Y(y)$ is similar to that for $X(x)$, and the boundary conditions on the walls perpendicular to axis $y$ ($y = 0$ and $y = b$) are similar to those for $x$-walls, the absolutely similar reasoning gives

$$Y = \sin \beta y, \quad \beta_m = \frac{\pi}{b} m, \quad \text{with } m = 1, 2, \ldots,$$

(2.92)

where the choice of the integer $m$ is independent of that of $n$. Now we see that according to Eq. (88), the separation constant $\gamma$ depends on two indices, $n$ and $m$, so that the relation may be rewritten as

$$\gamma_{nm} = \left[\alpha_n^2 + \beta_m^2\right]^{1/2} = \pi \left[\left(\frac{n}{a}\right)^2 + \left(\frac{m}{b}\right)^2\right]^{1/2}.$$

(2.93)

The corresponding solution of the differential equation for $Z$ may be represented as a linear combination of two exponents $\exp\{-\gamma_{nm}z\}$, or alternatively of two hyperbolic functions, $\sinh\gamma_{nm}z$ and $\cosh\gamma_{nm}z$, with arbitrary coefficients. At our choice of coordinate origin, the latter option is preferable, because $\cosh\gamma_{nm}z$ cannot satisfy the zero boundary condition at the bottom lid of the box ($z = 0$). Hence we may take $Z$ in the form

$$Z = \sinh \gamma_{nm}z,$$

(2.94)

which automatically satisfies that condition.

Now it is the right time to merge Eqs. (84)-(85) and (90)-(94), replacing the temporary index $k$ with the full set of possible eigenvalues, in our current case of two integer indices $n$ and $m$:

$$\phi(x, y, z) = \sum_{n,m=1}^{\infty} c_{nm} \sin \frac{\pi x}{a} \sin \frac{\pi y}{b} \sinh \gamma_{nm}z,$$

(2.95)

where $\gamma_{nm}$ is given by Eq. (93). This solution satisfies our boundary conditions on all walls of the box, besides the top lid, for arbitrary coefficients $c_{nm}$. The only job left is to choose these coefficients from the top-lid requirement:

$$\phi(x, y, c) = \sum_{n,m=1}^{\infty} c_{nm} \sin \frac{\pi x}{a} \sin \frac{\pi y}{b} \sinh \gamma_{nm}c = V(x, y).$$

(2.96)

It looks bad to have just one equation for the infinite set of coefficients $c_{nm}$. However, the decisive help comes from the fact that the functions of $x$ and $y$ that participate in Eq. (96), form full, orthogonal sets of 1D functions. The last term means that the integrals of the products of the functions with different integer indices over the region of interest equal zero. Indeed, a direct integration gives

$$\int_0^a \sin \frac{\pi x}{a} \sin \frac{\pi n'x}{a} \, dx = \frac{a}{2} \delta_{nm'},$$

(2.97)

where $\delta_{nm'}$ is the Kronecker symbol, and similarly for $y$ (with the evident replacements $a \rightarrow b$, and $n \rightarrow m$). Hence, a fruitful way to proceed is to multiply both sides of Eq. (96) by the product of the basis functions, with arbitrary indices $n'$ and $m'$, and integrate the result over $x$ and $y$: 
Due to Eq. (97), all terms on the left-hand side of the last equation, besides those with \( n = n' \) and \( m = m' \), vanish, and (replacing \( n' \) with \( n \), and \( m' \) with \( m \), for notation brevity) we finally get

\[
\sum_{n, m=1}^{\infty} c_{nm} \sin \gamma_{nm} c \int_0^a \frac{\sin \frac{\pi nx}{a}}{a} dx \int_0^b \frac{\sin \frac{\pi mx}{b}}{b} dy = \frac{4}{ab \sinh \gamma_{nm} c} \int_0^b dy V(x, y) \sin \frac{\pi mx}{a} \sin \frac{\pi ny}{b}. \tag{2.98}
\]

The relations (93), (95) and (99) give the complete solution of the posed boundary problem; we can see both good and bad news here. The first bit of bad news is that in the general case we still need to work out the integrals (99) – formally, the infinite number of them. In some cases, it is possible to do this analytically. For example, if the top lid in our problem is a single conductor, i.e. has a constant potential, we may take \( V(x, y) = \text{const} = V_0 \), and the both 1D integrations are elementary; for example

\[
\int_0^a \sin \frac{\pi nx}{a} dx = \frac{2a}{\pi n} \begin{cases} 1, & \text{for } n \text{ odd,} \\ 0, & \text{for } n \text{ even,} \end{cases}
\tag{2.100}
\]

and similarly for the integral over \( y \), so that

\[
c_{nm} = \frac{16V_0}{\pi^2 nm \sinh \gamma_{nm} c} \begin{cases} 1, & \text{if both } n \text{ and } m \text{ are odd,} \\ 0, & \text{otherwise.} \end{cases}
\tag{2.101}
\]

The second bad news is that even at such a happy occasion, we still have to sum up the series (95), so that our result may only be called analytical with some reservations, because in most cases we need a computer to get the finial numbers or plots.

Now the first good news. Computers are very efficient for both operations (95) and (99), i.e. for the summation and integration. (As was discussed in Sec. 1.2, random errors are averaged out at these operations.) As an example, Fig. 14 shows the plots of the electrostatic potential in a cubic box \((a = b = c)\), with an equipotential top lid \((V = V_0 = \text{const})\), obtained by a numerical summation of the series (95), using the analytical expression (101). The remarkable feature of this calculation is a very fast convergence of the series; for the middle cross-section of the cubic box \((z/c = 0.5)\), already the first term (with \( n = m = 1 \)) gives an accuracy about 6%, while the sum of four leading terms (with \( n, m = 1, 3 \)) reduces the error to just 0.2%. (For a longer box, \( c > a, b \), the convergence is even faster – see the discussion below.) Only close to the corners between the top lid and the side walls, where the potential changes very rapidly, several more terms are necessary to get a reasonable accuracy.

The second bit of good news is that our “semi-analytical” result allow its ultimate limits to be explored analytically. For example, Eq. (93) shows that for a very flat box \((c \ll a, b)\), \( \gamma_{n,mc} \ll \gamma_{n,nc} \ll 1 \) at least for the lowest terms of series (95), with \( n, m \ll c/a, c/b \). In these terms, the sinh functions in Eqs. (96) and (99) may be well approximated with their arguments, and their ratio by \( z/c \). So if we limit the summation to these terms, Eq. (95) gives a very simple result

\[
\phi(x, y) \approx \frac{z}{c} V(x, y), \tag{2.102}
\]

which means that each segment of the flat box behaves just as a plane capacitor. Only near the side walls, the higher terms in the series (95) are important, producing some deviations from Eq. (102). (For
the general problem with an arbitrary function $V(x,y)$, this is also true at all regions where this function changes sharply.)

![Graph showing electrostatic potential distribution inside a cubic box](image.jpg)

Fig. 2.14. The electrostatic potential’s distribution inside a cubic box ($a = b = c$) with a constant voltage $V_0$ on the top lid (Fig. 13), calculated numerically from Eqs. (93), (95) and (101). The dashed line on the left panel shows the contribution of the main term of the series (with $n = m = 1$) to the full result, for $z/c = 0.5$.

In the opposite limit ($a, b << c$), Eq. (93) shows that, in contrast, $\gamma_{n,m,c} >> 1$ for all $n$ and $m$. Moreover, the ratio $\sinh \gamma_{n,m,c}/\sinh \gamma_{n,m,c}$ drops sharply if either $n$ or $m$ is increased, if $z$ is not too close to $c$. Hence in this case a very good approximation may be obtained by keeping just the leading term, with $n = m = 1$, in Eq. (95), so that the challenge of summation disappears. (As was discussed above, this approximation works reasonably well even for a cubic box.) In particular, for the constant potential of the upper lid, we can use Eq. (101) and the exponential asymptotic for both sinh functions, to get a very simple formula:

$$\phi = \frac{16}{\pi^2} \sin \frac{\pi x}{a} \sin \frac{\pi y}{b} \exp \left\{ - \pi \left( \frac{a^2 + b^2}{ab} \right)^{1/2} \right\} (c - z).$$

(2.103)

These results may be readily generalized to some other problems. For example, if all walls of the box shown in Fig. 13 have an arbitrary potential distribution, we may use the linear superposition principle to represent the electrostatic potential distribution as the sum of six partial solutions of the type of Eq. (95), each with one wall biased by the corresponding voltage, and all other grounded ($\phi = 0$).
To summarize, the results given by the variable separation method in the Cartesian coordinates are closer to what we could call a genuinely analytical solution than to purely numerical solutions. Now, let us explore the issues that arise when this method is applied in other orthogonal coordinate systems.

2.6. Variable separation – polar coordinates

If a system of conductors is cylindrical, the potential distribution is independent of the coordinate $z$ along the cylinder axis: $\frac{\partial \phi}{\partial z} = 0$, and the Laplace equation becomes two-dimensional. If conductor’s cross-section is rectangular, the variable separation method works best in Cartesian coordinates $\{x, y\}$, and is just a particular case of the 3D solution discussed above. However, if the cross-section is circular, much more compact results may be obtained by using the polar coordinates $\{\rho, \varphi\}$. As we already know from Sec. 3(ii), these 2D coordinates are orthogonal, so that the two-dimensional Laplace operator is a sum of two separable terms.\footnote{See, e.g., MA Eq. (10.3) with $\frac{\partial}{\partial z} = 0$.} Requiring, just as we have done above, each component of the sum (84) to satisfy the Laplace equation, we get

$$
\frac{1}{\rho} \frac{\partial}{\partial \rho} \left( \rho \frac{\partial \phi_k}{\partial \rho} \right) + \frac{1}{\rho^2} \frac{\partial^2 \phi_k}{\partial \varphi^2} = 0.
$$

In a full analogy with Eq. (85), let us represent each particular solution as a product: $\phi_k = \mathcal{R}(\rho)\mathcal{F}(\varphi)$. Plugging this expression into Eq. (104) and then dividing all its parts by $\mathcal{R}\mathcal{F}/\rho^2$, we get

$$
\frac{\rho}{\mathcal{R}} \frac{d}{d\rho} \left( \rho \frac{d\mathcal{R}}{d\rho} \right) + \frac{1}{\mathcal{F}} \frac{d^2\mathcal{F}}{d\varphi^2} = 0.
$$

Following the same reasoning as for the Cartesian coordinates, we get two separated ordinary differential equations

$$
\rho \frac{d}{d\rho} \left( \rho \frac{d\mathcal{R}}{d\rho} \right) = \nu^2 \mathcal{R},
$$

$$
\frac{d^2\mathcal{F}}{d\varphi^2} + \nu^2 \mathcal{F} = 0,
$$

where $\nu^2$ is the variable separation constant.

Let us start their analysis from Eq. (106), plugging into it a probe solution $\mathcal{R} = c\rho^\alpha$, where $c$ and $\alpha$ are some constants. The elementary differentiation shows that if $\alpha \neq 0$, the equation is indeed satisfied for any $c$, with just one requirement on the constant $\alpha$, namely $\alpha^2 = \nu^2$. This means that the following linear superposition

$$
\mathcal{R} = a_\nu \rho^{+\nu} + b_\nu \rho^{-\nu}, \quad \text{for } \nu \neq 0,
$$

with any constant coefficients $a_\nu$ and $b_\nu$, is also a solution to Eq. (106). Moreover, the general theory of linear ordinary differential equations tells us that the solution of a second-order equation like Eq. (106) may only depend on just two constant factors that scale two linearly-independent functions. Hence, for all values $\nu^2 \neq 0$, Eq. (108) presents the \textit{general} solution of that equation. The case when $\nu = 0$, in which
the functions $\rho^+\nu$ and $\rho^-\nu$ are just constants and hence are not linearly-independent, is special, but in this case the integration of Eq. (106) is straightforward\(^{37}\), giving

$$R = a_0 + b_0 \ln \rho, \quad \text{for } \nu = 0. \quad (2.109)$$

In order to specify the separation constant, let us explore Eq. (107), whose general solution is

$$F = \begin{cases} c_\nu \cos \nu \phi + s_\nu \sin \nu \phi, & \text{for } \nu \neq 0, \\ c_0 + s_0 \phi, & \text{for } \nu = 0. \end{cases} \quad (2.110)$$

There are two possible cases here. In many boundary problems solvable in cylindrical coordinates, the free space region, in which the Laplace equation is valid, extends continuously around the origin point $\rho = 0$. In this region, the potential has to be continuous and uniquely defined, so that $F$ has to be a $2\pi$-periodic function of $\phi$. For that, one needs the product $\nu(\phi + 2\pi)$ to be equal to $\nu\phi + 2\pi n$, with $n$ an integer, immediately giving us a discrete spectrum of possible values of the variable separation constant:

$$\nu = n = 0, \pm 1, \pm 2, \ldots \quad (2.111)$$

In this case both functions $R$ and $F$ may be labeled with the integer index $n$. Taking into account that the terms with negative values of $n$ may be summed up with those with positive $n$, and that $s_0$ should equal zero (otherwise the $2\pi$-periodicity of function $F$ would be violated), we see that the general solution to the 2D Laplace equation may be represented as

$$\phi(\rho, \phi) = a_0 + b_0 \ln \rho + \sum_{n=1}^{\infty} \left( a_n \rho^n + \frac{b_n}{\rho^n} \right) (c_n \cos n \phi + s_n \sin n \phi). \quad (2.112)$$

Let us see how all this machinery works on the famous problem of a round cylindrical conductor placed into an electric field that is uniform and perpendicular to the cylinder’s axis at large distances (say, created by a large plane capacitor) – see Fig. 15a. First of all, let us explore the effect of system’s symmetries on the coefficients in Eq. (112). Selecting the coordinate system as shown in Fig. 15a, and taking the cylinder’s potential for zero, we immediately get $a_0 = 0$. Moreover, due to the mirror symmetry about the plane $[x, z]$, the solution has to be an even function of the angle $\phi$, and hence all coefficients $s_n$ should also equal zero. Also, at large distances ($\rho \gg R$) from the cylinder axis its effect on the electric field should vanish, and the potential should approach that of the uniform field $E = E_0 n_z$:

$$\phi \rightarrow -E_0 x = -E_0 \rho \cos \phi, \quad \text{for } \rho \rightarrow \infty. \quad (2.113)$$

This is only possible if in Eq. (112), $b_0 = 0$, and also all coefficients $a_n$ with $n \neq 1$ vanish, while the product $a_1 c_1$ should be equal to $-E_0$. Thus the solution is reduced to the following form

$$\phi(\rho, \phi) = -E_0 \rho \cos \phi + \sum_{n=1}^{\infty} \frac{B_n}{\rho^n} \cos n \phi, \quad (2.114)$$

in which the coefficients $B_n \equiv b_n c_n$ should be found from the boundary condition at $\rho = R$:

$$\phi(R, \phi) = 0. \quad (2.115)$$

\(^{37}\) Actually, we have already done it in Sec. 3 – see Eq. (43).
This requirement yields the following equation,

\[ \left( -E_0 R + \frac{B_1}{R} \right) \cos \varphi + \sum_{n=2}^{\infty} \frac{B_n}{R^n} \cos n \varphi = 0, \]  

(2.116)

which should be satisfied for all \( \varphi \). This equality, read backwards, may be considered as an expansion of a function identically equal to zero into a series over mutually orthogonal functions \( \cos n \varphi \).\(^{38}\) It is valid only if all coefficients of the expansion, including \( (-E_0 R + B_1/R) \), and all \( B_n \) for \( n \geq 2 \), are equal to zero. As a result, our final answer (valid only outside of the cylinder, i.e. for \( \rho \geq R \)), is

\[ \phi(\rho, \varphi) = -E_0 \left( \rho - \frac{R^2}{\rho} \right) \cos \varphi \equiv -E_0 \left( 1 - \frac{R^2}{x^2 + y^2} \right) x. \]  

(2.117)

This result (Fig. 15b) shows a smooth transition between the uniform field (113) far from the cylinder, to the equipotential surface of the cylinder (with \( \phi = 0 \)). Such smoothening is very typical for Laplace equation solutions. Indeed, as we know from Chapter 1, these solutions correspond to the lowest potential energy (1.65), i.e. the lowest integral of the potential gradient’s square, possible at the given boundary conditions.

To complete the problem, let us calculate the distribution of the surface charge density over the cylinder’s cross-section, using Eq. (3):

\[ \sigma = \varepsilon_0 E_n \bigg|_{\text{surface}} = -\varepsilon_0 \frac{\partial \phi}{\partial \rho} \bigg|_{\rho=R} = \varepsilon_0 E_0 \cos \varphi \frac{\partial}{\partial \rho} \left( \rho - \frac{R^2}{\rho} \right) \bigg|_{\rho=R} = 2\varepsilon_0 E_0 \cos \varphi. \]  

(2.118)

This very simple formula shows that with the field direction shown in Fig. 15a \( (E_0 > 0) \), the surface charge is positive on the right side of the cylinder and negative on its left side, thus creating a field directed from the right to the left, which exactly compensates the external field inside the conductor,

\(^{38}\) Mathematics tells us that such expansions are unique, so this is the only possible solution of Eq. (116).
where the net field is zero. (Please take one more look at the schematic Fig. 1a.) Note also that the net electric charge of the cylinder is zero, in the correspondence with the problem symmetry. Another useful by-product of the calculation (118) is that the surface electric field equals \(2E_0 \cos \varphi\), and hence its largest magnitude is twice the field far from the cylinder. Such electric field concentration is very typical for all convex conducting surfaces.

The last observation gets additional confirmation from the second possible topology, when Eq. (110) is used to describe problems with no angular periodicity. A typical example of this situation is a cylindrical conductor with a cross-section that features a corner limited by straight lines (Fig. 16). Indeed, at we may argue that at \(\rho < R\) (where R is the scale of radial extension of the straight sides of the corner, see Fig. 16), the Laplace equation may be satisfied by a sum of partial solutions \(\mathcal{R}(\rho) / \mathcal{A}(\varphi)\), if the angular components of the products satisfy the boundary conditions on the corner sides. Taking (just for the simplicity of notation) the conductor’s potential to be zero, and one of the corner’s sides as the \(x\)-axis (\(\varphi = 0\)), these boundary conditions are

\[
\mathcal{A}(0) = \mathcal{A}(\beta) = 0, \quad \text{(2.119)}
\]

where the angle \(\beta\) may be anywhere between 0 and \(2\pi\) – see Fig. 16.

Comparing this condition with Eq. (110), we see that it requires all \(c_v\) to vanish, and \(v\) to take one of the values of the following discrete spectrum:

\[
v_m \beta = \pi m, \quad \text{with} \quad m = 1, 2, \ldots \quad \text{(2.120)}
\]

Hence the full solution of the Laplace equation takes the form

\[
\phi = \sum_{m=1}^{\infty} a_m \rho^{m/\beta} \sin \frac{\pi m \varphi}{\beta}, \quad \text{for} \quad \rho < R, \quad 0 \leq \varphi \leq \beta, \quad \text{(2.121)}
\]

where the constants \(s_v\) have been incorporated into \(a_m\). The set of coefficients \(a_m\) cannot be universally determined, because it depends on the exact shape of the conductor outside the corner, and the externally applied electric field. However, whatever the set is, in the limit \(\rho \to 0\), the solution (121) is almost\(^{39}\) always dominated by the term with the lowest \(m = 1\):

\[
\phi \to a_1 \rho^{\pi/\beta} \sin \frac{\pi \varphi}{\beta}, \quad \text{(2.122)}
\]

\(^{39}\) Exceptions are possible only for highly symmetric configurations when the external field is specially crafted to make \(a_1 = 0\). In this case the solution at \(\rho \to 0\) is dominated by the first nonzero term of the series (121).
because the higher terms go to zero faster. This potential distribution corresponds to the surface charge density

\[ \sigma = \varepsilon_0 E_{\text{surface}} = -\varepsilon_0 \frac{\partial \phi}{\partial (\rho \varphi)} \bigg|_{\rho=\text{const}, \varphi \to +0} = -\varepsilon_0 \frac{\pi a_1}{\beta} \rho^{\pi / \beta - 1}. \]  

(2.123)

(It is similar, with the opposite sign, on the opposite face of the angle.)

The result (123) shows that if we are dealing with a usual, concave corner (\(\beta < \pi\), see Fig. 16a), the charge density (and the surface electric field) tends to zero. On the other case, at a “convex corner” with \(\beta > \pi\) (actually, a wedge – see Fig. 16b), both the charge and the field’s strength concentrate, formally diverging at \(\rho \to 0\). (So, do not sit on a roof’s ridge during a thunderstorm; rather hide in a ditch!) We have already seen qualitatively similar effects for the thin round disk and the split plane.

2.7. Variable separation – cylindrical coordinates

Now, let us discuss whether it is possible to generalize our approach to problems whose geometry is still axially-symmetric, but with a substantial dependence of the potential on the axial coordinate (\(\frac{\partial \phi}{\partial z} \neq 0\)). The classical example of such a problem is shown in Fig. 17. Here the side wall and the bottom lid of a hollow round cylinder are kept at a fixed potential (say, \(\phi = 0\)), but the potential \(V\) fixed at the top lid is different. Evidently, this problem is qualitatively similar to the rectangular box problem solved above (Fig. 13), and we will also try to solve it first for the case of arbitrary voltage distribution over the top lid: \(V = V(\rho, \varphi)\).

Following the main idea of the variable separation method, let us require that each partial function \(\phi_k\) in Eq. (84) satisfies the Laplace equation, now in the full cylindrical coordinates \(\{\rho, \varphi, z\}\): \(^{40}\)

\[ \frac{1}{\rho} \frac{\partial}{\partial \rho} \left( \rho \frac{\partial \phi_k}{\partial \rho} \right) + \frac{1}{\rho^2} \frac{\partial^2 \phi_k}{\partial \varphi^2} + \frac{\partial^2 \phi_k}{\partial z^2} = 0. \]  

(2.124)

Plugging in \(\phi_k\) in the form of the product \(\mathcal{R}(\rho)\mathcal{F}(\varphi)\mathcal{Z}(z)\) into Eq. (124) and dividing all resulting terms by \(\mathcal{R}\mathcal{F}\mathcal{Z}\), we get

\[ \frac{1}{\rho \mathcal{R}} \frac{d}{dp} \left( \rho \frac{d \mathcal{R}}{dp} \right) + \frac{1}{\rho^2 \mathcal{F}} \frac{d^2 \mathcal{F}}{d\varphi^2} + \frac{d^2 \mathcal{Z}}{dz^2} = 0. \]  

(2.125)

\(^{40}\) See, e.g., MA Eq. (10.3).
Since the first two terms of Eq. (125) can only depend on the polar variables $\rho$ and $\varphi$, while the third term, only on $z$, at least that term should equal a constant. Denoting it (just like in the rectangular box problem) by $\gamma^2$, we get, instead of Eq. (125), a set of two equations:

$$\frac{d^2 Z}{dz^2} = \gamma^2 Z, \quad (2.126)$$

$$\frac{1}{\rho R} \frac{d}{d\rho} \left( \rho \frac{dR}{d\rho} \right) + \gamma^2 + \frac{1}{\rho^2} \frac{d^2 \varphi}{d\varphi^2} = 0. \quad (2.127)$$

Now, multiplying all the terms of Eq. (127) by $\rho^2$, we see that the last term of the result, $(d^2 \varphi/d\varphi^2)/\rho^2$, may depend only on $\varphi$, and thus should be constant. Calling that constant $\mu^2$ (just as in Sec. 6 above), we separate Eq. (127) into an angular equation,

$$\frac{d^2 \varphi}{d\varphi^2} + \mu^2 \varphi = 0, \quad (2.128)$$

and a radial equation:

$$\frac{d^2 R}{d\rho^2} + 1 \frac{dR}{d\rho} + (\gamma^2 - \frac{\mu^2}{\rho^2})R = 0. \quad (2.129)$$

We see that the ordinary differential equations for the functions $Z(z)$ and $R(\varphi)$ (and hence their solutions) are identical to those discussed earlier in this chapter. However, Eq. (129) for the radial function $R(\rho)$ (called the Bessel equation) is more complex than in the 2D case, and depends on two independent constant parameters, $\gamma$ and $\mu$. The latter challenge may be readily overcome if we notice that any change of $\gamma$ may be reduced to the corresponding re-scaling of the radial coordinate $\rho$. Indeed, introducing a dimensionless variable $\xi \equiv \gamma \rho$,$^{41}$ Eq. (129) may be reduced to an equation with just one parameter, $\mu$:

$$\frac{d^2 R}{d\xi^2} + 1 \frac{dR}{d\xi} + \left(1 - \frac{\mu^2}{\xi^2}\right)R = 0. \quad (2.130)$$

Moreover, we already know that for angle-periodic problems, the spectrum of eigenvalues of Eq. (128) is discrete: $\mu = n$, with integer $n$.

Unfortunately, even in this case, Eq. (130) cannot be satisfied by a single “elementary” function, and is the canonical form of the Bessel equation. Its solutions that we need for our current problem are called the Bessel function of the first kind, of order $\mu$, commonly denoted as $J_\mu(\xi)$. Let me review in brief the properties of these functions that are most relevant for our problem – and many other problems discussed in this series.$^{42}$

First of all, the Bessel function of a negative integer order is very simply related to that with the positive order:

---

41 Note that this normalization is specific for each value of the variable separation parameter $\gamma$. Also, please notice that the normalization is meaningless for $\gamma = 0$, i.e. for the case $Z(z) = \text{const.}$ However, if we need the partial solutions for this particular value of $\gamma$, we can always use Eqs. (108)-(109).

42 For a more complete discussion of these functions, see the literature listed in MA Sec. 16, for example, Chapter 6 (written by F. Olver) in the famous collection compiled and edited by Abramowitz and Stegun.
enabling us to limit our discussion to the functions with \( n \geq 0 \). Figure 18 shows four of these functions with the lowest positive \( n \).

As its argument is increased, each function is initially close to a power law: \( J_0(\xi) \approx 1, \ J_1(\xi) \approx \xi/2, \ J_2(\xi) \approx \xi^2/8, \) etc. This behavior follows from the Taylor series

\[
J_n(\xi) = \left(\frac{\xi}{2}\right)^n \sum_{k=0}^{\infty} \frac{(-1)^k}{k!(n+k)!} \left(\frac{\xi}{2}\right)^{2k}, \tag{2.132}
\]

which is formally valid for any \( \xi \), and may even serve as an alternative definition of the functions \( J_n(\xi) \). However, the series is converging fast only at small arguments, \( \xi < n \), where its leading term is

\[
J_n(\xi) \bigg|_{\xi \to 0} \to \frac{1}{n!} \left(\frac{\xi}{2}\right)^n. \tag{2.133}
\]

At \( \xi \approx n + 1.86n^{1/3} \), the Bessel function reaches its maximum\(^{43}\)

\[
\max_\xi [J_n(\xi)] \approx \frac{0.675}{n^{1/3}}, \tag{2.134}
\]

and then starts to oscillate with a period gradually approaching \( 2\pi \), a phase shift that increases by \( \pi/2 \) with each unit increment of \( n \), and an amplitude that decreases as \( \xi^{-1/2} \). All these features are described by the following asymptotic formula:

\(^{43}\) These two formulas for the Bessel function peak are strictly valid for \( n \gg 1 \), but may be used for reasonable estimates starting already from \( n = 1 \); for example, \( \max_\xi [J_1(\xi)] \) is close to 0.58 and is reached at \( \xi \approx 2.4 \), just about 30% away from the values given by the asymptotic formulas.
\[ J_n(\xi) \bigg|_{\xi \to \infty} \to \left( \frac{2}{\pi \xi} \right)^{1/2} \cos \left( \xi - \frac{\pi}{4} - \frac{n\pi}{2} \right), \quad (2.135) \]

which starts to give a reasonable approximation very soon after the function peaks – see Fig. 18.\(^{44}\)

Now we are ready to revisit our case study (Fig. 17). Let us select functions the \(Z(z)\) so that they satisfy Eq. (126) and the bottom-lid boundary condition \(Z(0) = 0\), i.e. are proportional to \(\sinh \gamma z\) – cf. Eq. (94). Then we get

\[ \phi = \sum_{n=0}^{\infty} \sum_{\gamma} J_n(\gamma \rho)(c_{n\gamma} \cos n\varphi + s_{n\gamma} \sin n\varphi) \sinh \gamma z. \quad (2.136) \]

Next, we need to satisfy the zero boundary condition at the cylinder’s side wall \((\rho = R)\). This may be ensured by taking

\[ J_n(\gamma R) = 0. \quad (2.137) \]

Since each function \(J_n(x)\) has an infinite number of positive zeros (see Fig. 18 again), which may be numbered by an integer index \(m = 1, 2, \ldots\), Eq. (137) may be satisfied with an infinite number of discrete values of the separation parameter \(\gamma\):

\[ \gamma_{nm} = \frac{\xi_{nm}}{R}, \quad (2.138) \]

where \(\xi_{nm}\) is the \(m\)-th zero of the function \(J_n(x)\) – see the top numbers in the cells of Table 1. (Very soon we will see what do we need the bottom numbers for.)

Table 2.1. Approximate values of a few first zeros, \(\xi_{nm}\), of a few lowest-order Bessel functions \(J_n(\xi)\) (the top number in each cell), and the values of \(dJ_n(\xi)/d\xi\) at these points (the bottom number).

</table>

\(^{44}\)Eq. (135) and Fig. 18 clearly show the close analogy between the Bessel functions and the usual trigonometric functions, sine and cosine. To emphasize this similarity, and help the reader to develop more gut feeling of the Bessel functions, let me mention one fact of the elasticity theory: while the sinusoidal functions describe, in particular, fundamental standing waves on a guitar string, the functions \(J_n(\xi)\) describe, in particular, fundamental standing waves on an elastic round membrane (say, a round drum), with \(J_0(\xi)\) describing their lowest (fundamental) mode – the only mode with a nonzero amplitude of the membrane center’s oscillations.
Hence, Eq. (136) may be represented in a more explicit form:

$$\phi(\rho, \varphi, z) = \sum_{n=0}^{\infty} \sum_{m=1}^{\infty} J_n \left( \frac{\xi_{nm}}{R} \right) \left( c_{nm} \cos n \varphi + s_{nm} \sin n \varphi \right) \sinh \left( \frac{\xi_{nm}}{R} \right).$$

(2.139)

Here the coefficients \( c_{nm} \) and \( s_{nm} \) have to be selected to satisfy the only remaining boundary condition – that on the top lid:

$$\phi(\rho, \varphi, l) \equiv \sum_{n=0}^{\infty} \sum_{m=1}^{\infty} J_n \left( \frac{\xi_{nm}}{R} \right) \left( c_{nm} \cos n \varphi + s_{nm} \sin n \varphi \right) \sinh \left( \frac{\xi_{nm}}{R} L \right) = V(\rho, \varphi).$$

(2.140)

To use it, let us multiply both parts of Eq. (140) by \( J_n(\xi_{nm}; \rho/R) \cos n' \varphi \), integrate the result over the lid area, and use the following property of the Bessel functions:

$$\int_{0}^{1} J_n(\xi_{nm}s) J_n(\xi_{nm}s) s ds = \frac{1}{2} [J_{n+1}(\xi_{nm})]^{2} \delta_{nm}. \quad (2.141)$$

The last relation expresses a very specific (“2D”) orthogonality of the Bessel functions with different indices \( m \) – do not confuse them with the function orders \( n \), please! Since it relates two Bessel functions with the same index \( n \), it is natural to ask why its right-hand side contains the function with a different index \((n + 1)\). Some gut feeling of that may come from one more very important property of the Bessel functions, the so-called recurrence relations:

$$J_{n+1}(\xi) + J_{n-1}(\xi) = \frac{2nJ_n(\xi)}{\xi}, \quad (2.142a)$$

$$J_{n+1}(\xi) - J_{n-1}(\xi) = 2\frac{dJ_n(\xi)}{d\xi}, \quad (2.142b)$$

which in particular yield the following formula (convenient for working out some Bessel function integrals):

$$\frac{d}{d\xi} \left[ \xi^n J_n(\xi) \right] = \xi^n J_{n-1}(\xi). \quad (2.143)$$

For our current purposes, let us apply the recurrence relations at the special points \( \xi_{nm} \). At these points, \( J_n \) vanishes, and the system of two equations (142) may be readily solved to get, in particular,

$$J_{n+1}(\xi_{nm}) = -\frac{dJ_n}{d\xi}(\xi_{nm}),$$

(2.144)

so that the square bracket on the right-hand side of Eq. (141) is just \((dJ_n/d\xi)^2\) at \( \xi = \xi_{nm} \). Thus the values of the Bessel function derivatives at the zero points, given by the lower numbers in the cells of Table 1, are as important for boundary problem solutions as the zeros themselves.

45 The Bessel functions of the same argument but different orders are also orthogonal, but in a different way:

$$\int_{0}^{1} J_n(\xi) J_n(\xi) \frac{d\xi}{\xi} = \frac{1}{n + 1} \delta_{mn}.$$

46 These relations provide, in particular, a convenient way for numerical computation of all \( J_n(\xi) \) after \( J_0(\xi) \) has been computed. (The latter is usually done using Eq. (132) for smaller \( \xi \) and an extension of Eq. (135) for larger \( \xi \).) Note that most mathematical software packages, including all those listed in MA Sec. 16(iv), include ready subroutines for calculation of the functions \( J_n(\xi) \) and other special functions used in this lecture series. In this sense, the line separating these “special functions” from “elementary functions” is rather fine.
Since the angular functions $\cos n\varphi$ are also orthogonal—both to each other,

$$\int_0^{2\pi} \cos(n\varphi)\cos(n'\varphi)\,d\varphi = \pi\delta_{nn'},$$  \hspace{1cm} (2.145)

and to all functions $\sin n\varphi$, the integration over the lid area kills all terms of both series in Eq. (140), besides just one term proportional to $c_{nm}$, and hence gives an explicit expression for that coefficient. The counterpart coefficients $s_{nm}$ may be found by repeating the same procedure with the replacement of $\cos n'\varphi$ by $\sin n'\varphi$. This evaluation (left for the reader’s exercise) completes the solution of our problem for an arbitrary lid potential $V(\rho, \varphi)$.

Still, before leaving the Bessel functions (for a while only : -), we need to address two important issues. First, we have seen that in our cylinder problem (Fig. 17), the set of functions $J_n(\zeta_{nm}\rho/R)$ with different indices $m$ (which characterize the degree of Bessel function’s stretch along axis $\rho$) play the role similar to that of functions $\sin(n\pi x/a)$ in the rectangular box problem shown in Fig. 13. In this context, what is the analog of functions $\cos(n\pi x/a)$—which may be important for some boundary problems? In a more formal language, are there any functions of the same argument $\zeta \equiv \zeta_{nm}\rho/R$, that would be linearly independent of the Bessel functions of the first kind, while satisfying the same Bessel equation (130)?

The answer is yes. For the definition of such functions, we first need to generalize our prior formulas for $J_n(\zeta)$, and in particular Eq. (132), to the case of arbitrary, not necessarily real order $\nu$. Mathematics says that the generalization may be performed in the following way:

$$J_\nu(\zeta) = \left(\frac{\zeta}{2}\right)^\nu \sum_{k=0}^{\infty} \frac{(-1)^k}{k!\Gamma(\nu + k + 1)} \left(\frac{\zeta}{2}\right)^{2k},$$  \hspace{1cm} (2.146)

where $\Gamma(s)$ is the so-called gamma function that may be defined as$^{47}$

$$\Gamma(s) = \int_0^\infty \xi^{s-1} e^{-\xi} d\xi.$$  \hspace{1cm} (2.147)

The simplest, and the most important property of the gamma function is that for integer values of argument it gives the factorial of a number smaller by one:

$$\Gamma(n+1) = n! \equiv 1 \cdot 2 \cdots n,$$  \hspace{1cm} (2.148)

so it is essentially a generalization of the notion of the factorial to all real numbers.

The Bessel functions defined by Eq. (146) satisfy, after the replacements $n \to \nu$ and $n! \to \Gamma(n + 1)$, virtually all the relations discussed above, including the Bessel equation (130), the asymptotic formula (135), the orthogonality condition (141), and the recurrence relations (142). Moreover, it may be shown that $\nu \neq n$, functions $J_\nu(\zeta)$ and $J_n(\zeta)$ are linearly independent of each other, and hence their linear combination may be used to represent the general solution of the Bessel equation. Unfortunately, as Eq. (131) shows, for $\nu = n$ this is not true, and a solution linearly independent of $J_n(\zeta)$ has to be formed in a different way.

The most common way of overcoming this difficulty is first to define, for all $\nu \neq n$, the following functions:

---

$^{47}$ See, e.g., MA Eq. (6.7a). Note that $\Gamma(s) \to \infty$ at $s \to 0, -1, -2,$...
called the Bessel functions of the second kind, or more often the Weber functions,\(^{48}\) and then to follow the limit \(\nu \to n\). At this, both the numerator and denominator of the right-hand side of Eq. (149) tend to zero, but their ratio tends to a finite value called \(Y_n(x)\). It may be shown that the resulting functions are still the solutions of the Bessel equation and are linearly independent of \(J_n(x)\), though are related just as those functions if the sign of \(n\) changes:

\[
Y_{-n}(x) = (-1)^n Y_n(x). 
\]

(2.150)

Figure 19 shows a few Weber functions of the lowest integer orders.

The plots show that the asymptotic behavior is very much similar to that of \(J_n(x)\),

\[
Y_n(x) \to \left(\frac{2}{\pi x}\right)^{1/2} \sin \left(\frac{x}{4} - \frac{n\pi}{2}\right), \quad \text{for } x \to \infty, 
\]

but with the phase shift necessary to make these Bessel functions orthogonal to those of the first order – cf. Eq. (135). However, for small values of argument \(x\), the Bessel functions of the second kind behave completely differently from those of the first kind:

\[
Y_n(x) \to \begin{cases} 
\frac{2}{\pi} \left( \ln \frac{\xi}{2} + \gamma \right), & \text{for } n = 0, \\
-\frac{(n-1)!}{\pi} \left( \frac{\xi}{2} \right)^{-n}, & \text{for } n \neq 0,
\end{cases} 
\]

(2.152)

\(^{48}\) They are also sometimes called the Neumann functions, and denoted as \(N_n(x)\).
where \( \gamma \) is the so-called Euler constant, defined as follows:

\[
\gamma = \lim_{n \to \infty} \left( 1 + \frac{1}{2} + \frac{1}{3} + \ldots + \frac{1}{n} - \ln n \right) \approx 0.577157 \ldots
\]  

(2.153)

As Eqs. (152) and Fig. 19 show, the functions \( Y_n(\xi) \) diverge at \( \xi \to 0 \) and hence cannot describe the behavior of any physical variable, in particular the electrostatic potential.

One may wonder: if this is true, when do we need these functions in physics? Figure 20 shows an example of a simple boundary problem of electrostatics, whose solution by the variable separation method involves both functions \( J_n(\xi) \) and \( Y_n(\xi) \).

Here two round, conducting coaxial cylindrical tubes are kept at the same (say, zero) potential, but at least one of two lids has a different potential. The problem is almost completely similar to that discussed above (Fig. 17), but now we need to find the potential distribution in the free space between the tubes, i.e. for \( R_1 < \rho < R_2 \). If we use the same variable separation as in the simpler counterpart problem, we need the radial functions \( \mathcal{R}(\rho) \) to satisfy two zero boundary conditions: at \( \rho = R_1 \) and \( \rho = R_2 \). With the Bessel functions of just the first kind, \( J_n(\gamma \rho) \), it is impossible to do, because the two boundaries would impose two independent (and generally incompatible) conditions, \( J_n(\gamma R_1) = 0 \), and \( J_n(\gamma R_2) = 0 \), on one “stretching parameter” \( \gamma \). The existence of the Bessel functions of the second kind immediately saves the day, because if the radial function solution is represented as a linear combination,

\[
\mathcal{R} = c_J J_n(\gamma \rho) + c_Y Y_n(\gamma \rho),
\]  

(2.154)

two zero boundary conditions give two equations for \( \gamma \) and the ratio \( c \equiv c_J/c_Y \).\(^{49}\) (Due to the oscillating character of both Bessel functions, these conditions would be typically satisfied by an infinite set of discrete pairs \{\( \gamma \), \( c \)\}.) Note, however, that generally none of these pairs would correspond to zeros of either \( J_n \) or \( Y_n \), so that having an analog of Table 1 for the latter function would not help much. Hence, even the simple problems of this kind (like the one shown in Fig. 20) typically require numerical solutions of transcendental algebraic equations.

\(^{49}\) A pair of independent linear functions, used for the representation of the general solution of the Bessel equation, may be also chosen in a different way, using the so-called Hankel functions

\[
H_n^{(1,2)}(\xi) \equiv J_n(\xi) \pm iY_n(\xi).
\]

For representing the general solution of Eq. (130), this alternative is completely similar, for example, to use the pair of complex functions \( \exp\{\pm i\alpha x\} = \cos \alpha x \pm i \sin \alpha x \) instead of the pair of real functions \{\( \cos \alpha x \), \( \sin \alpha x \)\} for the representation of the general solution of Eq. (89) for \( X(x) \).
In order to complete the discussion of variable separation in the cylindrical coordinates, one more issue to address are the so-called modified Bessel functions: of the first kind, \( I_\nu(\xi) \), and of the second kind, \( K_\nu(\xi) \). They are two linearly-independent solutions of the modified Bessel equation,

\[
\frac{d^2 \mathcal{R}}{d\xi^2} + \frac{1}{\xi} \frac{d\mathcal{R}}{d\xi} - \left( 1 + \frac{\nu^2}{\xi^2} \right) \mathcal{R} = 0 , \tag{2.155}
\]

which differs from Eq. (130) “only” by the sign of one of its terms. Figure 21 shows a simple problem that leads to this equation: a round thin conducting cylindrical pipe is sliced, perpendicular to its axis, to rings of equal height \( h \), which are kept at equal but sign-alternating potentials.

![Fig. 2.21. A typical boundary problem whose solution may be conveniently described in terms of the modified Bessel functions.](image)

If the gaps between the sections are narrow, \( t \ll h \), we may use the variable separation method for the solution to this problem, but now we evidently need periodic (rather than exponential) solutions along the \( z \)-axis, i.e. linear combinations of \( \sin kz \) and \( \cos kz \) with various real values of the constant \( k \). Separating the variables, we arrive at a differential equation similar to Eq. (129), but with the negative sign before the separation constant:

\[
\frac{d^2 \mathcal{R}}{d\rho^2} + \frac{1}{\rho} \frac{d\mathcal{R}}{d\rho} - \left( k^2 + \frac{\nu^2}{\rho^2} \right) \mathcal{R} = 0 . \tag{2.156}
\]

The same radial coordinate’s normalization, \( \xi \equiv k \rho \), immediately leads us to Eq. (155), and hence (for \( \nu = n \)) to the modified Bessel functions \( I_\nu(\xi) \) and \( K_\nu(\xi) \).

Figure 22 shows the behavior of such functions, of a few lowest orders. One can see that at \( \xi \to 0 \) the behavior is virtually similar to that of the “usual” Bessel functions – cf. Eqs. (132) and (152), with \( K_n(\xi) \) multiplied (due to purely historical reasons) by an additional coefficient, \( \pi/2 \):

\[
I_\nu(\xi) \to \frac{1}{n!} \left( \frac{\xi}{2} \right)^n , \quad K_\nu(\xi) \to \begin{cases} - \left[ \ln \left( \frac{\xi}{2} \right) + \gamma \right] , & \text{for } n = 0 , \\ \frac{1}{n!} \left( \frac{\xi}{2} \right)^{-n} & \text{for } n \neq 0 , \end{cases} \tag{2.157}
\]

However, the asymptotic behavior of the modified functions is very much different, with \( I_\nu(x) \) exponentially growing, and \( K_\nu(\xi) \) exponentially dropping at \( \xi \to \infty \):

\[
I_\nu(\xi) \to \left( \frac{1}{2\pi \xi} \right)^{1/2} e^{\xi} , \quad K_\nu(\xi) \to \left( \frac{\pi}{2\xi} \right)^{1/2} e^{-\xi} . \tag{2.158}
\]
This behavior is completely natural in the context of the problem shown in Fig. 21, in which the electrostatic potential may be represented as a sum of terms proportional to $I_n(\gamma \rho)$ inside the thin pipe, and to $K_n(\gamma \rho)$ outside it.

To complete our brief survey of the Bessel functions, let me note that all of them discussed so far may be considered as particular cases of Bessel functions of the complex argument, say $J_n(z)$ and $Y_n(z)$, or, alternatively, $H_n^{(1,2)}(z) \equiv J_n(z) \pm iY_n(z)$. At that, the “usual” Bessel functions $J_n(\xi)$ and $Y_n(\xi)$ may be considered as the sets of values of these generalized functions on the real axis ($z = \xi$), while the modified functions as their particular case at $z = i\xi$, also with real $\xi$:

$$I_\nu(\xi) = i^{-\nu} J_\nu(i\xi), \quad K_\nu(\xi) = \frac{\pi}{2} i^{\nu+1} H_\nu^{(1)}(i\xi).$$  \hspace{1cm} (2.159)

Moreover, this generalization of the Bessel functions to the whole complex plane $z$ enables the use of their values along other directions on that plane, for example under angles $\pi/4 \pm \pi/2$. As a result, one arrives at the so-called Kelvin functions:

$$\text{ber}_\nu \xi + i \text{bei}_\nu \xi \equiv J_\nu(\xi e^{-i\pi/4}),$$

$$\text{ker}_\nu \xi + i \text{kei}_\nu \xi \equiv i \frac{\pi}{2} H_\nu^{(1)}(\xi e^{-3i\pi/4}),$$ \hspace{1cm} (2.160)

which are also useful for some important problems in physics and engineering. Unfortunately, I do not have time to discuss these problems in this course.\textsuperscript{51}

\textsuperscript{50} These complex functions still obey the general relations (143) and (146), with $\xi$ replaced with $\zeta$.

\textsuperscript{51} In the QM part of this series we will run into the so-called spherical Bessel functions $j_n(\zeta)$ and $y_n(\zeta)$, which may be expressed via the Bessel functions of semi-integer orders. Surprisingly enough, these functions turn out to be simpler than $J_n(\zeta)$ and $Y_n(\zeta)$.
2.8. Variable separation – spherical coordinates

The spherical coordinates are very important in physics, because of the (at least approximate) spherical symmetry of many physical objects – from nuclei and atoms, to water drops in clouds, to planets and stars. Let us again require each component \( \phi_k \) of Eq. (84) to satisfy the Laplace equation. Using the full expression for the Laplace operator in spherical coordinates,\(^{52}\) we get

\[
\frac{1}{r^2} \frac{\partial}{\partial r} \left( r^2 \frac{\partial \phi_k}{\partial r} \right) + \frac{1}{r^2 \sin \theta} \frac{\partial}{\partial \theta} \left( \sin \theta \frac{\partial \phi_k}{\partial \theta} \right) + \frac{1}{r^2 \sin^2 \theta} \frac{\partial^2 \phi_k}{\partial \varphi^2} = 0.
\] (2.161)

Let us look for a solution of this equation in the following variable-separated form:

\[
\phi_k = \frac{R(r)}{r} \mathcal{P}(\cos \theta) \mathcal{F}(\varphi),
\] (2.162)

Separating the variables one by one, starting from \( \varphi \), just like this has been done in cylindrical coordinates, we get the following equations for the partial functions participating in this solution:

\[
\frac{d^2 R}{dr^2} - \frac{l(l+1)}{r^2} R = 0,
\] (2.163)

\[
\frac{d}{d\xi} \left[ (1-\xi^2) \frac{d \mathcal{P}}{d\xi} \right] + \left[ l(l+1) - \frac{\nu^2}{1-\xi^2} \right] \mathcal{P} = 0,
\] (2.164)

\[
\frac{d^2 \mathcal{F}}{d\varphi^2} + \nu^2 \mathcal{F} = 0,
\] (2.165)

where \( \xi \equiv \cos \theta \) is a new variable used in lieu of \( \theta \) (so that \(-1 \leq \xi \leq +1\)), while \( \nu \) and \( l(l+1) \) are the separation constants. (The reason for selection of the latter one in this form will be clear in a minute.)

One can see that Eq. (165) is very simple, and is absolutely similar to the Eq. (107) we have got for the cylindrical coordinates. Moreover, the equation for the radial functions is simpler than in the cylindrical coordinates. Indeed, let us look for its partial solution in the form \( \alpha r^\alpha \) – just as we have done with Eq. (106). Plugging this solution into Eq. (163), we immediately get the following condition on the parameter \( \alpha \):

\[
\alpha(\alpha-1) = l(l+1).
\] (2.166)

This quadratic equation has two roots, \( \alpha = l + 1 \) and \( \alpha = -l \), so that the general solution to Eq. (163) is

\[
R = a_i r^{\alpha_i} + b_i/r^\alpha.
\] (2.167)

However, the general solution of Eq. (164) (called either the general or associated Legendre equation) cannot be expressed via what is usually called elementary functions.\(^{53}\) Let us start its discussion from the axially-symmetric case, when \( \partial \phi/\partial \varphi = 0 \). This means \( \mathcal{F}(\varphi) = \text{const} \), and thus \( \nu = 0 \), so that Eq. (164) is reduced to the so-called Legendre differential equation:

\[^{52}\text{See, e.g., MA Eq. (10.9).}\]

\[^{53}\text{Actually, there is no generally accepted line between the “elementary” and “special” functions.}\]
One can readily check that the solutions of this equation for integer values of \( l \) are specific (Legendre) polynomials\(^{54}\) that may be described by the following Rodrigues’ formula:

\[
\mathcal{P}_l(\xi) = \frac{1}{2^l \, l!} \frac{d^l}{d\xi^l} (\xi^2 - 1)^l, \quad l = 0, 1, 2, \ldots
\]  

As this formula shows, the first few Legendre polynomials are pretty simple:

\[
\begin{align*}
\mathcal{P}_0(\xi) &= 1, \\
\mathcal{P}_1(\xi) &= \xi, \\
\mathcal{P}_2(\xi) &= \frac{1}{2} (3\xi^2 - 1), \\
\mathcal{P}_3(\xi) &= \frac{1}{2} (5\xi^3 - 3\xi), \\
\mathcal{P}_4(\xi) &= \frac{1}{8} (35\xi^4 - 30\xi^2 + 3), \ldots 
\end{align*}
\]  

though such explicit expressions become more and more bulky as \( l \) is increased. As Fig. 23 shows, all these polynomials, which are defined on the [-1, +1] segment, end at the same point: \( \mathcal{P}_l(1) = +1 \), while starting either at the same point or at the opposite point: \( \mathcal{P}_l(-1) = (-1)^l \). Between these two end points, the \( l \)th polynomial has \( l \) zeros. It is straightforward to use Eq. (169) for proving that these polynomials form a full, orthogonal set of functions, with the following normalization rule:

\[
\int_{-1}^{+1} \mathcal{P}_l(\xi) \mathcal{P}_r(\xi) d\xi = \frac{2}{2l+1} \delta_{lr},
\]  

so that any function \( f(\xi) \) defined on the segment [-1, +1] may be represented as a unique series over the polynomials\(^{55}\).

Thus, taking into account the additional division by \( r \) in Eq. (162), the general solution of any axially-symmetric Laplace problem may be represented as

\[
\phi(r, \theta) = \sum_{l=0}^{\infty} \left( a_l r^l + \frac{b_l}{r^{l+1}} \right) \mathcal{P}_l(\cos \theta).
\]  

Note a strong similarity between this solution and Eq. (112) for the 2D Laplace problem in the polar coordinates. However, besides the difference in the angular functions, there is also a difference (by one) in the power of the second radial function, and this difference immediately shows up in problem solutions.

\(^{54}\) For the reader’s reference: if \( l \) is not integer, the general solution of Eq. (2.168) may be represented as a linear combination of the so-called Legendre functions (not polynomials!) of the first and second kind, \( \mathcal{P}(\xi) \) and \( \mathcal{Q}(\xi) \).

\(^{55}\) This is why, at least for the purposes of this course, there is no good reason for pursuing (more complex) solutions to Eq. (168) for non-integer values of \( l \), mentioned in the previous footnote.
Indeed, let us solve a problem similar to that shown in Fig. 15: find the electric field around a conducting sphere of radius $R$, placed into an initially uniform external field $E_0$ (whose direction I will take for the $z$-axis) – see Fig. 24a.

If we select the arbitrary constant in the electrostatic potential so that $\phi|_{z=0} = 0$, then in Eq. (172) we should take $a_0 = b_0 = 0$. Now, just as has been argued for the cylindrical case, at $r \gg R$ the potential should approach that of the uniform field:

$$\phi \rightarrow -E_0 z = -E_0 r \cos \theta,$$

(2.173)

so that in Eq. (172), only one of the coefficients $a_l$ survives: $a_1 = -E_0 \delta_{l,1}$. As a result, from the boundary condition on the surface, $\phi(R, \theta) = 0$, we get the following equation for the coefficients $b_l$:

Fig. 2.23. A few lowest Legendre polynomials $P_l(\xi)$.

Fig. 2.24. Conducting sphere in a uniform electric field: (a) the problem’s geometry, and (b) the equipotential surface pattern given by Eq. (176). The pattern is qualitatively similar but quantitatively different from that for the conducting cylinder in a perpendicular field – cf. Fig. 15.
\[
0 = \left( -E_0 R + \frac{b_1}{R^3} \right) \cos \theta + \sum_{l \geq 1} \frac{b_l}{R^{2l+1}} \mathcal{P}_l (\cos \theta).
\]  
(2.174)

Now repeating the argumentation that led to Eq. (117), we may conclude that Eq. (174) is satisfied if

\[
b_l = E_0 R^3 \delta_{l,1},
\]  
(2.175)

so that, finally, Eq. (172) is reduced to

\[
\phi = -E_0 \left( r - \frac{R^3}{r^2} \right) \cos \theta.
\]  
(2.176)

This distribution, shown in Fig. 24b, is very much similar to Eq. (117) for the cylindrical case (cf. Fig. 15b, with the account for a different plot orientation), but with a different power of the radius in the second term. This difference leads to a quantitatively different distribution of the surface electric field:

\[
E_n = \frac{\partial \phi}{\partial r} \bigg|_{r=R} = 3E_0 \cos \theta,
\]  
(2.177)

so that its maximal value is a factor of 3 (rather than 2) larger than the external field.

Now let me briefly (mostly just for the reader’s reference) mention the Laplace equation solutions in the general case (with no axial symmetry). If the free space surrounds the origin from all sides, the solutions to Eq. (165) have to be \(2\pi\)-periodic, and hence \(\nu = n = 0, \pm 1, \pm 2, \ldots\) Mathematics says that Eq. (164) with integer \(\nu = n\) and a fixed integer \(l\) has a solution only for a limited range of \(n\):\(^{56}\)

\[
-l \leq n \leq l.
\]  
(2.178)

These solutions are called the associated Legendre functions (generally, they are not polynomials!) For \(n \geq 0\), these functions may be defined via the Legendre polynomials, using the following formula:\(^{57}\)

\[
\mathcal{P}_l^n (\xi) = (-1)^n (1 - \xi^2)^{n/2} \frac{d^n}{d\xi^n} \mathcal{P}_l (\xi).
\]  
(2.179)

On the segment \(\xi \in [-1, +1]\), each set of the associated Legendre functions with a fixed index \(n\) and non-negative values of \(l\) form a full, orthogonal set, with the normalization relation,

\[
\int_{-1}^{+1} \mathcal{P}_l^n (\xi) \mathcal{P}_{l'}^n (\xi) d\xi = \frac{2}{2l+1} \frac{(l+n)!}{(l-n)!} \delta_{ll'},
\]  
(2.180)

that is evidently a generalization of Eq. (171).

Since these relations may seem a bit intimidating, let me write down explicit expressions for a few \(\mathcal{P}_l^n (\cos \theta)\) with the lowest values of \(l\) and \(n \geq 0\), which are most important for applications.

\[
l = 0:\quad \mathcal{P}_0^0 (\cos \theta) = 1;
\]  
(2.181)

---

\(^{56}\) In quantum mechanics, the letter \(n\) is typically reserved used for the “principal quantum number”, while the azimuthal functions are numbered by index \(m\). However, here I will keep using \(n\) as their index, because for this course’s purposes, this seems more logical in the view of the similarity of the spherical and cylindrical functions.

\(^{57}\) Note that some texts use different choices for the front factor (called the Condon-Shortley phase) in the functions \(\mathcal{P}_l^m\), which do not affect the final results for the spherical harmonics \(Y_l^m\).
The reader should agree there is not much to fear in these functions – they are just certain sums of products of functions \( \cos \theta \equiv \xi \) and \( \sin \theta \equiv (1 - \xi^2)^{1/2} \). Fig. 25 below shows the plots of a few lowest functions \( P_l^n(\xi) \).

Using the associated Legendre functions, the general solution (162) to the Laplace equation in the spherical coordinates may be expressed as

\[
\phi(r, \theta, \varphi) = \sum_{l=0}^{\infty} \left( a_l r^l + \frac{b_l}{r^{l+1}} \right) \sum_{n=0}^{l} P_l^n(\cos \theta) \hat{\mathcal{P}}_n(\varphi), \quad \hat{\mathcal{P}}_n(\varphi) = c_n \cos n \varphi + s_n \sin n \varphi .
\]

Since the difference between the angles \( \theta \) and \( \varphi \) is somewhat artificial, physicists prefer to think not about functions \( \mathcal{P} \) and \( \mathcal{F} \) in separation, but directly about their products that participate in this solution.\(^{58}\)

\(^{58}\) In quantum mechanics, it is more convenient to use a slightly different, alternative set of basic functions of the same problem, namely the following complex functions called the spherical harmonics:

\[
Y_l^n(\theta, \varphi) \equiv \left[ \frac{2l + 1}{4\pi} \frac{(l - n)!}{(l + n)!} \right]^{1/2} P_l^n(\cos \theta) e^{in\varphi},
\]

which are defined for both positive and negative \( n \) (within the limits \(-l \leq n \leq +l\) – see, e.g., QM Secs. 3.6 and 5.6. (Note again that in that field, the index \( n \) is traditionally denoted as \( m \), and called the magnetic quantum number.)
As a rare exception for my courses, in order to save time, I will skip giving an example of using the associated Legendre functions in electrostatics, because quite a few such examples of that will be given in the quantum mechanics part of these series.

2.9. Charge images

So far, we have discussed various methods of solution of the Laplace boundary problem (35). Let us now move on to the discussion of its generalization, the Poisson equation (1.41), that we need when besides conductors, we also have “stand-alone” charges with a known spatial distribution \( \rho(r) \). (This will also allow us, better equipped, to revisit the Laplace problem in the next section.)

Let us start with a somewhat limited, but very useful charge image (or “image charge”) method. Consider a very simple problem: a single point charge near a conducting half-space – see Fig. 26.

![Fig. 2.26. The simplest problem readily solvable by the charge image method. The points’ colors are used, as before, to denote the charges of the original (red) and opposite (blue) sign.](image)

Let us prove that its solution, above the conductor’s surface \( (z \geq 0) \), may be represented as:

\[
\phi(\mathbf{r}) = \frac{1}{4\pi \varepsilon_0} \left( \frac{q}{r_1} - \frac{q}{r_2} \right) = \frac{q}{4\pi \varepsilon_0} \left( \frac{1}{|\mathbf{r} - \mathbf{r}'|} - \frac{1}{|\mathbf{r} - \mathbf{r}''|} \right),
\]

or in a more explicit form, using the cylindrical coordinates shown in Fig. 26:

\[
\phi(\mathbf{r}) = \frac{q}{4\pi \varepsilon_0} \left( \frac{1}{\rho^2 + (z - d)^2} \right)^{1/2} - \frac{1}{\rho^2 + (z + d)^2 \rho^2} \right)^{1/2},
\]

where \( \rho \) is the distance of the observation point from the “vertical” line on which the charge is located. Indeed, this solution evidently satisfies both the boundary condition \( \phi = 0 \) at the surface of the conductor \( (z = 0) \), and the Poisson equation (1.41), with the single \( \delta \)-functional source at point \( \mathbf{r}' = \{0, 0, d\} \) on its right-hand side, because the second singularity of the solution, at point \( \mathbf{r}'' = \{0, 0, -d\} \), is outside the region of the solution’s validity \( (z \geq 0) \). Physically, this solution may be interpreted as the sum of the fields of the actual charge \( (+q) \) at point \( \mathbf{r}' \), and an equal but opposite charge \( (-q) \) at the “mirror image” point \( \mathbf{r}'' \) (Fig. 26). This is the basic idea of the charge image method. Before moving on to more complex problems, let us discuss the situation shown in Fig. 26 in a little bit more detail, due to its fundamental importance.

First, we can use Eqs. (3) and (186) to calculate the surface charge density:
\[
\sigma = -\varepsilon_0 \frac{\partial \phi}{\partial z} \bigg|_{z=0} = -\frac{q}{4\pi} \frac{\partial}{\partial z} \left( \frac{1}{(\rho^2 + (z-d)^2)^{1/2}} - \frac{1}{(\rho^2 + (z+d)^2)^{1/2}} \right)_{z=0} = -\frac{q}{4\pi} \frac{2d}{(\rho^2 + d^2)^{3/2}}. \tag{2.187}
\]

From this, the total surface charge is
\[
Q = \int_A \sigma d^2r = 2\pi \int_0^\infty \sigma(\rho) \rho d\rho = -\frac{q}{2} \int_0^\infty \frac{2d}{(\rho^2 + d^2)^{3/2}} \rho d\rho. \tag{2.188}
\]

This integral may be easily worked out using the substitution \( \xi = \rho^2/d^2 \) (giving \( d\xi = 2\rho d\rho/d^2 \)):
\[
Q = -\frac{q}{2} \int_0^\infty \frac{d\xi}{(\xi + 1)^{1/2}} = -q. \tag{2.189}
\]

This result is very natural, because the conductor “wants” to bring as much surface charge from its interior to the surface as necessary to fully compensate the initial charge (+q) and hence to kill the electric field at large distances as efficiently as possible, hence reducing the total electrostatic energy (1.65) to the lowest possible value.

For a better feeling of this polarization charge of the surface, let us take our calculations to the extreme – to the \( q \) equal to one elementary change \( e \), and place a particle with this charge (for example, a proton) at a macroscopic distance – say 1 m – from the conductor’s surface. Then, according to Eq. (189), the total polarization charge of the surface equals to that of an electron, and according to Eq. (187), its spatial extent is of the order of \( d^2 = 1 \text{ m}^2 \). This means that if we consider a much smaller part of the surface, \( \Delta A \ll d^2 \), its polarization charge magnitude \( \Delta Q = \sigma\Delta A \) is much less than one electron! For example, Eq. (187) shows that the polarization charge of quite a macroscopic area \( \Delta A = 1 \text{ cm}^2 \) right under the initial charge \( (\rho = 0) \) is \( e\Delta A/2\pi d^2 \approx 1.6\times10^{-5} e \). Can this be true, or our theory is somehow limited to the charges \( q \) much larger than \( e \)? (After all, the theory is substantially based on the approximate macroscopic model (1); maybe this is the culprit?)

Surprisingly enough, the answer to this question has become clear (at least to some physicists :-) only as late as in the mid-1980s when several experiments demonstrated, and theorists accepted, some rather grudgingly, that the usual polarization charge formulas are valid for elementary charges as well, i.e., such the polarization charge \( \Delta Q \) of a macroscopic surface area can indeed be less than \( e \). The underlying reason for this paradox is the physical nature of the polarization charge of a conductor’s surface: as was discussed in Sec. 1, it is due not to new charged particles brought into the conductor (such charge would be in fact quantized in the units of \( e \)), but to a small shift of the free charges of a conductor by a very small distance from their equilibrium positions that they had in the absence of the external field induced by charge \( q \). This shift is not quantized, at least on the scale relevant to our problem, and hence neither is \( \Delta Q \).

This understanding has paved a way toward the invention and experimental demonstration of several new devices including so-called single-electron transistors,\(^{59}\) which are used, in particular, for ultrasensitive measurement of polarization charges as small as \( \sim 10^{-6} e \). Another important class of single-electron devices is the current standards based on the fundamental relation \( I = -ef \), where \( I \) is the

\(^{59}\) Actually, this term (for which the author of these notes should be blamed :-) is misleading: the operation of the “single-electron transistor” is based on the interplay of discrete charges (multiples of \( e \)) transferred between conductors, and sub-single-electron polarization charges – see, e.g., K. Likharev, *Proc. IEEE* \textbf{87}, 606 (1999).
dc current carried by electrons transferred with the frequency $f$. The experimentally achieved\textsuperscript{60} relative accuracy of such standards is of the order of $10^{-7}$, and is not too far from that provided by the competing approach based on the combination of the Josephson effect and the quantum Hall effect.\textsuperscript{61}

Second, let us find the potential energy $U$ of the charge-to-surface interaction. For that, we may use the value of the electrostatic potential (185) at the point of the charge itself ($r = r'$), of course ignoring the infinite potential created by the real charge, so that the remaining potential is that of the image charge

$$
\phi_{\text{image}}(r') = -\frac{1}{4\pi\varepsilon_0} \frac{q}{2d}.
$$

(2.190)

Looking at the definition of the electrostatic potential, given by Eq. (1.31), it may be tempting to immediately write $U = q\phi_{\text{image}} = -\left(\frac{1}{4\pi\varepsilon_0}\right)\frac{q^2}{2d}$ [WRONG!], but this would be incorrect. The reason is that the potential $\phi_{\text{image}}$ is not independent of $q$, but is actually induced by this charge. This is why the correct approach is to calculate $U$ from Eq. (1.61), with just one term:

$$
U = \frac{1}{2} q\phi_{\text{image}} = -\frac{1}{4\pi\varepsilon_0} \frac{q^2}{4d},
$$

(2.191)

giving twice lower energy than in the wrong result cited above. In order to double-check Eq. (191), and also get a better feeling of the factor ½ that distinguishes it from the wrong guess, we can recalculate $U$ as the integral of the force exerted on the charge by the conductor (i.e., in our formalism, by the image charge):

$$
U = -\int_{\infty}^{d} F(z)dz = \frac{1}{4\pi\varepsilon_0} \int_{\infty}^{d} \frac{q^2}{(2z)^2} dz = -\frac{1}{4\pi\varepsilon_0} \frac{q^2}{4d}.
$$

(2.192)

This calculation clearly accounts for the gradual build-up of the force $F$, as the real charge is brought from afar (where we have opted for $U=0$) toward the surface.

This result has several important applications. For example, let us plot the electrostatic energy $U$ for an electron, i.e. a particle with charge $q = -e$, near a metallic surface, as a function of $d$. For that, we may use Eq. (191) until our macroscopic model (1) becomes invalid, and $U$ transitions to some negative constant value ($-\psi$) inside the conductor – see Fig. 27a. Since our calculation was for an electron with zero potential energy at infinity, at relatively low temperatures, $k_BT << \psi$, electrons in metals may occupy only the states with energies below $-\psi$ (the so-called Fermi level\textsuperscript{62}). The positive constant $\psi$ is called the workfunction, because it describes the smallest work necessary to remove the electron from a metal. As was discussed in Sec. 1, in good metals the electric field screening takes place at interatomic distances $a_0 \approx 10^{-10}$ m. Plugging $d = a_0$ and $q = -e$ into Eq. (191), we get $\psi \approx 6\times10^{-19}$ J $\approx 3.5$ eV. This very crude estimate is in a surprisingly good agreement with the experimental values of the workfunction, ranging between 4 and 5 eV for most metals.\textsuperscript{63}

\textsuperscript{60} See, e.g., M. Keller et al., \textit{Appl. Phys. Lett.} \textbf{69}, 1804 (1996); F. Stein et al., Metrologia \textbf{54}, 1 (2017).

\textsuperscript{62} More discussion of these states may be found in SM Secs. 3.3 and 6.3.

\textsuperscript{63} More discussion of the workfunction, and its effect on the electrons’ kinetics, is given in SM Sec. 6.3.
Next, let us consider the effect of an additional uniform external electric field $E_0$ applied normally to a metallic surface, and toward it, on this potential profile. We can add the potential energy that the field gives to the electron at distance $d$ from the surface, $U_{\text{ext}} = -eE_0d$, to that created by the image charge. (As we know from Eq. (1.53), since the field $E_0$ is independent of the electron’s position, its recalculation into the potential energy does not require the coefficient $\frac{1}{2}$.) As the result, the potential energy of an electron near the surface becomes

$$U(d) = -eE_0d - \frac{1}{4\pi\varepsilon_0} \frac{e^2}{4d}, \quad \text{for } d \gg a_0,$$

with a similar crossover to $U = -\psi$ inside the conductor – see Fig. 27b. One can see that at the appropriate sign, and a sufficient magnitude of the applied field, it lowers the potential barrier that prevents electrons from leaving the conductor. At $E_0 \sim \psi/a_0$ (for metals, $\sim 10^{10}$ V/m), this suppression becomes so strong that electrons with energies at, and just below the Fermi level start quantum-mechanical tunneling through the remaining thin barrier. This is the field emission effect, which is used in vacuum electronics to provide efficient cathodes that do not require heating to high temperatures.\(^{64}\)

Returning to the basic electrostatics, let us find some other conductor geometries where the method of charge images may be effectively applied. First, let us consider the right corner (Fig. 28a). Reflecting the initial charge in the vertical plane we get the image shown in the top left corner of that panel. This image makes the boundary condition $\phi = \text{const}$ satisfied on the vertical surface of the corner. However, in order for the same to be true on the horizontal surface, we have to reflect both the initial charge and the image charge in the horizontal plane, flipping their signs. The final configuration of 4 charges, shown in Fig. 28a, evidently satisfies all boundary conditions. The resulting potential distribution may be readily written as the generalization of Eq. (185). From it, the electric field and electric charge distributions, and the potential energy and forces acting on the charge may be calculated exactly as above – an easy exercise left for the reader.

Next, consider a corner with angle $\pi/4$ (Fig. 28b). Here we need to repeat the reflection operation not 2 but 4 times before we arrive at the final pattern of 8 positive and negative charges. (Any attempt to continue this process would lead to an overlap with the already existing charges.) This reasoning may be

---

\(^{64}\) The practical use of such “cold” cathodes is affected by the fact that, as it follows from our discussion in Sec. 4, any nanoscale irregularity of a conducting surface (a protrusion, an atomic cluster, or even a single “adatom” stuck to it) may cause a strong increase of the local field well above the applied uniform field $E_0$, making the electron emission reproducibility and stability in time significant challenges. In addition, the impact-ionization effects may lead to an avalanche-type electric breakdown already at fields as low as $\sim 3 \times 10^6$ V/m.
readily extended to corners of angles \( \beta = \pi n \), with any integer \( n \), which require \( 2n \) charges (including the initial one) to satisfy all the boundary conditions.

Some configurations require an infinite number of images, but are still tractable. The most important of them is a system of two parallel conducting surfaces, i.e. an unbiased plane capacitor of infinite area (Fig. 28c). Here the repeated reflection leads to an infinite system of charges \( \pm q \) at points

\[
x^+_j = 2aj \pm d ,
\]

where \( d \) (with \( 0 < d < a \)) is the position of the initial charge, and \( j \) an arbitrary integer. The resulting infinite sum for the potential of the real charge \( q \), created by the field of its images,

\[
\phi(d) = \frac{1}{4 \pi \varepsilon_0} \left[ -\frac{q}{2d} + \sum_{j=0}^{\pm} \sum_{\pm} \frac{\pm q}{d - x^+_j} \right] \equiv -\frac{q}{4 \pi \varepsilon_0} \left[ \frac{1}{2d} + \frac{d^2}{a^3} \sum_{j=0}^{\pm} \frac{1}{j^2 - (d/a)^2} \right],
\]

is converging (in its last form) very fast. For example, the exact value, \( \phi(D/2) = -2\ln2 (q/4\pi\varepsilon_0D) \), differs by less than 5% from the approximation using just the first term of the sum.
The same method may be applied to 2D (cylindrical) and 3D rectangular conducting boxes that require, respectively, a 2D or 3D infinite rectangular lattices of images; for example in a 3D box with sides $a$, $b$, and $c$, charges $\pm q$ are located at points (Fig. 28d)

$$\mathbf{r}_{jkl}^\pm = 2ja + kb + lc \pm \mathbf{r'},$$  \hspace{1cm} (2.196)

where $\mathbf{r'}$ is the location of the initial (real) charge, and $j$, $k$, and $l$ are arbitrary integers. Figure 28e shows the results of the summation of the potentials of such charge set, including the real one, in a 2D box (within the plane of the real charge). One can see that the equipotential surfaces, concentric near the charge, are naturally leaning along the conducting walls of the box, which has to be equipotential.

Even more surprisingly, the image charge method works very efficiently not only for rectilinear geometries, but also for spherical ones. Indeed, let us consider a point charge $q$ at distance $d$ from the center of a conducting, grounded sphere of radius $R$ (Fig. 29a), and try to satisfy the boundary condition $\phi = 0$ for the electrostatic potential on the sphere’s surface using an imaginary charge $q'$ located at some point beyond the surface, i.e. inside the sphere.

From the problem’s symmetry, it is clear that the point should be at the line passing through the real charge and the sphere’s center, at some distance $d'$ from the center. Then the total potential created by the two charges at an arbitrary point with $r \geq R$ (Fig. 29a) is

$$\phi(r,\theta) = \frac{1}{4\pi\varepsilon_0} \left[ \frac{q}{(r^2 + d^2 - 2rd\cos\theta)^{1/2}} + \frac{q'}{(r^2 + d'^2 - 2rd'\cos\theta)^{1/2}} \right].$$  \hspace{1cm} (2.197)

This expression shows that we can make the two fractions to be equal and opposite at all points on the sphere’s surface (i.e. for any $\theta$ at $r = R$), if we take

$$d' = \frac{R^2}{d}, \quad q' = -\frac{R}{d}q.$$  \hspace{1cm} (2.198)

Since the solution to any Poisson boundary problem is unique, Eqs. (197) and (198) give us such solution for this problem. Fig. 29b shows a typical equipotential pattern following from this solution. It may be surprising how formulas that simple may describe such a nontrivial field distribution.

---

65 In geometry, such points, with $dd' = R^2$, are referred to as the result of mutual inversion in a sphere of radius $R$. 
Now let us calculate the total charge $Q$ on the grounded sphere’s surface, induced by the external charge $q$. We could do this, as we have done for the conducting plane, by the brute-force integration of the surface charge density $\sigma = -\varepsilon_0 \partial \phi / \partial r | r = R$. It is more elegant, however, to use the following Gauss law argument. Eq. (197) is valid (at $r \geq R$) regardless whether we are dealing with our real problem (charge $q$ and the conducting sphere) or with the equivalent charge configuration – with the point charges $q$ and $q'$, but no sphere at all. Hence, according to Eq. (1.16), the Gaussian integral over a surface with radius $r = R + 0$, and the total charge inside the sphere should be also the same. Hence we immediately get

\[ Q = q' = -\frac{R}{d} q. \]  

(2.199)

The similar argumentation may be used to calculate the charge-to-sphere interaction force:

\[ F = qE_{\text{image}}(d) = q \frac{q'}{4\pi\varepsilon_0 (d - d')^2} = -\frac{q^2}{4\pi\varepsilon_0} \frac{R}{d} \frac{1}{(d - R^2 / d)^2} = \frac{-q^2}{4\pi\varepsilon_0} \frac{Rd}{(d^2 - R^2)^2}. \]  

(2.200)

(Nota que esta expresión es legítima sólo si $d > R$.) At large distances, $d >> R$, this attractive force decreases as $1/d^3$. This unusual dependence arises because, as Eq. (199) specifies, the induced charge of the sphere, responsible for the force, is not constant but decreases as $1/d$. In the next chapter, we will see that such force is also typical for the interaction between a point charge and a point dipole.

All previous formulas were for a sphere that is grounded to keep its potential equal to zero. But what if we keep the sphere galvanically insulated, so that its net charge is fixed, for example, equals zero? Instead of solving this problem from scratch, let us use (again!) the almighty linear superposition principle. For that, we may add to the previous problem an additional charge, equal to $Q = -q'$, to the sphere, and argue that this addition gives, at all points, an additional, spherically-symmetric potential that does not depend on the potential induced by the external charge $q$, and was calculated in Sec. 1.2 – see Eq. (1.19). For the interaction force, such addition yields

\[ F = \frac{qq'}{4\pi\varepsilon_0 (d - d')^2} + \frac{qq'}{4\pi\varepsilon_0 d^2} = -\frac{q^2}{4\pi\varepsilon_0} \left[ \frac{Rd}{(d^2 - R^2)^2} - \frac{R}{d^3} \right]. \]  

(2.201)

At large distances, the two terms proportional to $1/d^3$ cancel each other, giving $F \propto 1/d^5$. Such a rapid force decay is due to the fact that the field of the uncharged sphere is equivalent to that of two (equal and opposite) induced charges $+q'$ and $-q'$, and the distance between them $(d - d' = d - R^2/d)$ tends to zero at $d \to \infty$. The potential energy of such interaction behaves as $U \propto 1/d^6$ at $d \to \infty$; in the next chapter we will see that this is the general law of the induced dipole interaction.

### 2.10. Green’s functions

I have spent so much time/space discussing the potential distributions created by a single point charge in various conductor geometries, because for any of the geometries, the generalization of these results to the arbitrary distribution $\rho(\mathbf{r})$ of free charges is straightforward. Namely, if a single charge $q$, located at some point $\mathbf{r}'$, creates the electrostatic potential

\[ \phi(\mathbf{r}) = \frac{1}{4\pi\varepsilon_0} qG(\mathbf{r}, \mathbf{r}'), \]  

(2.202)
then, due to the linear superposition principle, an arbitrary charge distribution (either discrete or continuous) creates the potential

\[ \phi(\mathbf{r}) = \frac{1}{4\pi\varepsilon_0} \sum q_j G(\mathbf{r}, \mathbf{r}_j) = \frac{1}{4\pi\varepsilon_0} \int \rho(\mathbf{r}') G(\mathbf{r}, \mathbf{r}') d^3r'. \]  

(2.203)

The function \( G(\mathbf{r}, \mathbf{r}') \) is called the (spatial) Green’s function – the notion very fruitful and hence popular in all fields of physics.\(^{66}\) Evidently, as Eq. (1.35) shows, in the unlimited free space

\[ G(\mathbf{r}, \mathbf{r}') = \frac{1}{|\mathbf{r} - \mathbf{r}'|}, \]

(2.204)
i.e. the Green’s function depends only on one scalar argument – the distance between the field-observation point \( \mathbf{r} \) and the field-source (charge) point \( \mathbf{r}' \). However, as soon as there are conductors around, the situation changes. In this course, I will only discuss the Green’s functions that vanish as soon as the radius-vector \( \mathbf{r} \) points to the surface (S) of any conductor:\(^{67}\)

\[ G(\mathbf{r}, \mathbf{r}') \bigg|_{\mathbf{r} \in S} = 0. \]  

(2.205)

With this definition, it is straightforward to deduce the Green’s functions for the solutions of the last section’s problems in which conductors were grounded (\( \phi = 0 \)). For example, for a semi-space \( z \geq 0 \) limited by a conducting plane (Fig. 26), Eq. (185) yields

\[ G = \frac{1}{|\mathbf{r} - \mathbf{r}'|} - \frac{1}{|\mathbf{r} - \mathbf{r}''|}, \quad \text{with } \rho'' = \rho' \text{ and } z'' = -z'. \]  

(2.206)

We see that in the presence of conductors (and, as we will see later, any other polarizable media), the Green’s function may depend not only on the difference \( \mathbf{r} - \mathbf{r}' \), but on each of these two arguments in a specific way.

So far, this looks just like re-naming our old results. The really non-trivial result of this formalism for electrostatics is that, somewhat counter-intuitively, the knowledge of the Green’s function for a system with grounded conductors (Fig. 30a) enables the calculation of the field created by voltage-biased conductors (Fig. 30b), with the same geometry. To show this, let us use the so-called Green’s theorem of the vector calculus.\(^{68}\) The theorem states that for any two scalar, differentiable functions \( f(\mathbf{r}) \) and \( g(\mathbf{r}) \), and any volume \( V \),

\[ \int_S \left( f \nabla^2 g - g \nabla^2 f \right) d^3r = \int \left( f \nabla g - g \nabla f \right)_s d^2r, \]  

(2.207)

where \( S \) is the surface limiting the volume. Applying the theorem to the electrostatic potential \( \phi(\mathbf{r}) \) and the Green’s function \( G \) (also considered as a function of \( \mathbf{r} \)), let us use the Poisson equation (1.41) to replace \( \nabla^2 \phi \) with \((-\rho/\varepsilon_0)\), and notice that \( G \), considered as a function of \( \mathbf{r} \), obeys the Poisson equation with the \( \delta \)-functional source:

\[ \nabla^2 G(\mathbf{r}, \mathbf{r'}) = -4\pi\delta(\mathbf{r} - \mathbf{r'}). \]  

(2.208)

---

\(^{66}\) See, e.g., CM Sec. 5.1, QM Secs. 2.2 and 7.4, and SM Sec. 5.5.

\(^{67}\) \( G \) so defined is sometimes called the Dirichlet function.

\(^{68}\) See, e.g., MA Eq. (12.3). Actually, this theorem is a ready corollary of the better-known divergence (“Gauss”) theorem, MA Eq. (12.2).
(Indeed, according to its definition (202), this function may be formally considered as the field of a point charge \( q = 4\pi \varepsilon_0 \).) Now swapping the notation of the radius-vectors, \( r \leftrightarrow r' \), and using the Green’s function symmetry, \( G(r, r') = G(r', r) \), we get

\[
-4\pi \phi(r) - \int \frac{\rho(r')}{\varepsilon_0} G(r, r') d^3r' = \oint_S \phi(r') \frac{\partial G(r, r')}{\partial n'} - G(r, r') \frac{\partial \phi(r')}{\partial n'} d^2r'.
\]  

(2.209)

Let us apply this relation to the volume \( V \) of free space between the conductors, and the boundary \( S \) drawn immediately outside of their surfaces. In this case, by its definition, the Green’s function \( G(r, r') \) vanishes at the conductor surface (\( r \in S \)) – see Eq. (205). Now changing the sign of \( \partial n' \) (so that it would be the outer normal for conductors, rather than free space volume \( V \)), dividing all terms by \( 4\pi \), and partitioning the total surface \( S \) into the parts (numbered by index \( j \)) corresponding to different conductors (possibly, kept at different potentials \( \phi_k \)), we finally arrive at the famous result:

\[
\phi(r) = \frac{1}{4\pi\varepsilon_0} \int_V \rho(r') G(r, r') d^3r' + \frac{1}{4\pi} \sum_k \phi_k \oint_{S_k} \frac{\partial G(r, r')}{\partial n'} d^2r'.
\]  

(2.210)

While the first term on the right-hand side of this relation is a direct and evident expression of the superposition principle, given by Eq. (203), the second term is highly non-trivial: it describes the effect of conductors with non-zero potentials \( \phi_k \) (Fig. 30b), using the Green’s function calculated for the similar system with grounded conductors, i.e. with all \( \phi_k = 0 \) (Fig. 30a). Let me emphasize that since our volume \( V \) excludes conductors, the first term on the right-hand side of Eq. (210) includes only the stand-alone charges in the system (in Fig. 30, marked \( q_1, q_2, \) etc.), but not the surface charges of the conductors – which are taken into account, implicitly, by the second term.

In order to illustrate what a powerful tool Eq. (210) is, let us use to calculate the electrostatic field in two systems. In the first of them, a plane, circular, conducting disk, separated with a very thin cut from the remaining conducting plane, is biased with potential \( \phi = V \), while the rest of the plane is grounded – see Fig. 31.

---

69 This symmetry, evident for the particular cases (204) and (206), may be readily proved for the general case by applying Eq. (207) to functions \( f(r) \equiv G(r, r') \) and \( g(r) \equiv G(r, r'') \). With this substitution, the left-hand side of that equality becomes equal to \(-4\pi [G(r', r') - G(r', r'')]\), while the right-hand side is zero, due to Eq. (205).

70 In some textbooks, the sign before the surface integral is negative, because their authors use the outer normal to the free-space region \( V \) rather than that occupied by conductors – as I do.
If the width of the gap between the circle and the rest of the plane is negligible, we may apply Eq. (210) without stand-alone charges, \( \rho'(r') = 0 \), and the Green’s function for the uncut plane – see Eq. (206).\(^{71}\) In the cylindrical coordinates, with the origin at the disk’s center (Fig. 31), the function is

\[
G(r, r') = \frac{1}{\left[\rho^2 + \rho'^2 - 2\rho\rho'\cos(\varphi - \varphi') + (z - z')^2\right]^{1/2}} - \frac{1}{\left[\rho^2 + \rho'^2 - 2\rho\rho'\cos(\varphi - \varphi') + (z + z')^2\right]^{1/2}}. \tag{2.211}
\]

(The sum of the first three terms under the square roots in Eq. (211) is just the squared distance between the horizontal projections \( \rho \) and \( \rho' \) of the vectors \( r \) and \( r' \) (or \( r'' \)) correspondingly, while the last terms are the squares of their vertical displacements.)

Now we can readily calculate the derivative participating in Eq. (210):

\[
\frac{\partial G}{\partial z'} \bigg|_{z'=0} = \frac{2z}{(\rho^2 + \rho'^2 - 2\rho\rho'\cos(\varphi - \varphi') + z^2)^{3/2}}. \tag{2.212}
\]

Due to the axial symmetry of the system, we may take \( \varphi \) for zero. With this, Eqs. (210) and (212) yield

\[
\phi = \frac{V}{4\pi} \oint_S \frac{\partial G(r, r')}{\partial n'} d^2r' = \frac{Vz}{2\pi} \int_0^R d\varphi' \int_0^\rho \frac{\rho' d\rho'}{(\rho^2 + \rho'^2 - 2\rho\rho'\cos\varphi' + z^2)^{3/2}}. \tag{2.213}
\]

This integral is not overly pleasing, but may be readily worked out at least for points on the symmetry axis (\( \rho = 0 \)):

\[
\phi = Vz \int_0^R \frac{\rho' d\rho'}{(\rho^2 + z^2)^{3/2}} = V \int_0^R \frac{d\xi}{(\xi + 1)^{3/2}} = V \left[ 1 - \frac{z}{(R^2 + z^2)^{1/2}} \right]. \tag{2.214}
\]

This expression shows that if \( z \to 0 \), the potential tends to \( V \) (as it should), while at \( z \gg R \),

\[
\phi \to V \frac{R^2}{2z^2}. \tag{2.215}
\]

\(^{71}\) Indeed, if all parts of the cut plane are grounded, a narrow cut does not change the field distribution, and hence the Green’s function, significantly.
Now, let us use the same Eq. (210) to solve the (in :-:)famous problem of the cut sphere (Fig. 32). Again, if the gap between the two conducting semi-spheres is very thin ($t \ll R$), we may use the Green’s function for the grounded (and uncut) sphere. For a particular case $r' = d\mathbf{n}_z$, this function is given by Eqs. (197)-(198); generalizing the former relation for an arbitrary direction of vector $r'$, we get

$$G = \frac{1}{\left[ r^2 + r'^2 - 2rr' \cos \gamma \right]^{1/2}} - \frac{R/r'}{\left[ r^2 + (R^2/r')^2 - 2r(R^2/r') \cos \gamma \right]^{1/2}}, \quad \text{for } r, r' \geq R, \quad (2.216)$$

where $\gamma$ is the angle between the vectors $r$ and $r'$, and hence $r''$ – see Fig. 32.

![Fig. 2.32. A system of two separated, oppositely biased semi-spheres.](image)

Now, calculating the Green’s function’s derivative,

$$\left. \frac{\partial G}{\partial r'} \right|_{r=R+0} = -\frac{(r^2 - R^2)}{R\left[ r^2 + R^2 - 2Rr \cos \gamma \right]^{3/2}}, \quad (2.217)$$

and plugging it into Eq. (210), we see that the integration is again easy only for the field on the symmetry axis ($r = zn_z$, $\gamma = \theta$), giving:

$$\phi = \frac{V}{2} \left[ 1 - \frac{z^2 - R^2}{z(z^2 + R^2)^{1/2}} \right]. \quad (2.218)$$

For $z \to R$, this relation yields $\phi \to V/2$ (just checking :-), while for $z \gg R$,

$$\phi \to \frac{V}{4z^2}. \quad (2.219)$$

As will be discussed in the next chapter, such a field is typical for an electric dipole.

2.11. Numerical methods

Despite the richness of analytical methods, for many boundary problems (especially in geometries without a high degree of symmetry), numerical methods is the only way to the solution. Despite the current abundance of software codes and packages offering their automatic numerical
solution, it is important for every educated physicist to understand “what is under their hood”, at least because most universal programs exhibit mediocre performance in comparison with custom codes written for particular problems, and sometimes do not converge at all, especially for fast-changing (say, exponential) functions. The very brief discussion presented here is a (hopefully, useful) fast glance under the hood, though it is certainly insufficient for professional numerical research work.

The simplest of the numerical approaches to the solution of partial differential equations, such as the Poisson or the Laplace equations (1.41)-(1.42), is the finite-difference method, in which the sought continuous scalar function \( f(r) \), such as the potential \( \phi(r) \), is represented by its values in discrete points of a rectangular grid (frequently called mesh) of the corresponding dimensionality – see Fig. 33.

Each partial second derivative of the function is approximated by the formula that readily follows from the linear approximations of the function \( f \) and then its partial derivatives – see Fig. 33a:

\[
\frac{\partial^2 f}{\partial r_j^2} = \frac{\partial}{\partial r_j} \left( \frac{\partial f}{\partial r_j} \right) \approx \frac{1}{h} \left( \frac{\partial f}{\partial r_j} \right)_{r_j+h/2} - \frac{\partial f}{\partial r_j} \left( \frac{f_{r_j+h/2} - f_{r_j-h/2}}{h} \right) = \frac{f_{r_j+h} - 2f_r + f_{r_j-h}}{h^2},
\]

where \( f_{r_j} \equiv f(r_j + h) \) and \( f_{r_j}^\leftarrow \equiv f(r_j - h) \). (The relative error of this approximation is of the order of \( h^4 \partial^4 f/\partial r_j^4 \).) As a result, the action of a 2D Laplace operator on the function \( f \) may be approximated as

\[
\frac{\partial^2 f}{\partial x^2} + \frac{\partial^2 f}{\partial y^2} \approx \frac{f_{r_j+h} - 2f_r + f_{r_j-h}}{h^2} + \frac{f_{r_j+k} - 2f_r + f_{r_j-k}}{h^2} = \frac{f_{r_j+h} + f_{r_j-k} + f_{r_j+k} - 4f_r}{h^2},
\]

and of the 3D operator, as

\[
\frac{\partial^2 f}{\partial x^2} + \frac{\partial^2 f}{\partial y^2} + \frac{\partial^2 f}{\partial z^2} \approx \frac{f_{r_j+h} + f_{r_j-k} + f_{r_j+k} + f_{r_j+l} + f_{r_j-l} - 6f_r}{h^2}.
\]

(The notation used in Eqs. (221)-(222) should be clear from Figs. 33b and 33c, respectively.)

---

72 See, for example, MA Secs. 16 (iii) and (iv).
73 It is almost similar to that given in CM Sec. 8.5, and is reproduced here for the reader’s convenience, being illustrated with examples from this (EM) course.
As a simple example, let us apply this scheme to find the electrostatic potential distribution inside a cylindrical box with conducting walls and square cross-section $a \times a$, using an extremely coarse mesh with step $h = a/2$ (Fig. 34). In this case, our function, the electrostatic potential $\phi(x, y)$, equals zero at the side and bottom walls, and $V_0$ at the top lid, so that, according to Eq. (221), the 2D Laplace equation may be approximated as

$$\frac{0 + 0 + V_0 + 0 - 4\phi}{(a/2)^2} = 0.$$  \hspace{1cm} (2.223)

The resulting value for the potential in the center of the box is $\phi = V_0/4$.

![Fig. 2.34. Numerically solving an internal 2D boundary problem for a conducting, cylindrical box with a square cross-section, using a very coarse mesh (with $h = a/2$).](image)

Surprisingly, this is the exact value! This may be proved by solving this problem by the variable separation method, just as this has been done for a similar 3D problem in Sec. 5. The result is

$$\phi(x, y) = \sum_{n=1}^{\infty} c_n \sin \frac{\pi n x}{a} \sinh \frac{\pi n y}{a},$$

$$c_n = \frac{4V_0}{\pi n \sinh(\pi n)} \begin{cases} 1, & \text{if } n \text{ is odd}, \\ 0, & \text{otherwise}. \end{cases}$$  \hspace{1cm} (2.224)

so that at the central point $(x = y = a/2)$,

$$\phi = \frac{4V_0}{\pi} \sum_{j=0}^{\infty} \frac{\sin[\pi(2j+1)/2] \sinh[\pi(2j+1)/2]}{(2j+1) \sinh[\pi(2j+1)]} \equiv \frac{2V_0}{\pi} \sum_{j=0}^{\infty} (-1)^j \frac{1}{(2j+1) \cosh[\pi(2j+1)/2]}.$$  \hspace{1cm} (2.225)

The last series equals exactly to $\pi/8$, so that $\phi = V_0/4$.

For a similar 3D problem (a cubic box), with a similar 3D mesh, Eq. (222) yields

$$\frac{0 + 0 + V_0 + 0 + 0 + 0 - 6\phi}{(a/2)^2} = 0,$$  \hspace{1cm} (2.226)

so that $\phi = V_0/6$. Unbelievably enough, this result is also exact! (This follows from our variable separation result expressed by Eqs. (95) and (99) with $a = b = c$.)

Though such exact results should be considered as a happy coincidence rather than the general law, they still show that numerical methods, even with relatively crude meshes, may be more computationally efficient than the “analytical” approaches, like the variable separation method with its infinite-sum results that, in most cases, require computers anyway – at least for the result’s comprehension and analysis.

A more powerful (but also much more complex) approach is the finite-element method in which the discrete point mesh, typically with triangular cells, is (automatically) generated in accordance with
the system geometry. Such mesh generators provide higher point concentration near sharp convex parts of conductor surfaces, where the field concentrates and hence the potential changes faster, and thus ensure better accuracy-to-speed trade-off than the finite-difference methods on a uniform grid. The price to pay for this improvement is the algorithm’s complexity that makes manual adjustments much harder. Unfortunately, in this series I do not have time for going into the details of that method, and have to refer the reader to the special literature on this subject.

### 2.12. Exercise problems

2.1. Calculate the force (per unit area) exerted on a conducting surface by an external electric field, normal to it. Compare the result with the definition of the electric field, given by Eq. (1.6), and comment.

2.2. Certain electric charges $Q_A$ and $Q_B$ have been placed on two metallic, concentric spherical shells – see the figure on the right. What is the full charge of each of the surfaces $S_1$-$S_4$?

2.3. Calculate the mutual capacitance between the terminals of the lumped capacitor circuit shown in the figure on the right. Analyze and interpret the result for major particular cases.

2.4. Calculate the mutual capacitance between the terminals of the semi-infinite lumped-capacitor circuit shown in the figure on the right, and the law of decay of the applied voltage along the system.

2.5. A system of two thin conducting plates is located over a ground plane as shown in the figure on the right, where $A_1$ and $A_2$ are the areas of the indicated plate parts, while $d'$ and $d''$ are the distances between them. Neglecting the fringe effects, calculate:

(i) the effective capacitance of each plate, and
(ii) their mutual capacitance.

---

75 See, e.g., CM Fig. 8.14.
2.6. A wide, thin plane film, carrying a uniform electric charge density $\sigma$, is placed inside a plane capacitor whose plates are connected with a wire (see the figure on the right), and were initially electroneutral. Neglecting the edge effects, calculate the surface charges of the plates, and the net force acting on the film (per unit area).

2.7. Following up on the discussion of two weakly coupled spheres in Sec. 2, find an approximate expression for the mutual capacitance (per unit length) between two very thin, parallel wires, both with round cross-sections, but each with its own radius. Compare the result with that for two small spheres, and interpret the difference.

2.8. Use the Gauss law to calculate the mutual capacitance of the following two-electrode systems, with the cross-section shown in Fig. 7 (reproduced on the right):

(i) a conducting sphere inside a concentric spherical cavity in another conductor, and
(ii) a conducting cylinder inside a coaxial cavity in another conductor.
(In this case, we speak about the capacitance per unit length).

Compare the results with those obtained in Sec. 2.2 using the Laplace equation solution.

2.9. Calculate the electrostatic potential distribution around two barely separated conductors in the form of coaxial, round cones (see the figure on the right), with voltage $V$ between them. Compare the result with that of a similar 2D problem, with the cones replaced by plane-face wedges. Can you calculate the mutual capacitances between the conductors in these systems? If not, can you estimate them?

2.10. Calculate the mutual capacitance between two rectangular, plane electrodes of area $A = a \times l$, with a small angle $\varphi_0 \ll a/\rho_0$ between them – see the figure on the right.

2.11. Using the results for a single thin round disk, obtained in Sec. 4, consider a system of two such disks at a small distance $d \ll R$ from each other – see the figure on the right. In particular, calculate:

(i) the reciprocal capacitance matrix of the system,
(ii) the mutual capacitance between the disks,
(iii) the partial capacitance, and
(iv) the effective capacitance of one disk,
(all in the first nonzero approximation in $d/R \ll 1$). Compare the results (ii)-(iv) and interpret their similarities and differences.
2.12. Calculate the mutual capacitance (per unit length) between two cylindrical conductors forming a system with the cross-section shown in the figure on the right, in the limit \( t \ll w \ll R \).

Hint: You may like to use elliptical (not “ellipsoidal”!) coordinates \( \{\alpha, \beta\} \) defined by the following equality:

\[
x + iy = c \cosh(\alpha + i\beta),
\]

with the appropriate choice of the constant \( c \). In these orthogonal 2D coordinates, the Laplace operator is very simple: \(^77\)

\[
\nabla^2 \equiv \frac{1}{c^2 (\cosh^2 \alpha - \cos^2 \beta)} \left( \frac{\partial^2}{\partial \alpha^2} + \frac{\partial^2}{\partial \beta^2} \right).
\]

2.13. Formulate 2D electrostatic problems that can be solved using each of the following analytic functions of the complex variable \( z \equiv x + iy \):

(i) \( \omega = \ln z \),
(ii) \( \omega = z^{1/2} \),

and solve these problems.

2.14. On each side of a cylindrical volume with a rectangular cross-section \( a \times b \), with no electric charges inside it, the electric field is uniform, normal to the side’s plane, and opposite to that on the opposite side – see the figure on the right. Calculate the distribution of the electric potential inside the volume, provided that the field magnitude on the vertical sides equals \( E \). Suggest a practicable method to implement such potential distribution.

2.15. Complete the solution of the problem shown in Fig. 12, by calculating the distribution of the surface charge of the semi-planes. Can you calculate the mutual capacitance between the plates (per unit length)? If not, can you estimate it?

2.16. A straight, long, thin, round-cylindrical metallic pipe has been cut, along its axis, into two equal parts – see the figure on the right.

(i) Use the conformal mapping method to calculate the distributions of the electrostatic potential, created by voltage \( V \) applied between the two parts, both outside and inside the pipe, and of the surface charge.

(ii) Calculate the mutual capacitance between pipe’s halves (per unit length), taking into account a small width \( 2t \ll R \) of the cut.

Hints: In Task (i), you may like to use the following complex function:

\(^77\) This fact should not be surprising, because Eq. (*) is essentially the conformal map \( z = c \cosh \omega \), where \( z \equiv x + iy \), and \( \omega \equiv \alpha + i\beta \) – see the discussion in Sec. 4.
\[ w = \ln \left( \frac{R + z}{R - z} \right), \]

while in Task (ii), it is advisable to use the solution of the previous problem.

2.17. Solve Task (i) of the previous problem using the variable separation method, and compare the results.

2.18. Use the variable separation method to calculate the potential distribution above the plane surface of a conductor, with a strip of width \( w \) separated by very thin cuts, and biased with voltage \( V \) – see the figure below.

\[
\begin{array}{c}
\phi = 0 \\
-\frac{w}{2} \quad \frac{w}{2} \quad +\frac{w}{2} \\
\phi = V \\
\phi = 0
\end{array}
\]

2.19. The previous problem is now slightly modified: the cut-out and voltage-biased part of the conducting plane is now not a strip, but a square with side \( w \). Calculate the potential distribution above the conductor’s surface.

2.20. Each electrode of a large plane capacitor is cut into long strips of equal width \( w \), with very narrow gaps between them. These strips are kept at the alternating potentials, as shown in the figure on the right. Use the variable separation method to calculate the electrostatic potential distribution in space, and explore the limit \( w \ll d \).

2.21. Complete the cylinder problem started in Sec. 7 (see Fig. 17), for the cases when the top lid’s voltage is fixed as follows:

(i) \( V = V_0 J_1(\xi_1, \rho R) \sin \phi \), where \( \xi_1 \approx 3.832 \) is the first root of the Bessel function \( J_1(\xi) \);
(ii) \( V = V_0 = \text{const.} \)

For both cases, calculate the electric field at the centers of the lower and upper lids. (For Task (ii), an answer including series and/or integrals is acceptable.)

2.22. Solve the problem shown in Fig. 21. In particular:

(i) calculate and sketch the distribution of the electrostatic potential inside the system for various values of the ratio \( R/h \), and
(ii) simplify the results for the limit \( R/h \to 0 \).

2.23. Use the variable separation method to find the potential distribution inside and outside of a thin spherical shell of radius \( R \), with a fixed potential distribution: \( \phi(R, \theta, \phi) = V_0 \sin \theta \cos \phi \).
2.24. A thin spherical shell carries electric charge with areal density $\sigma = \sigma_0 \cos \theta$. Calculate the spatial distribution of the electrostatic potential and the electric field, both inside and outside the shell.

2.25. Use the variable separation method to calculate the potential distribution both inside and outside of a thin spherical shell of radius $R$, separated with a very thin cut, along the central plane $z = 0$, into two halves, with voltage $V$ applied between them – see the figure on the right. Analyze the solution; in particular, compare the field at the axis $z$, for $z > R$, with Eq. (218).

*Hint:* You may like to use the following integral of a Legendre polynomial with odd index $l = 1, 3, 5, \ldots = 2n - 1$: 78

$$I_n = \int_0^\pi P_{2n-1}(\xi)d\xi = \frac{1}{n!} \left( \frac{1}{2} \right) \left( -\frac{3}{2} \right) \left( -\frac{5}{2} \right) \left( \frac{3}{2} - n \right) = (-1)^{n-1} \frac{(2n-3)!!}{2n(2n-2)!!}.$$

2.26. Calculate, up to the terms $O(1/r^2)$, the long-range electric field induced by a cut and voltage-biased conducting sphere – similar to that discussed in Sec. 7 (see Fig. 32) and in the previous problem, but with the cut’s plane at an arbitrary distance $d < R$ from the center – see the figure on the right.

2.27. A small conductor (in this context, usually called the *single-electron island*) is placed between two conducting electrodes, with voltage $V$ applied between them. The gap between the island and one of the electrodes is so narrow that electrons may tunnel quantum-mechanically through this “junction” – see the figure on the right. Neglecting thermal excitations, calculate the equilibrium charge of the island as a function of $V$.

*Hint:* To solve this problem, you do not need to know much about the quantum-mechanical tunneling between conductors, besides that such tunneling of an electron, followed by energy relaxation of the resulting excitations, may be considered as a single inelastic (energy-dissipating) event. At negligible thermal excitations, such an event takes place only when it decreases the total potential energy of the system. 79

---

78 As a reminder, the *double factorial* (also called “semifactorial”) operator (!!) is similar to the usual factorial operator (!), but with the product limited to numbers of the same parity as its argument – in our particular case, of the odd numbers in the numerator, and even numbers in the denominator.

79 Strictly speaking, this model, implying negligible quantum-mechanical coherence of the tunneling events, is correct only if the junction transparency is sufficiently low, so that its effective electric resistance is much higher than the quantum unit of resistance (see, e.g., QM Sec. 3.2), $R_Q \equiv \pi \hbar/2e^2 \approx 6.5 \, \text{k}\Omega$ – which may be readily done in experiment.
2.28. The system discussed in the previous problem is now generalized as the figure on the right shown. If the voltage $V'$ applied between two bottom electrodes is sufficiently large, electrons can successively tunnel through two junctions of this system (called the single-electron transistor), carrying dc current between these electrodes. Neglecting thermal excitations, calculate the region of voltages $V$ and $V'$ where such a current is fully suppressed (Coulomb-blocked).

2.29. Use the image charge method to calculate the full surface charges induced in the plates of a very broad, voltage-unbiased plane capacitor of thickness $D$ by a point charge $q$ separated from one of the electrodes by distance $d$.

2.30. Prove the statement, made in Sec. 9, that the 2D boundary problem, shown in the figure on the right, can be solved using a finite number of image charges if the angle $\beta$ equals $\pi n$, where $n = 1, 2, \ldots$.

2.31. Use the image charge method to calculate the potential energy of the electrostatic interaction between a point charge placed in the center of a spherical cavity that was carved inside a grounded conductor, and the cavity’s walls. Looking at the result, could it be obtained in a simpler way (or ways)?

2.32. Use the method of images to find the Green’s function of the system shown in the figure on the right, where the bulge on the conducting plane has the shape of a semi-sphere of radius $R$.

2.33. Use the spherical inversion, expressed by Eq. (198), to develop an iterative method for a more and more precise calculation of the mutual capacitance between two similar metallic spheres of radius $R$, with centers separated by distance $d > 2R$.

2.34. A metallic sphere of radius $R_1$, carrying electric charge $Q$, is placed inside a spherical cavity of radius $R_2 > R_1$, cut inside another metal. Calculate the electric force exerted on the sphere if its center is displaced by a small distance $\delta \ll R_1, R_2 - R_1$ from that of the cavity – see the figure on the right.

2.35. Within the simple models of the electric field screening in conductors, discussed in Sec. 2.1, analyze the partial screening of the electric field of a point charge $q$ by a plane, uniform conducting
film of thickness \( t \ll \lambda \), where \( \lambda \) is (depending on charge carrier statistics) either the Debye or the Thomas-Fermi screening length – see, respectively, Eqs. (8) or (10). Assume that the distance \( d \) between the charge and the film is much larger than \( t \).

2.36. Suggest a convenient definition of the Green’s function for 2D electrostatic problems, and calculate it for:

(i) the unlimited free space, and
(ii) the free space above a conducting plane.

Use the latter result to re-solve Problem 18.

2.37. Calculate the 2D Green’s functions for the free spaces:

(i) outside a round conducting cylinder, and
(ii) inside a round cylindrical hole in a conductor.

2.38. Solve Task (i) of Problem 16 (see also Problem 17), using the Green’s function method.

2.39. Solve the 2D boundary problem that was discussed in Sec. 11 (Fig. 34) using:

(i) the finite difference method, with a finer square mesh, \( h = a/3 \), and
(ii) the variable separation method.

Compare the results at the mesh points, and comment.
Chapter 3. Dipoles and Dielectrics

In contrast to conductors, the motion of charges in dielectrics is limited to the interior of an atom or a molecule, so that the electric polarization of these materials by an external field takes a different form. This issue is the main subject of this chapter, but in preparation for its analysis, we have to start with a general discussion of the electric field induced by a spatially-restricted system of charges.

3.1. Electric dipole

Let us consider a localized system of charges, of a linear size scale \( a \), and derive a simple but approximate expression for the electrostatic field induced by the system at a distant point \( \mathbf{r} \). For that, let us select a reference frame with the origin either somewhere inside the system, or at a distance of the order of \( a \) from it (Fig. 1).

Then positions of all charges of the system satisfy the following condition:

\[
r' \ll r . \tag{3.1}
\]

Using this condition, we can expand the general expression (1.38) for the electrostatic potential \( \phi(\mathbf{r}) \) of the system into the Taylor series in small parameter \( r' \). For any spatial function of the type \( f(\mathbf{r} - \mathbf{r}') \), the expansion may be represented as

\[
f(\mathbf{r} - \mathbf{r}') = f(\mathbf{r}) - \sum_{j=1}^{3} r'_j \frac{\partial f}{\partial r_j}(\mathbf{r}) + \frac{1}{2!} \sum_{j,j'=1}^{3} r'_j r'_j' \frac{\partial^2 f}{\partial r_j \partial r_{j'}}(\mathbf{r}) - ... \tag{3.2}
\]

Applying this formula to the free-space Green’s function \( 1/|\mathbf{r} - \mathbf{r}'| \) in Eq. (1.38), we get the so-called multipole expansion of the electrostatic potential:

\[
\phi(\mathbf{r}) = \frac{1}{4\pi \varepsilon_0} \left( \frac{1}{r} Q + \frac{1}{r^3} \sum_{j=1}^{3} r_j p_j + \frac{1}{2r^5} \sum_{j,j'=1}^{3} r_j r_{j'} \mathcal{E}_{j'} + ... \right) , \tag{3.3}
\]

whose \( r \)-independent parameters are defined as follows:

\[
Q \equiv \int \rho(\mathbf{r'}) d^3 r' , \quad p_j \equiv \int \rho(\mathbf{r'}) r'_j d^3 r' , \quad \mathcal{E}_{j'} \equiv \int \rho(\mathbf{r'}) \left( 3 r'_j r'_{j'} - r'^2 \delta_{j'j} \right) d^3 r' . \tag{3.4}
\]

---

1 See, e.g., MA Eq. (2.11b).
Indeed, the two leading terms of the expansion (2) may be rewritten in the vector form \( f(r) - r' \cdot \nabla f(r) \), and the gradient of such a spherically-symmetric function \( f(r) = 1/r \) is just \( n, df/dr \), so that

\[
\frac{1}{|r - r'|} \approx \frac{1}{r} - r' \cdot n, \quad \frac{d}{dr} \left( \frac{1}{r} \right) = \frac{1}{r} + \frac{r'}{r^3},
\]

immediately giving the two first terms of Eq. (3). The proof of the third, quadrupole term in Eq. (3) is similar but a bit longer, and is left for the reader’s exercise.

Evidently, the scalar parameter \( Q \) in Eqs. (3)-(4) is just the total charge of the system. The constants \( p_j \) may be considered as Cartesian components of the following vector:

\[
p \equiv \int \rho(r')r'd^3r',
\]

called the system’s electric dipole moment, and \( Q_{ji} \) are the Cartesian components of a tensor – system’s electric quadrupole moment. If \( Q \neq 0 \), all higher terms on the right-hand side of Eq. (3), at large distances (1), are just small corrections to the first one, and in many cases may be ignored. However, the net charge of many systems is exactly zero, the most important examples being neutral atoms and molecules. For such neural systems, the second (dipole-moment) term, \( \phi_d \), in Eq. (3) is, most frequently, the leading one. (Such systems are called electric dipoles.) Due to its importance, let us rewrite the expression for this term in three other, equivalent forms:

\[
\phi_d \equiv \frac{1}{4\pi\varepsilon_0} \frac{r \cdot p}{r^3} \equiv \frac{1}{4\pi\varepsilon_0} \frac{p\cos\theta}{r^3} \equiv \frac{1}{4\pi\varepsilon_0} \left( \frac{pz}{x^2 + y^2 + z^2} \right)^{3/2},
\]

that are more convenient for some applications. Here \( \theta \) is the angle between the vectors \( p \) and \( r \), and in the last (Cartesian) representation, the \( z \)-axis is directed along the vector \( p \). Fig. 2a shows equipotential surfaces of the dipole field – or rather their cross-sections by any plane in which the vector \( p \) resides.

Fig. 3.2. (a) The equipotential surfaces and (b) the electric field lines of a dipole. (Panel (b) adapted from http://en.wikipedia.org/wiki/Dipole under the GNU Free Documentation License.)
The simplest example of a system whose field, at large distances, approaches the dipole field (7), is a system of two equal but opposite point charges ("poles"), \(+q\) and \(-q\), with the radius-vectors, respectively, \(\mathbf{r}_+\) and \(\mathbf{r}_-\):

\[
\rho(\mathbf{r}) = (+q)\delta(\mathbf{r} - \mathbf{r}_+) + (-q)\delta(\mathbf{r} - \mathbf{r}_-).
\]

(3.8)

For this system (sometimes called the physical dipole), Eq. (4) yields

\[
\mathbf{p} = (+q)\mathbf{r}_+ + (-q)\mathbf{r}_- = q(\mathbf{r}_+ - \mathbf{r}_-) = q\mathbf{a},
\]

(3.9)

where \(\mathbf{a}\) is the vector connecting the points \(\mathbf{r}_+\) and \(\mathbf{r}_-\). Note that in this case (and indeed for all systems with \(Q = 0\)), the dipole moment does not depend on the choice of the reference frame’s origin.

A less trivial example of a dipole is a conducting sphere of radius \(R\) in a uniform external electric field \(\mathbf{E}_0\). As a reminder, this problem was solved in Sec. 2.8, and its result is expressed by Eq. (2.176). The first term in the parentheses of that relation describes just the external field (2.173), so that the field of the sphere itself (i.e. that of the surface charge induced by \(\mathbf{E}_0\)) is given by the second term:

\[
\phi_s = \frac{\mathbf{E}_0 R^3}{r^2} \cos \theta.
\]

(3.10)

Comparing this expression with the second form of Eq. (7), we see that the sphere has an induced dipole moment

\[
\mathbf{p} = 4\pi\varepsilon_0 \mathbf{E}_0 R^3.
\]

(3.11)

This is an interesting example of a virtually pure dipole field: at all points outside the sphere \((r > R)\), the field has neither a quadrupole moment nor any higher moments.

Other examples of dipole fields are given by two more systems discussed in Chapter 2 – see Eqs. (2.215) and (2.219). Those systems, however, do have higher-order multipole moments, so that for them, Eq. (7) gives only the long-distance approximation.

Now returning to the general properties of the dipole field (7), let us calculate its characteristics. First of all, we may use Eq. (7) to calculate the electric field of a dipole:

\[
\mathbf{E}_d = -\nabla \phi_d = -\frac{1}{4\pi\varepsilon_0} \nabla \left( \frac{\mathbf{r} \cdot \mathbf{p}}{r^3} \right) = -\frac{1}{4\pi\varepsilon_0} \nabla \left( \frac{p \cos \theta}{r^2} \right).
\]

(3.12)

The differentiation is easiest in the spherical coordinates, using the well-known expression for the gradient of a scalar function in these coordinates\(^2\) and taking the \(z\)-axis parallel to the dipole moment \(\mathbf{p}\). From the last form of Eq. (12) we immediately get

\[
\mathbf{E}_d = \frac{p}{4\pi\varepsilon_0 r^3} \left( 2\mathbf{n} \cdot \mathbf{r} \cos \theta + \mathbf{n} \cdot \mathbf{p} \sin \theta \right) \equiv \frac{1}{4\pi\varepsilon_0} \frac{3\mathbf{r} \cdot \mathbf{p} - p \mathbf{r}^2}{r^5}.
\]

(3.13)

Fig. 2b above shows the electric field lines given by Eqs. (13). The most important features of this result is a faster drop of the field’s magnitude \((E_d \propto 1/r^3\), rather than \(E \propto 1/r^2\) for a point charge), and the change of the signs of all field components as functions of the polar angle \(\theta\).

\(^2\) See, e.g., MA Eq. (10.8) with \(\partial / \partial \varphi = 0\).
Next, let us use Eq. (1.55) to calculate the potential energy of interaction between a dipole and an external electric field. Assuming that the external field does not change much at distances of the order of \( a \) (Fig. 1), we may expand the external potential \( \phi_{\text{ext}}(r) \) into the Taylor series, and keep only its two leading terms:

\[
U = \int \rho(r) \phi_{\text{ext}}(r) d^3r \approx \int \rho(r) [\phi_{\text{ext}}(0) + r \cdot \nabla \phi_{\text{ext}}(0)] d^3r = Q \phi_{\text{ext}}(0) - p \cdot E_{\text{ext}}.
\] (3.14)

The first term is the potential energy the system would have if it were a point charge. If the net charge \( Q \) is zero, that term disappears, and the leading contribution is due to the dipole moment:

\[
U = -p \cdot E_{\text{ext}}, \quad \text{for } p = \text{const}.
\] (3.15a)

Note that this result is only valid for a fixed dipole, with \( p \) independent of \( E_{\text{ext}} \). In the opposite limit, when the dipole is induced by the field, i.e. \( p \propto E_{\text{ext}} \) (see again Eq. (11) as an example of such a proportionality), we need to start with Eq. (1.60) rather than Eq. (1.55), and get

\[
U = -\frac{1}{2} p \cdot E_{\text{ext}}, \quad \text{for } p \propto E_{\text{ext}}.
\] (3.15b)

In particular, combining Eqs. (13) and Eq. (15a), we may get the following important formula for the interaction of two independent dipoles:

\[
U_{\text{int}} = \frac{1}{4\pi\varepsilon_0} \frac{p_1 \cdot p_2 r^2 - 3(r \cdot p_1)(r \cdot p_2)}{r^5} = \frac{1}{4\pi\varepsilon_0} \frac{p_{1x}p_{2x} + p_{1y}p_{2y} + 2p_{1z}p_{2z}}{r^3},
\] (3.16)

where \( r \) is the vector connecting the dipoles, and the \( z \)-axis is directed along this vector. It is easy to prove (this exercise is left for the reader) that if the magnitude of each dipole moment is fixed (the approximation valid, in particular, for weak interaction of so-called polar molecules), this potential energy reaches its minimum at, and hence favors the parallel orientation of the dipoles along the line connecting them. Note also that in this case, \( U_{\text{int}} \) is proportional to \( 1/r^3 \). On the other hand, if each moment \( p \) has a random value plus a component due to its polarization by the electric field of its counterpart: \( \Delta p_{1,2} \propto E_{2,1} \propto 1/r^3 \), their average interaction energy (which may be calculated from Eq. (16) with the additional factor \( \frac{1}{2} \)) is always negative and is proportional to \( 1/r^6 \). Such negative potential describes, in particular, the long-range, attractive part (the so-called London dispersion force) of the interaction between electrically neutral atoms and molecules.\(^3\)

According to Eqs. (15), in order to reach the minimum of \( U \), the electric field “tries” to align the dipole direction along its own. The quantitative expression of this effect is the torque \( \tau \) exerted by the field. The simplest way to calculate it is to sum up all the elementary torques \( d\tau = r \times dF_{\text{ext}} = r \times E_{\text{ext}}(r) \rho(r) d^3r \) exerted on all elementary charges of the system:

\[
\tau = \int r \times E_{\text{ext}}(r) \rho(r) d^3r \approx p \times E_{\text{ext}}(0),
\] (3.17)

where to make the last step, the spatial dependence of the external field was again neglected. The spatial dependence of \( E_{\text{ext}} \) cannot, however, be ignored at the calculation of the total force exerted by the field on the dipole (with \( Q = 0 \)). Indeed, Eqs. (15) shows that if the field is constant, the dipole energy is the

\[^3\] This force is calculated, using several models, in the QM and SM parts of this series.
same at all spatial points, and hence the net force is zero. However, if the field has a non-zero gradient, a total force does appear; for a field-independent dipole,

\[
F = -\nabla U = \nabla (p \cdot E_{\text{ext}}),
\]

where the derivative has to be taken at the dipole’s position (in our notation, at \(r = 0\)). If the dipole that is being moved in a field retains its magnitude and orientation, then the last formula is equivalent to

\[
F = (p \cdot \nabla)E_{\text{ext}}. \tag{3.19}
\]

Alternatively, the last expression may be obtained similarly to Eq. (14):

\[
F = \int \rho(r)E_{\text{ext}}(r)d^3r \approx \int \rho(r)[E_{\text{ext}}(0) + (r \cdot \nabla)E_{\text{ext}}]d^3r = QE_{\text{ext}}(0) + (p \cdot \nabla)E_{\text{ext}}. \tag{3.20}
\]

Finally, let me add a note on the so-called coarse-grain model of the dipole. The dipole approximation explored above is asymptotically correct only at large distances, \(r \gg a\). However, for some applications (including the forthcoming discussion of the molecular field effects in Sec. 3) it is important to have an expression that would be approximately valid everywhere in space, though maybe without exact details at \(r \sim a\), and also give the correct result for the space average of the electric field,

\[
\overline{E} \equiv \frac{1}{V} \int_{V'} E d^3r, \tag{3.21}
\]

where \(V\) is a regularly-shaped volume much larger than \(a^3\), for example a sphere of a radius \(R \gg a\), with the dipole at its center. For the field \(E_d\) given by Eq. (13), such an average is zero. Indeed, let us consider the Cartesian components of that vector in a reference frame with the z-axis directed along the vector \(p\). Due to the axial symmetry of the field, the averages of the components \(E_x\) and \(E_y\) evidently vanish. Let us use Eq. (13) to spell out the “vertical” component of the field (parallel to the dipole moment vector):

\[
E_z \equiv \frac{p}{p} \cdot \frac{1}{4\pi \varepsilon_0 r^3} \left(2n_x \cdot p \cos \theta - n_\theta \cdot p \sin \theta\right) = \frac{p}{4\pi \varepsilon_0 r^3} \left(2\cos^2 \theta - \sin^2 \theta\right). \tag{3.22}
\]

Integrating this expression over the whole solid angle \(\Omega = 4\pi\), at fixed \(r\), using a convenient variable substitution \(\cos \theta \equiv \xi\), we get

\[
\int_{4\pi} E_z d\Omega = 2\pi \int_0^\pi E_z \sin \theta d\theta = \frac{p}{2\varepsilon_0 r^3} \int_0^\pi \left(2\cos^2 \theta - \sin^2 \theta\right) \sin \theta d\theta = \frac{p}{2\varepsilon_0 r^3} \int_{-1}^{+1} \left(3\xi^2 - 1\right) d\xi = 0. \tag{3.23}
\]

On the other hand, the exact electric field of an arbitrary charge distribution, with the total dipole moment \(p\), obeys the following equality:

\[
\int_{V'} \mathbf{E}(r)d^3r = \frac{p}{3\varepsilon_0} \equiv -\frac{1}{4\pi \varepsilon_0} \frac{4\pi}{3} p, \tag{3.24}
\]

where the integration is over any sphere containing all the charges. A proof of this formula for the general case requires a straightforward, but somewhat tedious integration.\(^5\) The origin of Eq. (24) is

\(^4\) The equivalence may be proved, for example, by using MA Eq. (11.6) with \(f = p = \text{const}\) and \(g = E_{\text{ext}}\), taking into account that according to the general Eq. (1.28), \(\nabla \times E_{\text{ext}} = 0\).
illustrated in Fig. 3 on the example of the dipole created by two equal but opposite charges – see Eqs. (8)-(9). The zero average (23) of the dipole field (13) does not take into account the contribution of the region between the charges (where Eq. (13) is not valid), which is directed mostly against the dipole vector (9).

\[ \mathbf{E}_{\text{avg}} = \frac{1}{4\pi\varepsilon_0} \left[ \frac{3\mathbf{r} \cdot \mathbf{p} - \mathbf{p} r^2}{r^5} - \frac{4\pi}{3} \mathbf{p} \delta(r) \right], \quad (3.25) \]

so that its average satisfies Eq. (24). Evidently, such a modification does not change the field at large distances \( r >> a \), i.e. in the region where the expansion (3), and hence Eq. (13), are valid.

### 3.2. Dipole media

Let us generalize Eq. (7) to the case of several (possibly, many) dipoles \( \mathbf{p}_j \) located at arbitrary points \( \mathbf{r}_j \). Using the linear superposition principle, we get

\[ \phi_d(\mathbf{r}) = \frac{1}{4\pi\varepsilon_0} \sum_j \mathbf{p}_j \cdot \frac{\mathbf{r} - \mathbf{r}_j}{|\mathbf{r} - \mathbf{r}_j|^3}. \quad (3.26) \]

If our system (medium) contains many similar dipoles, distributed in space with density \( n(\mathbf{r}) \), we may approximate the last sum with a macroscopic potential, which is the average of the “microscopic” potential (26) over a local volume much larger than the distance between the dipoles, and as a result is given by the integral

\[ \phi_d(\mathbf{r}) = \frac{1}{4\pi\varepsilon_0} \int \mathbf{P}(\mathbf{r}') \cdot \frac{\mathbf{r} - \mathbf{r}'}{|\mathbf{r} - \mathbf{r}'|^3} d^3 r', \quad \text{with } \mathbf{P}(\mathbf{r}) \equiv n(\mathbf{r}) \mathbf{p}, \quad (3.27) \]

where vector \( \mathbf{P}(\mathbf{r}) \), called the electric polarization, has the physical meaning of the net dipole moment per unit volume. (Note that by its definition, \( \mathbf{P}(\mathbf{r}) \) is also a “macroscopic” field.)

Now comes a very impressive trick, which is the basis of all the theory of “macroscopic” electrostatics (and eventually, electrodynamics). Just as was done at the derivation of Eq. (5), Eq. (27) may be rewritten in the equivalent form

---

where $\nabla'$ means the del operator (in this particular case, the gradient) acting in the “source space” of vectors $r'$. The right-hand side of Eq. (28), applied to any volume $V$ limited by surface $S$, may be integrated by parts to give \(^6\)

$$
\phi_d(r) = \frac{1}{4\pi\varepsilon_0} \int_{S} \mathbf{P}(r') \cdot \nabla' \frac{1}{|r - r'|} d^3 r',
$$

(3.28)

If the surface does not carry an infinitely dense ($\delta$-functional) sheet of additional dipoles, or it is just very distant, the first term on the right-hand side is negligible.\(^7\) Now comparing the second term with the basic equation (1.38) for the electric potential, we see that this term may be interpreted as the field of certain effective electric charges with density

$$
\rho_{\text{ef}} = -\nabla \cdot \mathbf{P}.
$$

(3.30)

Figure 4 illustrates the physics of this key relation for a cartoon model of a simple multi-dipole system: a layer of uniformly-distributed two-point-charge units oriented perpendicular to the layer surface. (In this case $\nabla \cdot \mathbf{P} = dP/dx$.) One can see that the $\rho_{\text{ef}}$ defined by Eq. (30) may be interpreted as the density of the uncompensated surface charges of polarized elementary dipoles.

Next, from Sec. 1.2, we already know that Eq. (1.38) is equivalent to the inhomogeneous Maxwell equation (1.27) for the electric field, so that the macroscopic electric field of the dipoles (defined as $\mathbf{E}_d = -\nabla \phi_d$, where $\phi_d$ is given by Eq. (27)) obeys a similar equation, with the effective charge density (30).

Now let us consider a more general case when a system, besides the compensated charges of the dipoles, also has certain stand-alone charges (not parts of the dipoles already taken into account in the

---

\(^6\) To prove this (almost evident) formula strictly, it is sufficient to apply the divergence theorem given by MA Eq. (12.2), to the vector function $\mathbf{f} = \mathbf{P}(r')/|r - r'|$, in the “source space” of radius-vectors $r'$.

\(^7\) Just like in the case of Eq. (1.9), if we want to describe such a dipole sheet using only the second term in Eq. (29), we may always do that by including a delta-functional part into the polarization distribution $\mathbf{P}(r')$. 
polarization \( \mathbf{P} \).\(^8\) As was discussed in Sec. 1.1, if we average this charge over the inter-point-charge distances, i.e. approximate it with a continuous “macroscopic” density \( \rho(r) \), then its macroscopic electric field also obeys Eq. (1.27), but with the stand-alone charge density. Due to the linear superposition principle, for the \textit{total macroscopic field} \( \mathbf{E} \) of these charges and dipoles we may write

\[
\nabla \cdot \mathbf{E} = \frac{1}{\varepsilon_0} \left( \rho + \rho_{\text{ef}} \right) = \frac{1}{\varepsilon_0} \left( \rho - \nabla \cdot \mathbf{P} \right).
\tag{3.31}
\]

This is already the main result of the “macroscopic” electrostatics. However, it is evidently tempting (and very convenient for applications) to rewrite Eq. (31) in a different form by carrying the dipole-related term of this equality over to its left-hand side. The resulting formula is called the \textit{macroscopic Maxwell equation for} \( \mathbf{D} \):

\[
\nabla \cdot \mathbf{D} = \rho,
\tag{3.32}
\]

where \( \mathbf{D}(r) \) is a new “macroscopic” field, called the \textit{electric displacement}, defined as\(^9\)

\[
\mathbf{D} \equiv \varepsilon_0 \mathbf{E} + \mathbf{P}.
\tag{3.33}
\]

The comparison of Eqs. (32) and (1.27) shows that \( \mathbf{D} \) (or more strictly, the fraction \( \mathbf{D}/\varepsilon_0 \)) may be interpreted as the “would-be” macroscopic electric field that \textit{would be} created by stand-alone charges in the absence of the dipole medium polarization. In contrast, the \( \mathbf{E} \) participating in Eqs. (31) and (33) is the genuine macroscopic electric field, exact at distances much larger than that between the adjacent elementary stand-alone charges and dipoles.

In order to have a better look into the physics of the fields \( \mathbf{E} \) and \( \mathbf{D} \), let us first rewrite the macroscopic Maxwell equation (32) in the integral form. Applying the divergence theorem to an arbitrary volume \( V \) limited by surface \( S \), we get the following \textit{macroscopic Gauss law}:

\[
\int_S \mathbf{D} \cdot d^2 r = \int_V \rho \, d^3 r \equiv Q,
\tag{3.34}
\]

where \( Q \) is the total \textit{stand-alone} charge inside volume \( V \).

This general result may be used to find the boundary conditions for \( \mathbf{D} \) at a sharp interface between two different dielectrics. (The analysis is applicable to a dielectric/free-space boundary as well.) For that, let us apply Eq. (34) to a pillbox formed at the interface (see the solid rectangle in Fig. 5), which is sufficiently small on the spatial scales of the dielectrics’ non-uniformity and the interface’s curvature, but still containing many elementary dipoles. Assuming that the interface does not have stand-alone surface charges, we immediately get

\[
(D_n)_1 = (D_n)_2,
\tag{3.35}
\]

\(^8\) In some texts, these charges are called “free”. This term is somewhat misleading, because they may well be bound, i.e. unable to move freely.

\(^9\) Note that according to its definition (33), the dimensionality of \( \mathbf{D} \) in the SI units is different from that of \( \mathbf{E} \). In contrast, in the Gaussian units the electric displacement is defined as \( \mathbf{D} = \mathbf{E} + 4\pi \mathbf{P} \), so that \( \nabla \cdot \mathbf{D} = 4\pi \rho \) (the relation \( \rho_{\text{ef}} = -\nabla \cdot \mathbf{P} \) remains the same as in SI units), and the dimensionalities of \( \mathbf{D} \) and \( \mathbf{E} \) coincide. Philosophically, this coincidence is a certain perceptual handicap, because it is frequently convenient to consider the scalar components of \( \mathbf{E} \) as generalized forces, and those of \( \mathbf{D} \) as generalized coordinates (see Sec. 5 below), and it is somewhat comforting to have their dimensionalities different.
i.e. the normal component of the electric displacement has to be continuous. Note that a similar statement for the macroscopic electric field $\mathbf{E}$ is generally not valid, because the polarization vector $\mathbf{P}$ may have, and typically does have a leap at a sharp interface (say, due to the different polarizability of the two different dielectrics), providing a surface layer of the effective charges (30) – see again the example in Fig. 4.

However, we still can make an important statement about the behavior of $\mathbf{E}$ at the interface. Indeed, the macroscopic field electric fields, defined by Eqs. (29) and (31), are evidently still potential ones, and hence obey the macroscopic Maxwell equation, similar to Eq. (1.28):

$$\nabla \times \mathbf{E} = 0. \tag{3.36}$$

Integrating this equality along a narrow contour stretched along the interface (see the dashed rectangle in Fig. 5), we get

$$\left[ \mathbf{E}_t \right]_1 = \left[ \mathbf{E}_t \right]_2. \tag{3.37}$$

Note that this condition is compatible with (and may be derived from) the continuity of the macroscopic electrostatic potential $\phi$ (related to the macroscopic field $\mathbf{E}$ by the relation similar to Eq. (1.33), $\mathbf{E} = -\nabla \phi$), at each point of the interface: $\phi_1 = \phi_2$.

In order to see how do these boundary conditions work, let us consider the simple problem shown in Fig. 6. A very broad plane capacitor, with zero voltage between its conducting plates (as may be fixed, e.g., by their connection with an external wire), is partly filled with a material with a uniform polarization $\mathbf{P}_0$, oriented normal to the plates. Let us calculate the spatial distribution of the fields $\mathbf{E}$ and $\mathbf{D}$, and also the surface charge density of each conducting plate.

Due to the symmetry of the system, vectors $\mathbf{E}$ and $\mathbf{D}$ are all evidently normal to the plates, and do not depend on the position in the capacitor’s plane, so that we can limit the field analysis to the...
calculation of their \( z \)-components \( E(z) \) and \( D(z) \). In this case, Eq. (32) is reduced to \( dD/dz = 0 \) inside each layer (but not at their border!), so that within each of them, \( D \) is constant – say, \( D_1 \) in the layer with \( P = P_0 \), and \( D_2 \) in the free-space layer, where \( P = 0 \). As a result, according to Eq. (33), the (macroscopic) electric field inside each layer in also constant:

\[
D_1 = \varepsilon_0 E_1 + P_0, \quad D_2 = \varepsilon_0 E_2.
\]  

(3.38)

Since the voltage between the plates is zero, we may also require the integral of \( E \), taken along a path connecting the plates, to vanish. This gives us one more relation:

\[
E_1 d_1 + E_2 d_2 = 0.
\]  

(3.39)

Still, three equations (38)-(39) are insufficient to calculate the four fields in the system \( (E_{1,2} \) and \( D_{1,2} \)). The decisive help comes from the boundary condition (35):

\[
D_1 = D_2.
\]  

(3.40)

(Note that Eq. (35) is valid because the layer interface does not carry stand-alone electric charges, even though it has a polarization surface charge, whose areal density may be calculated by integrating Eq. (30) across the interface: \( \sigma_{ef} = P_0 \). Note also that in our simple system, Eq. (37) is identically satisfied due to the system’s symmetry, and does not give any additional information.)

Now solving the resulting system of four equations, we readily get

\[
E_1 = -\frac{P_0}{\varepsilon_0} \frac{d_2}{d_1 + d_2}, \quad E_2 = \frac{P_0}{\varepsilon_0} \frac{d_1}{d_1 + d_2}, \quad D_1 = D_2 = D = \frac{P_0}{d_1 + d_2} \frac{d_1}{d_1 + d_2}.
\]  

(3.41)

The areal densities of the electrode surface charges may now be readily calculated by the integration of Eq. (32) across each surface:

\[
\sigma_1 = -\sigma_2 = D = \frac{P_0}{d_1 + d_2} \frac{d_1}{d_1 + d_2}.
\]  

(3.42)

Note that due to the spontaneous polarization of the lower layer’s material, the capacitor plates are charged even in the absence of voltage between them, and that this charge is a function of the second electrode’s position \( (d_2) \).\(^{11}\) Also notice substantial similarity between this system (Fig. 6), and the one whose analysis was the subject of Problem 2.6.

### 3.3. Polarization of dielectrics

The general relations derived in the previous section may be used to describe the electrostatics of any dielectrics – materials with bound electric charges (and hence with negligible dc electric conduction). However, in order to form a full system of equations necessary to solve electrostatics problems, they have to be complemented by certain relations between the vectors \( P \) and \( E \).\(^{12}\)

---

\(^{11}\) This effect is used in most modern microphones. In such a device, the sensed sound wave’s pressure bends a thin conducting membrane playing the role of one of capacitor’s plates, and thus modulates the thickness (in Fig. 6, \( d_2 \)) of the air gap adjacent to the electret layer. This modulation produces proportional variations of the charges (42), and hence electric current in the wire connecting the plates, which is picked up by readout electronics.

\(^{12}\) This is one more example of constitutive relations (already mentioned in Sec. 2.1). In the problem solved at the end of the previous section, the role of such relation was played by the equality \( P_0 = \text{const} \).
In the most materials, in the absence of external electric field, the elementary dipoles \( \mathbf{p} \) either equal zero or have a random orientation in space, so that the net dipole moment of each macroscopic volume (still containing many such dipoles) equals zero: \( \mathbf{P} = 0 \) at \( \mathbf{E} = 0 \). Moreover, if the field changes are sufficiently slow, most materials may be characterized by a unique dependence of \( \mathbf{P} \) on \( \mathbf{E} \). Then using the Taylor expansion of function \( \mathbf{P}(\mathbf{E}) \), we may argue that in relatively low electric fields the function should be well approximated by a linear dependence between these two vectors. Such dielectrics are called *linear*. In an isotropic media, the coefficient of proportionality should be just a scalar. In the SI units, this scalar is defined by the following relation:

\[
\mathbf{P} = \chi_e \varepsilon_0 \mathbf{E},
\]

(3.43)

with the dimensionless constant \( \chi_e \) called the *electric susceptibility*. However, it is much more common to use, instead of \( \chi_e \), another dimensionless parameter,\(^{13}\)

\[
\kappa \equiv 1 + \chi_e,
\]

(3.44)

which is sometimes called the “relative electric permittivity”, but much more often, the *dielectric constant*. This parameter is very convenient, because combining Eqs. (43) and (44),

\[
\mathbf{P} = (\kappa - 1) \varepsilon_0 \mathbf{E}.
\]

(3.45)

and then plugging the resulting relation into the general Eq. (33), we get simply

\[
\mathbf{D} = \kappa \varepsilon_0 \mathbf{E}, \quad \text{or} \quad \mathbf{D} = \varepsilon \mathbf{E},
\]

(3.46)

where another popular parameter,\(^{14}\)

\[
\varepsilon \equiv \kappa \varepsilon_0 \equiv (1 + \chi_e) \varepsilon_0.
\]

(3.47)

\( \varepsilon \) is called the *electric permittivity* of the material.\(^{15}\) Table 1 gives the approximate values of the dielectric constant for several representative materials.

In order to understand the range of these values, let me discuss (rather superficially) two simplest mechanisms of the electric polarization. The first of them is typical for liquids and gases of *polar* atoms/molecules, which have their own, spontaneous dipole moments \( \mathbf{p} \).\(^{16}\) In the absence of an external electric field, the orientation of such dipoles may be random, with the average polarization \( \mathbf{P} = n(\mathbf{p}) \) equal to zero – see the top panel of Fig. 7a.

\(^{13}\) In older physics literature, the dielectric constant is often denoted by letter \( \varepsilon_r \), while in the electrical engineering literature, its notation is frequently \( K \).

\(^{14}\) The reader may be perplexed by the use of 3 different but uniquely related parameters (\( \chi_e, \kappa \equiv 1 + \chi_e, \) and \( \varepsilon \equiv \kappa \varepsilon_0 \)) for the description of just one scalar property. Unfortunately, such redundancy is typical for physics, whose different sub-field communities have different, well-entrenched traditions.

\(^{15}\) In the Gaussian units, \( \chi_e \) is defined by the following relation: \( \mathbf{P} = \chi_e \mathbf{E} \), while \( \varepsilon \) is defined just as in the SI units, \( \mathbf{D} = \varepsilon \mathbf{E} \). Because of that, in the Gaussian units, the constant \( \varepsilon \) is dimensionless and equals \((1 + 4 \pi \chi_e)\). As a result, \( \varepsilon_{\text{Gaussian}} = (\varepsilon \varepsilon_0)|_{\text{SI}} \equiv \kappa \), so that \( \chi_e \varepsilon_{\text{Gaussian}} = (\chi_e \varepsilon_0)|_{\text{SI}}/4 \pi \), sometimes creating confusion with the numerical values of the latter parameter – dimensionless in both systems.

\(^{16}\) A typical example is the water molecule \( \text{H}_2\text{O} \), with the negative oxygen ion offset from the line connecting two positive hydrogen ions, thus producing a spontaneous dipole moment \( p = ea \), with \( a \approx 0.38 \times 10^{-10} \text{m} \sim r\text{H} \).

\(^{(a)}\) Anisotropic materials, such as silicon crystals, require a susceptibility tensor to give an exact description of the linear relation of the vectors \(\mathbf{P}\) and \(\mathbf{E}\). However, most important crystals (including Si) are only weakly anisotropic, so that they may be reasonably well characterized with a scalar (angle-average) susceptibility.

Fig. 3.7. Crude cartoons of two mechanisms of the induced electrical polarization: (a) a partial ordering of spontaneous elementary dipoles, and (b) an elementary dipole induction. The upper two panels correspond to \(\mathbf{E} = 0\), and the lower two panels, to \(\mathbf{E} \neq 0\).

A relatively weak external field does not change the magnitude of the dipole moments significantly, but according to Eqs. (15a) and (17), tries to orient them along the field, and thus creates a non-zero vector average \(\langle \mathbf{p} \rangle\) directed along the vector \(\langle \mathbf{E}_m \rangle\), where \(\mathbf{E}_m\) is the microscopic field at the point of the dipole’s location – cf. two panels of Fig. 7a. If the field is not too high \(p\langle \mathbf{E}_m \rangle \ll k_B T\), the induced average polarization \(\langle \mathbf{p} \rangle\) is proportional to \(\langle \mathbf{E}_m \rangle\). If we write this proportionality relation in the following traditional form,

\[
\langle \mathbf{p} \rangle = \alpha \mathbf{E}_m ,
\]

where \(\alpha\) is called the atomic (or, sometimes, “molecular”) polarizability, this means that \(\alpha\) is positive. If the concentration \(n\) of such elementary dipoles is low, the contribution of their own fields into the
microscopic field acting on each dipole is negligible, and we may identify \( \langle E_m \rangle \) with the macroscopic field \( E \). As a result, the second of Eqs. (27) yields

\[
P = n \langle p \rangle = \alpha n E.
\]  

(3.49)

Comparing this relation with Eq. (45), we get

\[
\kappa = 1 + \frac{\alpha}{\varepsilon_0} n,
\]

(3.50)

so that \( \kappa > 1 \) (i.e. \( \chi_e > 0 \)). Note that at this particular polarization mechanism (illustrated on the lower panel of Fig. 7a), the thermal motion “tries” to randomize the dipole orientation, i.e. reduce its ordering by the field, so that we may expect \( \alpha \), and hence \( \chi_e \equiv \kappa - 1 \) to increase as temperature \( T \) is decreased – the so-called paraelectricity. Indeed, the basic statistical mechanics\(^{17} \) shows that in this case, the electric susceptibility follows the law \( \chi_e \propto 1/T \).

The materials of the second, much more common class consist of non-polar atoms without intrinsic spontaneous polarization. A crude classical image of such an atom is an isotropic cloud of negatively charged electrons surrounding a positively charged nucleus – see the top panel of Fig. 7b. The external electric field shifts the positive charge in the direction of the vector \( E \), and the negative charges in the opposite direction, thus creating a similarly directed average dipole moment \( \langle p \rangle \).\(^{18} \) At relatively low fields, this average moment is proportional to \( E \), so that we again arrive at Eq. (48), with \( \alpha > 0 \), and if the dipole concentration \( n \) is sufficiently low, also at Eq. (50), with \( \kappa - 1 > 0 \). So, the dielectric constant is larger than 1 for both polarization mechanisms – please have one more look at Table 1.

In order to make a crude but physically transparent estimate of the difference \( \kappa - 1 \), let us consider the following toy model of a non-polar dielectric: a set of similar conducting spheres of radius \( R \), distributed in space with a low density \( n << 1/R^3 \). At such density, the electrostatic interaction of the spheres is negligible, and we can use Eq. (11) for the induced dipole moment of a single sphere. Then the polarizability definition (48) yields \( \alpha = 4\pi\varepsilon_0 R^3 \), so that Eq. (50) gives

\[
\kappa = 1 + 4\pi R^3 n.
\]

(3.51)

Let us use this result for a crude estimate of the dielectric constant of air at the so-called ambient conditions, meaning the normal atmospheric pressure \( P=1.013\times10^5 \) Pa and temperature \( T = 300 \) K. At these conditions the molecular density \( n \) may be, with a few-percent accuracy, found from the equation of state of an ideal gas:\(^{19} \) \( n \approx \frac{P}{k_B T} \approx (1.013\times10^5)/(1.38\times10^{-23}\times300) \approx 2.45\times10^{25} \) m\(^{-3} \). The molecule of the air’s main component, N\(_2\), has a van-der-Waals radius\(^{20} \) of 1.55\times10\(^{-10} \) m. Taking this radius for the \( R \) of our crude model, we get \( \chi_e \equiv \kappa - 1 \approx 1.15\times10^{-3} \). Comparing this number with the first line of Table 1,

\(^{17} \) See, e.g., SM Chapter 2.
\(^{18} \) Realistically, these effects are governed by quantum mechanics, so that the average here should be understood not only in the statistical-mechanical, but also (and mostly) in the quantum-mechanical sense. Because of that, for non-polar atoms, \( \alpha \) is typically a very weak function of temperature, at least on the usual scale \( T \sim 300\)K.
\(^{19} \) See, e.g., SM Secs. 1.4 and 3.1.
\(^{20} \) Such radius is defined by the requirement that the volume of the corresponding sphere, if used in the van-der-Waals equation (see, e.g., SM Sec. 4.1), gives the best fit to the experimental equation of state \( n = n (P,T) \).
we see that the model gives a surprisingly reasonable result: in order to get the experimental value, it is sufficient to decrease the effective $R$ of the sphere by just $\sim 30\%$, to $\sim 1.2 \times 10^{-10}$ m.\footnote{As will be discussed in QM Chapter 6, for a hydrogen atom in its ground state, the low-field polarizability may be calculated analytically: $\alpha = (9/2) \times 4 \pi e_r r_B^3$, corresponding to our metallic-ball model with a close value of the effective radius: $R = (9/2)^{1/3} r_B \approx 1.65 r_B \approx 0.87 \times 10^{-10}$ m.}

This result may encourage us to try using Eq. (51) for a larger density $n$. For example, as a crude model for a non-polar crystal, let us assume that the conducting spheres form a simple cubic lattice with the period $a = 2R$ (i.e., the neighboring spheres virtually touch). With this $n = 1/a^3 = 1/8R^3$, and Eq. (44) yields $\kappa = 1 + 4\pi/8 \approx 2.5$. This estimate provides a reasonable semi-qualitative explanation for the values of $\kappa$ listed in a few middle rows of Table 1. However, at such small distances, the electrostatic dipole-dipole interaction should be already essential, so that such simple model cannot even approximately describe the values of $\kappa$ much larger than 1, listed in the last rows of the table.

Such high values may be explained by the molecular field effect: each elementary dipole is polarized not only by the external field (as Eq. (49) assumes), but by the field of neighboring dipoles as well. Ottavino-Fabrizio Mossotti in 1850 and (perhaps, independently, but almost 30 years later) Rudolf Clausius suggested what is now known, rather unfairly, as the Clausius-Mossotti formula, which describes this effect well in a broad class of non-polar materials.\footnote{Applied to the high-frequency electric field, with $\kappa$ replaced by the square of the refraction coefficient $n$ at the field’s frequency (see Chapter 7), this formula is known as the Lorenz-Lorentz relation.} In our notation, it reads\footnote{I am leaving the proof of Eq. (52), using a formula that will be derived in the next section, for the reader’s exercise.}

$$\frac{\kappa - 1}{\kappa + 2} = \frac{an}{3\varepsilon_0}, \quad \text{so that} \quad \kappa = \frac{1 + 2an/3\varepsilon_0}{1 - an/3\varepsilon_0}. \quad (3.52)$$

If the dipole density is low in the sense $an \ll \varepsilon_0$, this relation is reduced to Eq. (50) corresponding to independent dipoles. However, at higher dipole density, both $\kappa$ and $\chi_e$ increase much faster, and tend to infinity as the density-polarizability product approaches a critical value $n_0$ in the simple Clausius-Mossotti model equal to $3\varepsilon_0/\alpha$.\footnote{The Clausius-Mossotti model does not give quantitatively correct results for most ferroelectric materials. For a review of modern approaches to the theory of their polarization, see, e.g., the paper by R. Resta and D. Vanderbilt in the recent review collection by K. Rabe, C. Ahn, and J.-M. Triscone (eds.), Physics of Ferroelectrics: A Modern Perspective, Springer, 2010.} This means that the zero-polarization state becomes unstable even in the absence of an external electric field.

This instability is a linear-theory (i.e. low-field) manifestation of a substantially nonlinear effect – the formation of spontaneous polarization even in the absence of external electric field. Such materials are called ferroelectrics, and may be experimentally recognized by the hysteretic behavior of their polarization as a function of the applied (external) electric field – see Fig. 8. As the plots show, the polarization of a ferroelectric depends on the applied field’s history. For example, the direction of its spontaneous remnant polarization $P_R$ may be switched by applying, and then removing a sufficiently high field (larger than the so-called coercive field $E_C$ – see Fig. 8) of the opposite orientation. The physics of this switching is rather involved; the polarization vector $P$ of a ferroelectric material is typically constant only within each of spontaneously formed spatial regions (called domains), with a typical size of a few tenths of a micron, and different (frequently, opposite) directions of the vector $P$ in
adjacent domains. The change of the applied electric field results not in the switching of the direction of $\mathbf{P}$ inside each domain, but rather in a shift of the domain walls, resulting in the change of the average polarization of the sample.

Depending on the ferroelectric’s material, temperature, and the sample’s geometry (a solid crystal, a ceramic material, or a thin film), the hysteretic loops may be rather different, ranging from a rather smooth form in the so-called soft ferroelectrics (which include most ferroelectric thin films) to an almost rectangular form in hard ferroelectrics – see Fig. 8. In low fields, soft ferroelectrics behave essentially as linear paraelectrics, but with a very high average dielectric constant – see the bottom line of Table 1 for such a classical material as BaTiO$_3$ (which is a soft ferroelectric at temperatures below $T_c \approx 120^\circ$C, and a paraelectric above this critical temperature). On the other hand, the polarization of a hard ferroelectric in the fields below its coercive field remains virtually constant, and the analysis of their electrostatics may be based on the condition $\mathbf{P} = \mathbf{P}_R = \text{const}$ – already used in the problem discussed in the end of the previous section.\(^{25}\) This condition is even more applicable to the so-called electrets – synthetic polymers with a spontaneous polarization that remains constant even in very high electric fields.

Some materials exhibit even more complex polarization effects, for example antiferroelectricity, helielectricity, and (practically very valuable) piezoelectricity. Unfortunately, we do not have time for a discussion of these exotic phenomena in this course;\(^{26}\) the main reason I am mentioning them is to emphasize again that the constitutive relation $\mathbf{P} = \mathbf{P}(\mathbf{E})$ is material-specific rather than fundamental.

---

\(^{25}\) Due to this property, hard ferroelectrics, such as the lead zirconate titanate (PZT) and strontium bismuth tantalite (SBT), with high remnant polarization $P_R$ (up to $\sim$1 C/m$^2$), may be used in nonvolatile random-access memories (dubbed either FRAM or FeRAM) – see, e.g., J. Scott, *Ferroelectric Memories*, Springer, 2000. In a cell of such a memory, binary information is stored in the form of one of two possible directions of spontaneous polarization at $\mathbf{E} = 0$ (see Fig. 8). Unfortunately, the time of spontaneous depolarization of ferroelectric thin films is typically well below 10 years – the industrial standard for data retention in nonvolatile memories, and this time may be decreased even more by “fatigue” from the repeated polarization recycling at information recording. Due to these reasons, the industrial production of FRAM is currently just a tiny fraction of the nonvolatile memory market, which is dominated by floating-gate memories – see, e.g., Sec. 4.2 below.

However, most insulators, in practicable fields, behave as linear dielectrics, so that the next section will be committed to the discussion of their electrostatics.

### 3.4. Electrostatics of linear dielectrics

First, let us discuss the simplest problem: how is the electrostatic field of a set of stand-alone charges of density $\rho(r)$ modified by a *uniform* linear dielectric medium, which obeys Eq. (46) with a space-independent dielectric constant $\kappa$. In this case, we may combine Eqs. (32) and (46) to write

$$\mathbf{\nabla} \cdot \mathbf{E} = \frac{\rho}{\varepsilon}. \quad (3.53)$$

As a reminder, in the free space we had a similar equation (1.27), but with a different constant, $\varepsilon_0 = \varepsilon / \kappa$. Hence all the results discussed in Chapter 1 are valid inside a uniform linear dielectric, for the macroscopic field the $\mathbf{E}$ (and the corresponding macroscopic electrostatic potential $\phi$), if they are reduced by the factor of $\kappa > 1$. Thus, the most straightforward result of the induced polarization of a dielectric medium is the electric field reduction. This is a very important effect, especially taken into account the very high values of $\kappa$ in such dielectrics as water – see Table 1. Indeed, it is the reduction of the attraction between positive and negative ions (called, respectively, *cations* and *anions*) in water that enables their substantial dissociation and hence almost all biochemical reactions, which are the basis of the biological cell functions – and hence of the life itself.

Let us apply this general result to the important particular case of the plane capacitor (Fig. 2.3) filled with a linear, uniform dielectric. Applying the macroscopic Gauss law (34) to a pillbox-shaped volume on the conductor surface, we get the following relation,

$$\sigma = D_n = \varepsilon E_n = -\varepsilon \frac{\partial \phi}{\partial n}, \quad (3.54)$$

which differs from Eq. (2.3) only by the replacement $\varepsilon_0 \rightarrow \varepsilon = \kappa \varepsilon_0$. Hence the charge density, calculated for the free-space case, should be increased by the factor of $\kappa$ – that’s it. In particular, this means that the mutual capacitance (2.28) has to be increased by this factor:

$$C = \frac{\kappa \varepsilon_0 A}{d} \equiv \frac{\varepsilon A}{d}. \quad (3.55)$$

(As a reminder, this increase of $C$ by $\kappa$ has been already incorporated, without derivation, into some estimates made in Secs. 2.1 and 2.2.)

If a linear dielectric is non-uniform, the situation is more complex. For example, let us consider the case of a sharp interface between two otherwise uniform dielectrics, free of stand-alone charges. In this case, we still may use Eq. (37) for the tangential component of the macroscopic electric field, and also Eq. (36), with $D_n = \varepsilon E_n$, which yields

$$(\varepsilon E_n)_1 = (\varepsilon E_n)_2, \quad \text{i.e. } \varepsilon_1 \frac{\partial \phi_1}{\partial n} = \varepsilon_2 \frac{\partial \phi_2}{\partial n}. \quad (3.56)$$
Let us apply these boundary conditions, first of all, to the very illuminating case of two very thin ($t << d$) slits cut in a uniform dielectric with an initially uniform\textsuperscript{27} electric field $E_0$ (Fig. 9). In both cases, a slit with $t \to 0$ cannot modify the field distribution outside it substantially.

![Fig. 3.9. Fields inside two narrow slits cut in a linear dielectric with a uniform field $E_0$.](image)

For slit A, with the plane normal to the applied field, we may apply Eq. (56) to the “major” (broad) interfaces, shown horizontal in Fig. 9, to see that the vector $D$ should be continuous. But according to Eq. (46), this means that in the free space inside the gap the electric field equals $D/\varepsilon_0$, and hence is $\kappa$ times higher than the applied field $E_0 = D/\kappa \varepsilon_0$. This field, and hence $D$, may be measured by a sensor placed inside the gap, showing that the electric displacement is by no means a purely mathematical construct.\textsuperscript{28} On the contrary, for the slit B parallel to the applied field, we may apply Eq. (37) to the major (now, vertical) interfaces of the slit, to see that now the electric field $E$ is continuous, while the electric displacement $D = \varepsilon_0 E$ inside the gap is a factor of $\kappa$ lower than its value in the dielectric. (Similarly to case A, any perturbations of the field uniformity, caused by the compliance with Eq. (56) at the minor interfaces, settle at distances $\sim t$ from them.)

For other problems with piecewise-constant $\varepsilon$, with more complex geometries we may need to apply the methods studied in Chapter 2. As in the free space, in the simplest cases we can select such a set of orthogonal coordinates that the electrostatic potential depends on just one of them. Consider, for example, two types of plane capacitor filling with two different dielectrics – see Fig. 10.

![Fig. 3.10. Plane capacitors filled with two different dielectrics.](image)

In the case (a), the voltage $V$ between the electrodes is the same for each part of the capacitor, and at least far from the dielectric interface, the electric field is vertical, uniform, and constant ($E = V/d$). Hence the boundary condition (37) is satisfied even if such a distribution is valid near the surface as well, i.e. at any point of the system. The only effect of different values of $\varepsilon$ in the two parts is that the

\textsuperscript{27} Actually, the following arguments and results are valid for \textit{any} external field distribution, provided that the slits are much smaller than the characteristic scale of the field’s change in space.

\textsuperscript{28} Superficially, this result violates the boundary condition (37) at the vertical (“minor”) interfaces of the gap A. This apparent contradiction may be resolved, taking into account that the slit deforms the field outside it, near its edges. These fringe effects extend from the edges only by the horizontal distances $\sim t$, so that the above relations for $E$ and $D$ are valid at most of the slit area.
electric displacement \( D = \varepsilon E \) and hence electrodes’ surface charge density \( \sigma = D \) are different in the two parts. Thus we can calculate the electrode charges \( Q_{1,2} \) of the two parts independently, and then add up the results to get the total mutual capacitance

\[
C = \frac{Q_1 + Q_2}{V} = \frac{1}{d} (\varepsilon_1 A_1 + \varepsilon_2 A_2). \tag{3.57}
\]

Note that this formula may be interpreted as the total capacitance of two separate lumped capacitors connected (by wires) in parallel. This is natural, because we may cut the system along the dielectric interface, without any effect on the fields in either part, and then connect the corresponding electrodes by external wires, again without any effect on the system – besides very close vicinities of capacitor’s edges.

Case (b) may be analyzed just as in the problem shown in Fig. 6, by applying Eq. (34) to a Gaussian pillbox with one lid inside the (for example) bottom electrode, and the other lid in any of the layers. As a result, we see that \( D \) anywhere inside the system should be equal to the surface charge density \( \sigma \) of the electrode, i.e. constant. Hence, according to Eq. (46), the electric field inside each dielectric layer is also constant: in the top layer \( E_1 = D_1/\varepsilon_1 = \sigma/\varepsilon_1 \), while in bottom layer, \( E_2 = D_2/\varepsilon_2 = \sigma/\varepsilon_2 \). Integrating the field \( E \) across the whole capacitor, we get

\[
V = \int_0^{d_1+d_2} E(z)dz = E_1d_1 + E_2d_2 = \left(\frac{d_1}{\varepsilon_1} + \frac{d_2}{\varepsilon_2}\right)\sigma, \tag{3.58}
\]

so that the mutual capacitance per unit area

\[
\frac{C}{A} \equiv \frac{\sigma}{V} = \left[\frac{d_1}{\varepsilon_1} + \frac{d_2}{\varepsilon_2}\right]^{-1}. \tag{3.59}
\]

Note that this result is similar to the total capacitance of an in-series connection of two plane capacitors based on each of the layers. This is also natural, because we could insert an uncharged, thin conducting sheet (rather than a cut as in the previous case) at the layer interface, which is an equipotential surface, without changing the field distribution in any part of the system. Then we could thicken the conducting sheet as much as we like (turning it into a wire), also without changing the fields in the dielectric parts of the system, and hence its capacitance.

Proceeding to problems with more complex geometry, let us consider the system shown in Fig. 11a: a dielectric sphere placed into an initially uniform external electric field \( E_0 \). According to Eq. (53) for the macroscopic electric field, and the definition of the macroscopic electrostatic potential, \( E = -\nabla \phi \), the potential satisfies the Laplace equation both inside and outside the sphere. Due to the spherical symmetry of the dielectric sample, this problem invites the variable separation method in spherical coordinates, which was discussed in Sec. 2.8. From that discussion, we already know, in particular, the general solution (2.172) of the Laplace equation outside of the sphere. In order to satisfy the uniform-field condition at \( r \to \infty \), we have to reduce this solution to

\[
\phi_{r \geq R} = -E_0 r \cos \theta + \sum_{l=1}^{\infty} \frac{b_l}{r^{l+1}} P_l(\cos \theta). \tag{3.60}
\]

Inside the sphere, we can also use Eq. (2.172), but keeping only the radial functions finite at \( r \to 0 \):
\[ \phi_{r \leq R} = \sum_{l=1}^{\infty} a_l r^l \rho_l (\cos \theta). \quad (3.61) \]

Now, spelling out the boundary conditions (37) and (56) at \( r = R \), we see that for all coefficients \( a_l \) and \( b_l \) with \( l \geq 2 \) we (just like for the conducting sphere, discussed in Sec. 2.8) get homogeneous equations that have only trivial solutions. Hence, all these terms may be dropped, while for the only surviving Legendre polynomial, proportional to \( \rho_l (\cos \theta) \equiv \cos \theta \), we get two equations:

\[
-E_0 \frac{2b_1}{R^3} = \kappa a_1, \quad -E_0 R + \frac{b_1}{R^2} = a_1 R. \quad (3.62)
\]

Solving this simple system of linear equations for \( a_1 \) and \( b_1 \), and plugging the result into Eqs. (60) and (61), we get the final solution of the problem:

\[
\phi_{r \leq R} = E_0 \left( -r + \frac{\kappa - 1}{2} R^3 \right) \cos \theta, \quad \phi_{r \geq R} = -E_0 \frac{3}{\kappa + 2} r \cos \theta. \quad (3.63)
\]

Fig. 3.11. A dielectric sphere in an initially uniform electric field: (a) the problem, and (b) the equipotential surfaces, as given by Eq. (62), for \( \kappa = 3 \).

Fig. 11b shows the equipotential surfaces given by this solution, for a particular value of the dielectric constant \( \kappa \). Note that according to Eq. (62), at \( r \geq R \) the dielectric sphere, just as the conducting sphere in a similar problem, produces (on the top of the uniform external field) a pure dipole field, with the dipole moment

\[
p = 4\pi R^3 \frac{\kappa - 1}{\kappa + 2} \epsilon_0 E_0 = 3 V \frac{\kappa - 1}{\kappa + 2} \epsilon_0 E_0, \quad \text{where } V = \frac{4\pi}{3} R^3 \quad (3.64)
\]

– an evident generalization of Eq. (11), to which Eq. (64) tends at \( \kappa \to \infty \). By the way, this property is common: for their electrostatic (but not transport!) properties, conductors may be adequately described as dielectrics with \( \kappa \to \infty \).

Another remarkable feature of Eqs. (63) is that the electric field and polarization inside the sphere are uniform, with \( R \)-independent values.
\[ E = \frac{3}{\kappa + 2} E_0, \quad D = \kappa \varepsilon_0 E = \frac{3\kappa}{\kappa + 2} \varepsilon_0 E_0, \quad P = D - \varepsilon_0 E = 3\varepsilon_0 \frac{\kappa - 1}{\kappa + 2} E_0. \] (3.65)

In the limit \( \kappa \to 1 \) (the “sphere made of free space”, i.e. no sphere at all), the electric field inside it naturally tends to the external one, and its polarization disappears. In the opposite limit \( \kappa \to \infty \), the electric field inside the sphere vanishes. Curiously enough, in this limit the electric displacement inside the sphere remains finite: \( D \to 3\varepsilon_0 E_0 \).

More complex problems with piecewise-uniform dielectrics also may be addressed by the methods discussed in Chapter 2, and I leave a few of them for the reader’s exercise. Let me discuss just one of such problems, because it exhibits a new feature of the charge image method which was discussed in Secs 2.9 (and is the basis of the Green’s function approach – see Sec. 2.10). Consider the system shown in Fig. 12, a point charge near a dielectric half-space, which evidently parallels the problem discussed in Sec. 2.9 – see Fig. 2.26.

As for the case of a conducting half-space, the Laplace equation for the electrostatic potential in the upper half-space \( z > 0 \) (besides the charge point \( \rho = 0, z = d \) may be satisfied using a single image charge \( q' \) at point \( \rho = 0, z = -d \), but now \( q' \) may differ from \(-q\)). In addition, in contrast to the case analyzed in Sec. 2.9, we should also calculate the field inside the dielectric (at \( z \leq 0 \)). This field cannot be contributed by the image charge \( q' \), because it would provide a potential divergence at its location. Thus, in that half-space we should try to use the real point source only, but maybe with a re-normalized charge \( q'' \) rather than the genuine charge \( q \) – see Fig. 12. As a result, we may look for the potential distribution in the form

\[ \phi(\rho, z) = \frac{1}{4\pi\varepsilon_0} \times \begin{cases} \frac{q}{(\rho^2 + (z - d)^2)^{1/2}} + \frac{q'}{(\rho^2 + (z + d)^2)^{1/2}} & \text{for } z \geq 0, \\ \frac{q''}{(\rho^2 + (z - d)^2)^{1/2}} & \text{for } z \leq 0, \end{cases} \] (3.66)

at this stage with unknown \( q' \) and \( q'' \). Plugging this solution into the boundary conditions (37) and (56) at \( z = 0 \) (with \( \partial/\partial n = \partial/\partial z \), we see that they are indeed satisfied (so that Eq. (66) does express the unique solution of the boundary problem), provided that the effective charges \( q' \) and \( q'' \) obey the following relations:
\[
q - q' = \kappa q'', \quad q + q' = q''.
\] (3.67)

Solving this simple system of linear equations, we get
\[
q' = -\frac{\kappa - 1}{\kappa + 1} q, \quad q'' = \frac{2}{\kappa + 1} q.
\] (3.68)

If \(\kappa \to 1\), then \(q' \to 0\), and \(q'' \to q\) – both facts very natural, because in this limit (no polarization at all!) we have to recover the unperturbed field of the initial point charge in both semi-spaces. In the opposite limit \(\kappa \to \infty\) (which, according to our discussion of the last problem, should correspond to a conducting half-space), \(q' \to -q\) (repeating the result we have discussed in detail in Sec. 2.9) and \(q'' \to 0\). The last result means that in this limit, the electric field \(E\) in the dielectric tends to zero – as it should.

### 3.5. Electric field energy in a dielectric

In Chapter 1, we have obtained two key results for the electrostatic energy: Eq. (1.55) for a charge interaction with an independent (“external”) field, and a similarly structured formula (1.60), but with an additional factor \(1/2\), for the field is produced by the charges under consideration. These relations are of course always valid for dielectrics as well, provided that the charge density includes all charges (including those bound into the elementary dipoles), but it is convenient to recast them into a form depending on the density \(\rho(r)\) of only stand-alone charges.

If a field is created only by stand-alone charges under consideration, and is proportional to \(\rho(r)\) (requiring that we deal with linear dielectrics only), we can repeat all the argumentation of the beginning of Sec. 1.3, and again arrive at Eq. (1.60), provided that \(\phi\) is now the macroscopic field’s potential. Now we can recast this result in the terms of fields – essentially as this was done in Eqs. (1.62)-(1.64), but now making a clear difference between the macroscopic electric field \(E = -\nabla \phi\) and the electric displacement field \(D\) that obeys the macroscopic Maxwell equation (32). Plugging \(\rho(r)\), expressed from that equation, into Eq. (1.60), we get
\[
U = \frac{1}{2} \int (\nabla \cdot D) \phi \, d^3r.
\] (3.69)

Using the fact\(^{29}\) that for any differentiable functions \(\phi\) and \(D\),
\[
(\nabla \cdot D) \phi = \nabla \cdot (\phi \, D) - (\nabla \phi) \cdot D,
\] (3.70)

we may rewrite Eq. (69) as
\[
U = \frac{1}{2} \int \nabla \cdot (\phi D) d^3r - \frac{1}{2} \int (\nabla \phi) \cdot D \, d^3r.
\] (3.71)

The divergence theorem, applied to the first term on the right-hand side, reduces it to a surface integral of \(\phi D_n\). (As a reminder, in Eq. (1.63) the integral was of \(\phi \nabla \phi \propto \phi E_n\).) If the surface of the volume we are considering is sufficiently far, this surface integral vanishes. On the other hand, the gradient in the second term of Eq. (71) is just (minus) field \(E\), so that it gives

---

\(^{29}\) See, e.g., MA Eq. (11.4a).
\[
U = \frac{1}{2} \int \mathbf{E} \cdot \mathbf{D} \, d^3r = \frac{1}{2} \int \mathbf{E}(\mathbf{r}) \mathbf{D}(\mathbf{r}) \, d^3r = \frac{\varepsilon_0}{2} \int \kappa(\mathbf{r}) E^2(\mathbf{r}) \, d^3r . \tag{3.72}
\]

This expression is a natural generalization of Eq. (1.65), and shows that we can, like we did in the free space, represent the electrostatic energy in a local form:\(^30\)

\[
U = \int u(\mathbf{r}) d^3r , \quad \text{with } u = \frac{1}{2} \mathbf{E} \cdot \mathbf{D} = \frac{\varepsilon_0}{\varepsilon} E^2 = \frac{D^2}{2\varepsilon} . \tag{3.73}
\]

As a sanity check, in the trivial case \(\varepsilon = \varepsilon_0\) (i.e. \(\kappa = 1\)), this result is reduced to Eq. (1.65).

Of course, Eq. (73) is valid only for linear dielectrics, because our starting point, Eq. (1.60), is only valid if \(\phi\) is proportional to \(\rho\). In order to make our calculation more general, we should intercept the calculations of Sec. 1.3 at an earlier stage, at which we have not yet used this proportionality. For example, the first of Eqs. (1.56) may be rewritten, in the continuous limit, as

\[
\delta U = \int \phi(\mathbf{r}) \delta \rho(\mathbf{r}) d^3r , \tag{3.74}
\]

where the symbol \(\delta\) means a small variation of the function – e.g., its change in time, sufficiently slow to ignore the relativistic and magnetic-field effects. Applying such variation to Eq. (32), and plugging the resulting relation \(\delta \rho = \nabla \cdot \delta \mathbf{D}\) into Eq. (74), we get

\[
\delta U = \int (\nabla \cdot \delta \mathbf{D}) \phi \, d^3r . \tag{3.75}
\]

(Note that in contrast to Eq. (69), this expression does not have the front factor \(\frac{1}{2}\).) Now repeating the same calculations as in the linear case, for the energy density variation we get a remarkably simple (and general!) expression,

\[
\delta u = \mathbf{E} \cdot \delta \mathbf{D} \equiv \sum_{j=1}^3 E_j \delta D_j , \tag{3.76}
\]

where the last expression uses the Cartesian components of the vectors \(\mathbf{E}\) and \(\mathbf{D}\). This is as far as we can go for the general dependence \(\mathbf{D}(\mathbf{E})\). If the dependence is linear and isotropic, as in Eq. (46), then \(\delta \mathbf{D} = \varepsilon \delta \mathbf{E}\) and

\[
\delta u = \varepsilon \mathbf{E} \cdot \delta \mathbf{E} \equiv \varepsilon \delta \left(\frac{E^2}{2}\right) . \tag{3.77}
\]

The integration of this expression over the variation, from the field equal to zero to a certain final distribution \(\mathbf{E}(\mathbf{r})\), brings us back to Eq. (73).

An important role of Eq. (76), in its last form, is to indicate that the Cartesian coordinates of \(\mathbf{E}\) may be interpreted as generalized forces, and those of \(\mathbf{D}\) as generalized coordinates of the field’s effect on a unit volume of the dielectric. This allows one, in particular, to form the proper Gibbs potential energy\(^31\) of a system with an electric field \(\mathbf{E}(\mathbf{r})\) fixed, at every point, by some external source:

---

\(^{30}\) In the Gaussian units, each of the last three expressions should be divided by \(4\pi\).

\(^{31}\) See, e.g., CM Sec. 1.4, in particular Eq. (1.41), and Sec. 2.1. Note that as Eq. (78) clearly illustrates, once again, that the difference between the potential energies \(U_G\) and \(U\), usually discussed in courses of statistical
The essence of this notion is that if the generalized external force (in our case, \( E \)) is fixed, the stable equilibrium of the system corresponds to the minimum of \( U_G \), rather than of the potential energy \( U \) as such – in our case, that of the field in our system.

As the simplest illustration, let us consider a very long cylinder (with an arbitrary cross-section’s shape), made of a uniform linear dielectric, placed into a uniform external electric field, parallel to the cylinder’s axis – see Fig. 13.

For this simple problem, the equilibrium value of \( D \) inside the cylinder may be, of course, readily found without any appeal to energies. Indeed, the solution of the Laplace equation inside the cylinder, with the boundary condition (37) is evident: \( E(r) = E_{\text{ext}} \), and so that Eq. (46) immediately yields \( D(r) = \varepsilon E_{\text{ext}} \). However, one may wonder why does the minimum of the potential energy \( U \), given by Eq. (73) in its last form,

\[
\frac{U}{V} = \frac{D^2}{2\varepsilon},
\]

(3.79)
correspond to a different (zero) value of \( D \). The Gibbs potential energy (78) immediately removes the contradiction. Indeed, for our uniform case, this energy per unit volume of the cylinder is

\[
\frac{U_G}{V} = \frac{U}{V} - \mathbf{E} \cdot \mathbf{D} = \frac{D^2}{2\varepsilon} - \mathbf{E} \cdot \mathbf{D} \equiv \sum_{j=1}^{3} \left( \frac{D_j^2}{2\varepsilon} - E_j D_j \right),
\]

(3.80)
and its minimum as a function of every Cartesian component of \( \mathbf{D} \) corresponds to the correct value of the displacement: \( D_j = \varepsilon E_j \), i.e. \( \mathbf{D} = \varepsilon \mathbf{E} = \varepsilon \mathbf{E}_{\text{ext}} \). So, the minimum of the Gibbs potential energy indeed correspond to the systems’ equilibrium, and it may be very useful for analyses of the polarization dynamics. Note also that Eq. (80), at this equilibrium point (only!), may be rewritten as

\[
\frac{U_G}{V} = \frac{U}{V} - \mathbf{E} \cdot \mathbf{D} = \frac{D^2}{2\varepsilon} - \frac{\mathbf{D} \cdot \mathbf{D}}{\varepsilon} \equiv \frac{D^2}{2\varepsilon},
\]

(3.81)
i.e. formally coincides with Eq. (79), besides the opposite sign. Another useful general relation (not limited to linear dielectrics) may be obtained by taking the variation of the $u_G$ expressed by Eq. (78), and then using Eq. (76):

$$\delta u_G = \delta u - \delta (E \cdot D) = E \cdot \delta D - (\delta E \cdot D + E \cdot \delta D) \equiv -D \cdot \delta E.$$ (3.82)

In order to see how do these expressions (with their perhaps counter-intuitive negative signs\(^{32}\)) work, let us plug $D$ from Eq. (33):

$$\delta u_G = -(\varepsilon_0 E + P) \cdot \delta E \equiv -\delta \left( \frac{\varepsilon_0 E^2}{2} \right) - P \cdot \delta E.$$ (3.83)

So far, this relation is general. In the particular case when the polarization $P$ is field-independent, we may integrate Eq. (83) over the electric field, from 0 to some finite value $E$, getting

$$u_G = -\frac{\varepsilon_0 E^2}{2} - P \cdot E.$$ (3.84)

Again, the Gibbs energy is relevant only if $E$ is dominated by an external field $E_{\text{ext}}$, independent of the orientation of the polarization $P$. If, in addition, $P(r) \neq 0$ only in some finite volume $V$, we may integrate Eq. (84) over the volume, getting

$$U_G = -p \cdot E_{\text{ext}} + \text{const}, \quad \text{with } p \equiv \int_V P(r) d^3r,$$ (3.85)

where “const” means the terms independent of $p$. In this expression, we may readily recognize Eq. (15a) for an electric dipole $p$ of a fixed magnitude, which was obtained in Sec. 1 in a different way.

This comparison shows again that $U_G$ is nothing extraordinary; it is just the relevant part of the potential energy of the system in a fixed external field, including the energy of its interaction with the field. Still, I would strongly recommend the reader to get a better gut feeling of the relation between the two potential energies, $U$ and $U_G$ – for example, by using them to solve a very simple problem: calculate the force of attraction between the plates of a plane capacitor.

### 3.6. Exercise problems

3.1. Prove Eqs. (3)-(4), starting from Eq. (1.38) and Eq. (2) of this chapter.

3.2. A plane thin ring of radius $R$ is charged with a constant linear density $\lambda$. Calculate the exact electrostatic potential distribution along the symmetry axis of the ring, and prove that at large distances, $r >> R$, the three leading terms of its multipole expansion are indeed correctly described by Eqs. (3)-(4).

3.3. In suitable reference frames, calculate the dipole and quadrupole moments of the following systems (see Figs. below):

(i) four point charges of the same magnitude, but alternating signs, placed in the corners of a square;

---

\(^{32}\) Some psychological relief may be provided that the fact that you may add to $U_G$ (and $U$) any constant – positive if you like.
(ii) a similar system, but with a pair charge sign alternation; and
(iii) a point charge in the center of a thin ring carrying a similar but opposite charge, uniformly
distributed along its circumference.

3.4. Without carrying out an exact calculation, can you predict the spatial dependence of the
interaction between various electric multipoles, including point charges (in this context, frequently
called electric monopoles), dipoles, and quadrupoles? Based on these predictions, what is the functional
dependence of the interaction between dumbbell-shaped diatomic molecules such as \( \text{H}_2, \text{N}_2, \text{O}_2 \), etc., on
the distance between them, if the distance is much larger than the molecular size?

3.5. Two similar electric dipoles, of fixed magnitude \( p \), located at a fixed distance \( r \) from each
other, are free to change their directions. What stable equilibrium position(s) may they take as a result of
their electrostatic interaction?

3.6. An electric dipole is located above an infinite, grounded
conducting plane (see the figure on the right). Calculate:
(i) the distribution of the induced charge in the conductor,
(ii) the dipole-to-plane interaction energy, and
(iii) the force and the torque acting on the dipole.

3.7. Calculate the net charge \( Q \) induced in a grounded conducting sphere
of radius \( R \) by a dipole \( p \) located at point \( r \) outside the sphere – see the figure on
the right.

3.8. Use two different approaches to calculate the energy of interaction between a grounded
conductor and an electric dipole \( p \), placed in the center of a spherical cavity of radius \( R \), carved in the
conductor.

3.9. A plane separating two parts of otherwise free space is densely and uniformly (with a
constant areal density \( n \)) filled with dipoles, with similar dipole moments \( p \) oriented in the direction
normal to the plane.

(i) Calculate the boundary conditions for the electrostatic potential on both sides of the plane.
(ii) Use the result of Task (i) to calculate the potential distribution created in space by a spherical surface, with radius \( R \), densely and uniformly filled with radially-oriented dipoles.

(iii) What condition should be imposed on the dipole density \( n \) for your results to be qualitatively valid?

3.10. Prove the Clausius-Mossotti relation (52) for the case of a cubic lattice of similar dipoles obeying Eq. (48): \( \mathbf{p} = \alpha \mathbf{E}_m \), where \( \mathbf{E}_m \) is the microscopic electric field at the dipole’s location point.

*Hint:* Use Eq. (65) to account for the difference between the external field and the macroscopic field.

3.11. A sphere of radius \( R \) is made of a material with a uniform, fixed polarization \( \mathbf{P}_0 \).

(i) Calculate the electric field everywhere in space – both inside and outside the sphere.

(ii) Compare the result for the internal field with Eq. (24).

3.12. Calculate the electric field at the center of a cube with side \( a \), made of a material with the uniform spontaneous polarization \( \mathbf{P}_0 \), directed parallel to one of cube’s sides.

3.13. A stand-alone charge \( Q \) is distributed, in some way, in the volume of a body made of a uniform linear dielectric with a dielectric constant \( \kappa \): Calculate the polarization charge \( Q_{ef} \) residing on the surface of the body, provided that it is surrounded by free space.

3.14. In two separate experiments, a thin, plane sheet of a linear dielectric with \( \kappa = \text{const} \) is placed into a uniform external electric field \( \mathbf{E}_0 \):

(i) with sheet’s surface parallel to the electric field, and

(ii) the surface normal to the field.

For each case, find the electric field \( \mathbf{E} \), the electric displacement \( \mathbf{D} \), and the polarization \( \mathbf{P} \) inside the dielectric (far from the sheet’s edges).

3.15. A point charge \( q \) is located at a distance \( r >> R \) from the center of a uniform sphere of radius \( R \), made of a uniform linear dielectric. In the first nonzero approximation in small parameter \( R/r \), calculate the interaction force, and the energy of interaction between the sphere and the charge.

3.16. A fixed dipole \( \mathbf{p} \) is placed in the center of a spherical cavity of radius \( R \), cut inside a uniform, linear dielectric. Calculate the electric field distribution everywhere in the system (both at \( r < R \) and at \( r > R \)).

*Hint:* You may start with the assumption that the field at \( r > R \) has a distribution typical for a dipole (but be ready for surprises :-).
3.17. A spherical capacitor (see the figure on the right) is filled with a linear dielectric whose permittivity $\varepsilon$ depends on spherical angles $\theta$ and $\phi$, but not on the distance $r$ from the system’s center. Derive an explicit expression for its capacitance $C$.

3.18. For each of the two capacitors shown in Fig. 10, calculate the electric forces (per unit area) exerted on the interface between the dielectrics, in terms of fields in the system.

3.19. A uniform electric field $E_0$ has been created (by distant external sources) inside a uniform linear dielectric. Find the change of the electric field, created by cutting out a cavity in the shape of a round cylinder of radius $R$, with its axis normal to the external field – see the figure on the right.

3.20. Similar small spherical particles, made of a linear dielectric, are dispersed in free space with a low concentration $n << 1/R^3$, where $R$ is particle's radius. Calculate the average dielectric constant of such a medium. Compare the result with the apparent but wrong answer

$$\bar{\kappa} - 1 = (\kappa - 1)nV,$$  \quad (WRONG!)

(where $\kappa$ is the dielectric constant of the particle's material and $V = (4\pi/3)R^3$ is its volume), and explain the origin of the difference.

3.21.* Calculate the spatial distribution of the electrostatic potential induced by a point charge $q$ placed at distance $d$ from a very wide parallel plate, of thickness $D$, made of a uniform linear dielectric – see the figure on the right.

3.22. Discuss the physical nature of Eq. (76). Apply your conclusions to a material with a fixed (field-independent) polarization $P_0$, and calculate the electric field’s energy of a uniformly polarized sphere (see Problem 11).

3.23. Use Eqs. (73) and (82) to calculate the force of attraction of plane capacitor’s plates (per unit area), for two cases:
(i) the capacitor is charged to a voltage $V$, and then disconnected from the battery, and 
(ii) the capacitor remains connected to the battery.

33 “Battery” is a traditional but misleading term for what is usually a single galvanic element. (This term stems from the name of Luigi Galvani, a pioneer of electric current studies. Another term derived from his name is the galvanic connection, meaning a direct connection of two conductors, enabling a dc current flow – see the next chapter.) The term “battery” had to be, in all fairness, reserved for the connection of several galvanic elements in series – as was pioneered by L. Galvani’s friend Alexander Volta in 1800.
Chapter 4. DC Currents

The goal of this chapter is to discuss the laws governing the distribution of stationary (“dc”) currents inside conducting media. In the most important case of linear (“Ohmic”) conductivity, the partial differential equations governing the distribution are reduced to the same Laplace and Poisson equations whose solution methods were discussed in detail in Chapter 2 – though sometimes with different boundary conditions. Because of that, the chapter is rather brief.

4.1. Continuity equation and the Kirchhoff laws

Until this point, our discussion of conductors has been limited to the cases when they are separated with insulators (meaning either the free space or some dielectric media), preventing any continuous motion of charges from one conductor to another, even if there is a non-zero voltage (and hence electric field) between them – see Fig. 1a.

Now let us connect the two conductors with a wire – a thin, elongated conductor (Fig. 1b). Then the electric field causes the motion of charges in the wire – from the conductor with a higher electrostatic potential toward that with lower potential, until the potentials equilibrate. Such a process is called charge relaxation. The main equation governing this process may be obtained from the fundamental experimental fact (already mentioned in Sec. 1.1) that electric charges cannot appear or disappear – though opposite charges may recombine with the conservation of the net charge. As a result, the charge $Q$ in the top conductor may change only due to the electric current $I$ through the wire:

$$\frac{dQ}{dt} = -I(t), \quad (4.1)$$

the relation that may be understood as the definition of the current.$^1$

---

$^1$ Just as a (hopefully, unnecessary :-) reminder, in the SI units the current is measured in amperes (A). In the legal metrology, the ampere (rather than the coulomb, which is defined as $1C = 1A \times 1s$) is a primary unit. (Its formal definition will be discussed in the next chapter.) In the Gaussian units, Eq. (1) remains the same, so that the current’s unit is the statcoulomb per second – the so-called statampere.
Let us express Eq. (1) in a differential form, introducing the notion of the current density vector \( \mathbf{j}(\mathbf{r}) \). This vector may be defined via the following relation for the elementary current \( dI \) crossing an elementary area \( dA \) (Fig. 2):

\[
dl = j dA \cos \theta = (j \cos \theta)dA = j_s dA,
\]

where \( \theta \) is the angle between the direction normal to the surface and the carrier motion direction (which is taken for the direction of vector \( \mathbf{j} \)).

![Diagram of current density vector](image)

Fig. 4.2. The current density vector \( \mathbf{j} \).

With that definition, Eq. (1) may be re-written as

\[
\frac{d}{dt} \int_V \rho d^3r = -\int_S j_s \cdot d^2r,
\]

where \( V \) is an arbitrary stationary volume limited by the closed surface \( S \). Applying to this volume the same divergence theorem as was repeatedly used in previous chapters, we get

\[
\int_V \left( \frac{\partial \rho}{\partial t} + \nabla \cdot \mathbf{j} \right) d^3r = 0.
\]

Since the volume \( V \) is arbitrary, this equation may be true only if

\[
\frac{\partial \rho}{\partial t} + \nabla \cdot \mathbf{j} = 0.
\]

This is the fundamental continuity equation – which is true even for time-dependent phenomena.\(^2\)

The charge relaxation, such as illustrated by Fig. 1b, is of course a dynamic, time-dependent process. However, electric currents may also exist in stationary situations, when a certain current source, for example a battery, drives the current against the electric field, and thus replenishes the conductor charges and sustains currents at a certain time-independent level – see Fig. 1c. (This process requires a persistent replenishment of the electrostatic energy of the system from either a source or a large storage of energy of a different kind – say, the chemical energy of the battery.) Let us discuss the laws governing the distribution of such dc currents. In this case (\( \partial / \partial t = 0 \)), Eq. (5) reduces to a very simple equation

\[
\nabla \cdot \mathbf{j} = 0.
\]

This relation acquires an even simpler form in the particular but important case of dc electric circuits (Fig. 3), the systems that may be represented as connections of components of two types:

\(^2\) Similar differential relations are valid for the density of any conserved quantity, for example for mass in the classical fluid dynamics (see, e.g., CM Sec. 8.3), and for the probability in statistical physics (SM Sec. 5.6) and quantum mechanics (QM Sec. 1.4).
(i) small-size \textit{(lumped) circuit elements} (also called “two-terminal devices”), meaning a passive resistor, a current source, etc. – generally, any “black box” with two or more terminals, and

(ii) \textit{perfectly conducting wires}, with a negligible drop of the electrostatic potential along them, that are galvanically connected at certain points, called \textit{nodes} (or “junctions”).

In the standard circuit theory, the electric charges of the nodes are considered negligible,\(^3\) and we may integrate Eq. (6) over the closed surface drawn around any node to get a simple equality

\[ \sum_j I_j = 0, \tag{4.7a} \]

where the summation is over all the wires (numbered with index \(j\)) connected in the node. On the other hand, according to its definition (2.25), the voltage \(V_k\) across each circuit element may be represented as the difference of the electrostatic potentials of the adjacent nodes, \(V_k = \phi_k - \phi_{k-1}\). Summing such differences around any closed loop of the circuit (Fig. 3), we get all terms canceled, so that

\[ \sum_k V_k = 0. \tag{4.7b} \]

These relations are called, respectively, the \textit{1st} and \textit{2nd Kirchhoff laws}\(^4\) – or sometimes the \textit{node rule} (7a) and the \textit{loop rule} (7b). They may seem elementary, and their genuine power is in the mathematical fact that a set of Eqs. (7), covering every node and every circuit element of the system at least once, gives a system of equations sufficient for the calculation of all currents and voltages in it – provided that the relation between current and voltage is known for each circuit element.

It is almost evident that in the absence of current sources, the system of equations (7) has only a trivial solution: \(I_j = 0, V_k = 0\) – with the exotic exception of superconductivity, to be discussed in Sec. 6.3. The current sources, that allow non-vanishing current flows, may be described by their \textit{electromotive forces (e.m.f.)} \(\mathcal{E}_k\), having the dimensionality of voltage, which have to be taken into account in the corresponding terms \(V_k\) of the sum (7b). Let me hope that the reader has some experience of using Eqs. (7) for analyses of simple circuits – say consisting of several resistors and batteries, so that I can save time by skipping their discussion. Still, due to their practical importance, I would recommend the reader to carry out a self-test by solving a couple of problems offered at the beginning of Sec. 6.

\(^3\) In many cases, the charge accumulation/relaxation may be described without an explicit violation of Eq. (7a), just by adding other circuit elements, \textit{lumped capacitors} (see Fig. 2.5 and its discussion), to the circuit under analysis. The resulting circuit may be used to describe not only the transient processes, but also ac currents. However, it will be more convenient for me to postpone the discussion of such \textit{ac circuits} until Chapter 6, where one more circuit element type, \textit{lumped inductances}, will be introduced.

\(^4\) Named after Gustav Kirchhoff (1824-1887) – who also suggested the differential form (8) of the Ohm law.
4.2. The Ohm law

As was mentioned above, the relations spelled out in Sec. 1 are sufficient for forming a closed system of equations for finding electric current and field in a system only if they are complemented with some constitutive relations between the scalars $I$ and $V$ in each lumped circuit element, i.e. between the vectors $\mathbf{j}$ and $\mathbf{E}$ in each point of the material of such an element. The simplest, and most frequently met relation of this kind is the famous Ohm law whose differential (or “local”) form is

$$ \mathbf{j} = \sigma \mathbf{E}, $$

where $\sigma$ is a constant called the Ohmic conductivity (or just the “conductivity” for short). Though the Ohm law (discovered, in its simpler form, by Georg Simon Ohm in 1827) is one of constitutive rather than fundamental relations, and is approximate for any conducting medium, we can argue that if:

(i) the medium carries no current at $\mathbf{E} = 0$ (mind superconductors!),
(ii) the medium is isotropic or almost isotropic (a notable exception: some organic conductors),
(iii) the mean free path $l$ of current carriers in this material is much smaller than the characteristic scale $a$ of the spatial variations of $\mathbf{j}$ and $\mathbf{E}$,

then the law may be viewed as the leading, linear term of the Taylor expansion of the local relation $\mathbf{j}(\mathbf{E})$, and thus is very common for relatively low fields.

Table 1 gives approximate experimental values of $\sigma$ for some representative (and/or practically important) materials. Note that the range of the values is very broad, even without going to such extremes as very pure metallic crystals at very low temperatures, where $\sigma$ may reach $\sim 10^{12}$ S/m.

5 In SI units, the conductivity is measured in S/m, where one siemens (S) is the reciprocal of the ohm: $1 \Omega^{-1} = 1 \text{S}$. The constant reciprocal to conductivity, $1/\sigma$, is called resistivity, and is commonly denoted by letter $\rho$. I will, however, try to avoid using this notion, because I am already overusing this letter in these notes.
In order to get some feeling what do these values mean, let us consider a very simple system (Fig. 4): a plane capacitor of area \( A \gg d^2 \), filled with a material that has not only a dielectric constant \( \kappa \); but also some Ohmic conductivity \( \sigma \), with much more conductive electrodes.

Assuming that these properties are compatible with each other,\(^6\) we may assume that the distribution of the electric potential (not too close to the capacitor’s edges) still obeys Eq. (2.39), so that the electric field is normal to the plates and uniform, with \( E = V/d \). Then, according to Eq. (6), the current density is also uniform, \( j = \sigma E = \sigma V/d \). From here, the total current between the plates is

\[
I = jA = \sigma EA = \frac{V}{d} A.
\]

(4.9)

On the other hand, from Eqs. (2.26) and (3.45), the instant value of the plate charge is \( Q = CV = (\kappa \varepsilon_0 A/d)V \). Plugging these relations into Eq. (1), we see that the speed of charge (and voltage) relaxation does not depend on the geometric parameters \( A \) and \( d \) of the capacitor:

\[
\frac{dV}{dt} = -\frac{V}{\tau_r}, \quad \text{with} \quad \tau_r \equiv \frac{\varepsilon \kappa}{\sigma} \equiv \frac{\varepsilon}{\sigma},
\]

(4.10)

so that the relaxation time constant \( \tau_r \) may be used to characterize the gap filling material as such.

As we already know (see Table 3.1), for most practical materials the dielectric constant \( \kappa \) is within one order of magnitude from 10, so that the numerator in the second of Eqs. (10) is of the order of \( 10^{-10} \) (SI units). As a result, according to Table 1, the charge relaxation time ranges from \( \sim 10^{14} \) s (more than a million years!) for the best insulators like teflon, to \( \sim 10^{18} \) s for the least resistive metals. What is the physics behind such a huge range of \( \sigma \), and why, for some materials, Table 1 gives them with such a large uncertainty? As in Chapters 2 and 3, I have time only for a brief, admittedly superficial discussion of these issues.\(^7\)

If the charge carriers move as classical particles (e.g., in plasmas or non-degenerate semiconductors), a very reasonable description of the conductivity is given by the famous Drude formula.\(^8\) In his picture, due to a weak electric field, the charge carriers are accelerated in its direction (on the top of their random motion in all directions, with a vanishing average velocity vector):

\[
\frac{dv}{dt} = \frac{q}{m} E,
\]

(4.11)

and as a result, their velocity acquires the average value

\[\text{Fig. 4.4. A “leaky” plane capacitor.}\]

\[\begin{align*}
\phi &= V \\
\phi &= 0 \\
\end{align*}\]

---

\(^6\) As will be discussed in Chapter 6, this is true is only valid if \( \sigma \) is not too high.

\(^7\) A more detailed discussion may be found in SM Chapter 6.

\(^8\) It was suggested by Paul Drude in 1900.
\[
v = \frac{dv}{dt} = \frac{q}{m} E \tau,
\]
(4.12)

where the phenomenological parameter \( \tau = l/2v \) (not to be confused with \( \tau! \)) may be understood as a half of the average time between carrier scattering events. From here, the current density:\(^9\)

\[
\mathbf{j} = qn\mathbf{v} = \frac{q^2 n \tau}{m} \mathbf{E}, \quad \text{i.e. } \sigma = \frac{q^2 n \tau}{m}.
\]
(4.13a)

(Notice the independence of \( \sigma \) of the charge sign.) Another form of the same result, more popular in the physics of semiconductors, is

\[
\sigma = q^2 n \mu, \quad \text{with } \mu = \frac{\tau}{m},
\]
(4.13b)

where the parameter \( \mu \), defined by the relation \( v \equiv \mu E \), is called the charge carrier mobility.

Most good conductors (e.g., metals) are essentially degenerate Fermi gases (or liquids), in which the average thermal energy of a particle, \( k_B T \) is much lower than the Fermi energy \( \varepsilon_F \). In this case, a quantum theory is needed for the calculation of \( \sigma \). Such theory was developed by the quantum physics’ godfather A. Sommerfeld in 1927 (and is sometimes called the Drude-Sommerfeld model). I have no time to discuss it in this course,\(^{10} \) and here will only notice that for a nearly-ideal, isotropic Fermi gas the result is reduced to Eq. (13), with a certain effective value of \( \tau \), so it may be used for estimates of \( \sigma \), with due respect to the quantum theory of scattering. In a typical metal, \( n \) is very high (~10\(^{23}\) cm\(^{-3}\)) and is fixed by the atomic structure, so that the sample quality may only affect \( \sigma \) via the scattering time \( \tau \).

At room temperature, the scattering of electrons by thermally-excited lattice vibrations (phonons) dominates, so that \( \tau \) and \( \sigma \) are high but finite, and do not change much from one sample to another. (Hence, the relatively accurate values given for metals in Table 1.) On the other hand, at \( T \to 0 \), a perfect crystal should not exhibit scattering at all, and its conductivity should be infinite. In practice, this is never true (for one, due to electron scattering from imperfect boundaries of finite-size samples), and the effective conductivity \( \sigma \) is infinite (or practically infinite, at least above the largest measurable values ~10\(^{20}\) S/m) only in superconductors.\(^{11} \)

On the other hand, the conductivity of quasi-insulators (including the deionized water) and semiconductors depends mostly on the carrier density \( n \), which is much lower than in metals. From the point of view of quantum mechanics, this happens because the ground-state wavefunctions of charge carriers are localized within an atom (or molecule), and their energies are separated from those of excited states, with space-extended wavefunctions, by a large energy gap (called the bandgap). For example, in SiO\(_2\) the bandgap approaches 9 eV, equivalent to \( \sim 4,000 \) K. This is why, even at room temperatures the density of thermally-excited free charge carriers in good insulators is negligible. In these materials, \( n \) is determined by impurities and vacancies, and may depend on a particular chemical synthesis or other fabrication technology, rather than on fundamental properties of the material. (On the contrary, the carrier mobility \( \mu \) in these materials is almost technology-independent.)

---

\(^9\) Note that \( j \) is usually defined as a macroscopic variable, by taking the area \( dA \) in Eq. (2) much larger than the square of inter-particle distances, so that no additional average sign is necessary in Eq. (13a).

\(^{10}\) For such a discussion see, e.g., SM Sec. 6.3.

\(^{11}\) The electrodynamic properties of superconductors are so interesting (and fundamentally important) that I will discuss them in more detail in Chapter 6.
The practical importance of the fabrication technology may be illustrated by the following example. In the cells of the so-called floating-gate memories, in particular the flash memories, which currently dominate the nonvolatile digital memory technology, data bits are stored as small electric charges \( Q \sim 10^{-16} \text{ C} \sim 10^3 e \) of highly doped silicon islands (so-called floating gates) separated from the rest of the integrated circuit with a ~10-nm-thick layer of the silicon dioxide, \( \text{SiO}_2 \). Such layers are fabricated by high-temperature oxidation of virtually perfect silicon crystals. The conductivity of the resulting high-quality (though amorphous) material is so low, \( \sigma \sim 10^{-19} \text{ S/m} \), that the relaxation time \( \tau_r \), defined by Eq. (10), is well above 10 years – the industrial standard for data retention in nonvolatile memories. In order to appreciate how good this technology is, the cited value should be compared with the typical conductivity \( \sigma \sim 10^{-16} \text{ S/m} \) of the usual, bulk \( \text{SiO}_2 \) ceramics.\(^{12}\)

4.3. Boundary problems

For an Ohmic conducting medium, we may combine Eqs. (6) and (8) to get the following differential equation

\[
\nabla \cdot (\sigma \nabla \phi) = 0. \tag{4.14}
\]

For a uniform conductor (\( \sigma = \text{const} \)), Eq. (14) is reduced to the Laplace equation for the electrostatic potential \( \phi \). As we already know from Chapters 2 and 3, its solution depends on the boundary conditions. These conditions depend on the interface type.

(i) Conductor-conductor interface. Applying the continuity equation (6) to a Gauss-type pillbox at the interface of two different conductors (Fig. 5), we get

\[
(n \mathbf{j})_1 = (n \mathbf{j})_2, \tag{4.15}
\]

so that if the Ohm law (8) is valid inside each medium, then

\[
\sigma_1 \frac{\partial \phi_1}{\partial n} = \sigma_2 \frac{\partial \phi_2}{\partial n}. \tag{4.16}
\]

Also, since the electric field should be finite, its potential \( \phi \) has to be continuous across the interface – the condition that may also be written as

\[
\]

\[^{12}\] This course is not an appropriate platform to discuss details of the floating-gate memory technology. However, I think that every educated physicist should know its basics, because such memories are presently the driver of all semiconductor integrated circuit technology development, and hence of the whole information technology progress. Perhaps the best available book on this topic is the review collection by J. Brewer and M. Gill (eds.), Nonvolatile Memory Technologies with Emphasis on Flash, IEEE Press, 2008.
Both these conditions (and hence the solutions of the boundary problems using them) are similar to those for the interface between two dielectrics – cf. Eqs. (3.46)-(3.47). Note that using the Ohm law, Eq. (17) may be rewritten as
\[
\frac{1}{\sigma_1}(j_1) = \frac{1}{\sigma_2}(j_2).
\] (4.18)

Comparing it with Eq. (15) we see that, generally, the current density’s magnitude changes at the interface: \( j_1 \neq j_2 \). It is also curious that if \( \sigma_1 \neq \sigma_2 \), the current line slope changes at the interface (Fig. 5), qualitatively similar to the refraction of light rays in optics – see Chapter 7.

(ii) Conductor-electrode interface. An electrode is defined as a body made of a “perfect conductor”, i.e. of a medium with \( \sigma \to \infty \). Then, at a fixed current density at the interface, the electric field in the electrode tends to zero, and hence it may be described by the equality
\[
\phi = \phi_j = \text{const}, \quad (4.19)
\]
where constants \( \phi_j \) may be different for different electrodes (numbered with index \( j \)). Note that with such boundary conditions, the Laplace boundary problem becomes exactly the same as in electrostatics – see Eq. (2.35) – and hence we can use all the methods (and some solutions :-) of Chapter 2 for finding the dc current distribution.

(iii) Conductor-insulator interface. For the description of an insulator, we can use \( \sigma = 0 \), so that Eq. (16) yields the following boundary condition,
\[
\frac{\partial \phi}{\partial n} = 0, \quad (4.20)
\]
for the potential derivative inside the conductor. From the Ohm law (8) in the form \( \mathbf{j} = -\sigma \mathbf{V} \phi \), we see that this is just the very natural requirement for the dc current not to flow into an insulator. Now note that this condition makes the Laplace problem inside the conductor completely well-defined, and independent on the potential distribution in the adjacent insulator. On the contrary, due to the continuity of the electrostatic potential at the border, its distribution inside the surrounding insulator has to follow that inside the conductor.

Let us discuss this conceptual issue on the following (apparently, trivial) example: dc current in a uniform wire of length \( l \) and a cross-section of area \( A \). The reader certainly knows the answer:
\[
I = \frac{V}{R}, \quad \text{where } R = \frac{V}{I} = \frac{l}{\sigma A}, \quad (4.21)
\]
where the constant \( R \) is called the resistance.\(^{13}\) However, let us derive this result formally from our theoretical framework. For the simple geometry shown in Fig. 6a, this is easy to do. Here the potential evidently has a linear 1D distribution

\(^{13}\) The first of Eqs. (21) is essentially the (historically, initial) integral form of the Ohm law, and is valid not only for a uniform wire, but also for any Ohmic conductor with any geometry in that \( I \) and \( V \) may be clearly defined.
both in the conductor and the surrounding free space, with both boundary conditions (16) and (17) satisfied at the conductor-insulator interfaces, and the condition (20) satisfied at the conductor-electrode interfaces. As a result, the electric field is constant and has only one component \( E_x = \frac{V}{l} \), so that inside the conductor

\[ j_x = \sigma E_x, \quad I = j_x A, \quad (4.23) \]
giving us the well-known Eq. (21).

However, what about the geometry shown in Fig. 6b? In this case, the field distribution in the free space around the conductor is dramatically different, but according to the boundary problem defined by Eqs. (14) and (20), inside the conductor the solution is exactly the same as it was in the former case. Now, the Laplace equation in the surrounding insulator has to be solved with the boundary values of the electrostatic potential, “dictated” by the distribution of the current (and hence potential) in the conductor. Note that as the result, the electric field lines are generally not normal to the conductor’s surface, because the surface is not equipotential.

Let us solve a problem in that this conduction hierarchy may be followed analytically to the very end. Consider an empty spherical cavity cut in a conductor with an initially uniform current flow with a constant density \( j_0 = n_x j_0 \) (Fig. 7a). Following the hierarchy, we have to solve the boundary problem in the conducting part of the system, i.e. outside the sphere \( r \geq R \), first. Since the problem is evidently axially-symmetric, we already know the general solution of the Laplace equation – see Eq. (2.172). Moreover, we know that in order to match the uniform field distribution at \( r \to \infty \), all coefficients \( a_i \) but one \((a_1 = -E_0 = -j_0/\sigma)\) have to be zero, and that the boundary conditions at \( r = R \) will give zero solutions for all coefficients \( b_i \) but one \((b_1)\), so that

\[ \phi = -\frac{j_0}{\sigma} r \cos \theta + \frac{b_1}{r^2} \cos \theta, \quad \text{for} \quad r \geq R. \quad (4.24) \]

In order to find the coefficient \( b_1 \), we have to use the boundary condition (20) at \( r = R \):

\[ \phi = \frac{V}{l}. \]
\[ \frac{\partial \phi}{\partial r} \bigg|_{r=R} = \left( -\frac{j_0}{\sigma} - \frac{2h}{R^3} \right) \cos \theta = 0. \]  

(4.25)

This gives \( b_1 = -j_0 R^3/2 \sigma \), so that, finally,

\[ \phi(r,\theta) = -\frac{j_0}{\sigma} \left( r + \frac{R^3}{2 r^2} \right) \cos \theta, \quad \text{for } r \geq R. \]  

(4.26)

(Note that this potential distribution corresponds to the dipole moment \( p = -E_0 R^3/2 \). It is straightforward to check that if the spherical cavity was cut in a dielectric, the potential distribution outside it would be similar, with \( p = -E_0 R^3(\kappa - 1)/(\kappa + 2) \). In the limit \( \kappa \to \infty \), these two results coincide, despite the rather different type of the problem: in the dielectric case, there is no current at all.)

Fig. 4.7. A spherical cavity cut in a uniform conductor: (a) the problem’s geometry, and (b) the equipotential surfaces as given by Eqs. (26) and (28).

Now, as the second step in the conductivity hierarchy, we may find the electrostatic potential distribution \( \phi(r,\theta) \) in the insulator, in this particular case inside the empty cavity \( r \leq R \). It should also satisfy the Laplace equation with the boundary values at \( r = R \), “dictated” by the distribution (26):

\[ \phi(R,\theta) = -\frac{3}{2} \frac{j_0}{\sigma} R \cos \theta. \]  

(4.27)

We could again solve this problem by the formal variable separation (keeping in the general solution (2.172) only the term proportional to \( a_n \), which does not diverge at \( r \to 0 \)), but if we notice that the boundary condition (27) depends on just one Cartesian coordinate, \( z = R \cos \theta \), the solution may be just guessed:

\[ \phi(r,\theta) = -\frac{3}{2} \frac{j_0}{\sigma} z = -\frac{3}{2} \frac{j_0}{\sigma} r \cos \theta, \quad \text{at } r \leq R. \]  

(4.28)

Indeed, it evidently satisfies the Laplace equation and the boundary condition (27), and corresponds to a constant electric field parallel to the vector \( j_0 \), and equal to \( 3j_0/2 \sigma \) – see Fig. 7b. Again, the cavity surface it not equipotential, and the electric field lines at \( r \leq R \) are not normal to it at almost all points.
The conductivity hierarchy says that static electrical fields and charges outside conductors (e.g., electric wires) do not affect currents flowing in the wires, and it is physically very clear why. For example, if a charge in the free space is slowly moved close to a wire, it (in accordance with the linear superposition principle) will only induce an additional surface charge (see Sec. 2.1) that screens the external charge’s field, without participating in the current flow inside the conductor.

Besides this conceptual issue, the two examples given above may be considered as applications of the first two methods discussed in Chapter 2 (the orthogonal coordinates (Fig. 6) and the variable separation (Fig. 7)) to dc current distribution problems. If we have a glance at other methods discussed in that chapter, we may notice that there is also an analog of the method of charge images. Indeed, let us consider the spherically-symmetric potential distribution of the electrostatic potential, similar to that given by the basic Eq. (1.35):

\[ \phi = \frac{c}{r}. \]  

(4.29)

As we know from Chapter 1, this is a particular solution of the 3D Laplace equation at all points but \( r = 0 \). In the free space, this distribution would correspond to a point charge \( q = 4\pi\varepsilon_0c \); but what about a uniform conductor? Calculating the corresponding electric field and current density,

\[ \mathbf{E} = -\nabla \phi = \frac{c}{r^3} \mathbf{r}, \quad \mathbf{j} = \sigma \mathbf{E} = \sigma \frac{c}{r^3} \mathbf{r}, \]  

(4.30)

we see that the total current flowing from the origin through a sphere of an arbitrary radius \( r \) does not depend on the radius:

\[ I = Aj = 4\pi r^2 j = 4\pi\sigma c. \]  

(4.31)

Plugging the resulting coefficient \( c \) into Eq. (29), we get

\[ \phi = \frac{I}{4\pi\sigma r}. \]  

(4.32)

Hence the Coulomb-type distribution of the electric potential in a conductor is possible (at least at some distance from the singular point \( r = 0 \)), and describes the dc current \( I \) flowing out of a small-size electrode – or into such an electrode, if the coefficient \( c \) is negative. Such current injection may be readily implemented experimentally; think for example about an insulated wire with a small bare end, inserted into a poorly conducting soil – an important method in geophysical research.\(^{14}\)

Now let the current injection point \( r' \) be close to a plane interface between the conductor and an insulator (Fig. 8). In this case, besides the Laplace equation, we should satisfy the boundary condition,

\[ n_\mathbf{j} = \sigma E_n = -\sigma \frac{\partial \phi}{\partial n} = 0, \]  

(4.33)

at the interface. It is clear that this can be done by replacing the insulator with an imaginary similar conductor with an additional current injection point, at the mirror image point \( r'' \). Note, however, that in contrast to the charge images, the sign of the imaginary current has to be similar, not opposite, to the initial one, so that the total electrostatic potential inside the conducting semi-space is

---

\(^{14}\) Such injection is even simpler in 2D situations – think about a wire soldered, in a small spot, to a thin conducting foil. (Note only that here the current density distribution law is different, \( j \propto 1/r \) rather than \( 1/r^2 \).)
\[ \phi(r) = \frac{I}{4\pi\sigma} \left( \frac{1}{|r - r'|} + \frac{1}{|r - r''|} \right). \] (4.34)

(The image current’s sign would be opposite at the interface between a conductor with a moderate conductivity and a perfect conductor (“electrode”), whose potential should be virtually constant.)

This result may be readily used, for example, to calculate the current density at a plane surface of a uniform conductor, as a function of distance \( \rho \) from point 0 (the surface’s point closest to the current injection site) – see Fig. 8. At such surface, Eq. (34) yields

\[ \phi = \frac{I}{2\pi\sigma \left( \rho^2 + d^2 \right)^{3/2}}, \] (4.35)

so that the current density is:

\[ j_\rho = \sigma E_\rho = -\sigma \frac{\partial \phi}{\partial \rho} = \frac{I}{2\pi \left( \rho^2 + d^2 \right)^{3/2}}. \] (4.36)

Deviations from Eqs. (35) and (36) may be used to find and characterize conductance inhomogeneities, say, those due to mineral deposits in the Earth’s crust.15

4.4. Energy dissipation

Let me conclude this brief chapter with an ultra-short discussion of energy dissipation in conductors. In contrast to the electrostatics situations in insulators (vacuum or dielectrics), at dc conduction the electrostatic energy \( U \) is “dissipated” (i.e. transferred to heat) at a certain rate \( \mathcal{P} \equiv -dU/dt \), with the dimensionality of power.16 This so-called dissipation may be evaluated by calculating the power of the electric field’s work on a single moving charge:

\[ \mathcal{P} = \mathbf{F} \cdot \mathbf{v} = q \mathbf{E} \cdot \mathbf{v}. \] (4.37)

15 The current injection may be also produced, due to electrochemical reactions, by an ore mass itself, so that one need only measure (and correctly interpret :-) the resulting potential distribution – the so-called self-potential method – see, e.g., Sec. 6.1 in W. Telford et al., Applied Geophysics, 2nd ed., Cambridge U. Press, 1990.

16 Since the electric field and hence the electrostatic energy are time-independent, this means that the energy is replenished at the same rate from the current source(s).
After the summation over all charges, Eq. (37) gives us the dissipation power. If the charge density $n$ is uniform, multiplying by it both parts of this relation, and taking into account that $qn = j$, for the energy dissipation in a unit volume we get the differential form of the Joule law\(^{17}\)

$$\rho \equiv \frac{\mathcal{P}}{V} = \frac{\mathcal{P}_n}{V} = qE \cdot v = E \cdot j. \quad (4.38)$$

In the case of the Ohmic conductivity (8), this expression may be also rewritten in two other forms:

$$\rho = \sigma E^2 = \frac{j^2}{\sigma}. \quad (4.39)$$

At the dc conduction, the electrostatic energy has to be permanently replenished by an equal flow of power from the current source(s). With our electrostatics background, it is also straightforward (and hence left for the reader’s exercise) to prove that the dc current distribution in a uniform Ohmic conductor, at a fixed voltage applied at its borders, corresponds to the minimum of the total dissipation in it,

$$\mathcal{P} = \int \rho d^3r = \sigma \int E^2 d^3r. \quad (4.40)$$

4.5. Exercise problems

4.1. DC voltage $V_0$ is applied to the end of a semi-infinite chain of lumped Ohmic resistors, shown in the figure on the right. Calculate the voltage across the $j^{th}$ link of the chain.

4.2. It is well known that properties of many dc current sources (e.g., batteries) may be reasonably well represented as a connection in series of a perfect voltage source and an Ohmic internal resistance. Discuss the option, and possible advantages, of using a different equivalent circuit that would include a perfect current source.

4.3. Calculate the resistance between two large, uniform Ohmic conductors separated with a very thin, plane, insulating partition, with a circular hole of radius $R$ in it – see the figure on the right.

*Hint:* You may like to use the degenerate ellipsoidal coordinates, which had been discussed in Sec. 2.4.

4.4. Calculate the effective (average) conductivity $\sigma_{ef}$ of a medium with many empty spherical cavities of radius $R$, carved at random positions in a uniform Ohmic conductor (see the figure on the right), in the limit of a low density $n \ll R^{-3}$ of the spheres.

*Hint:* Try to use the analogy with a dipole medium – see, e.g., Sec. 3.2.

\(^{17}\) Named after James Prescott Joule, who quantified this effect in 1841.
4.5. In two separate experiments, a narrow gap, possibly of irregular width, between two close metallic electrodes is filled with some material – in the first case, with a uniform linear insulator with an electric permittivity \( \varepsilon \), and in the second case, with a uniform conducting material with an Ohmic conductivity \( \sigma \). Neglecting the fringe effects, calculate the relation between the mutual capacitance \( C \) between the electrodes (in the first case) and the dc resistance \( R \) between them (in the second case).

4.6. Calculate the voltage \( V \) across a uniform, wide resistive slab of thickness \( t \), at distance \( l \) from the points of injection/pickup of the dc current \( I \) passed across the slab – see the figure on the right.

4.7. Calculate the voltage \( V \) between two corners of a square cut from a uniform, resistive sheet of a very small thickness \( t \), induced by dc current \( I \) that is passed between its two other corners – see the figure on the right.

4.8. Calculate the distribution of the dc current’s density in a thin, round, uniform resistive disk, if the current is inserted into a point at its rim, and picked up at the center.

4.9. The simplest reasonable model of a vacuum diode consists of two plane, parallel metallic electrodes of area \( A \), separated by a gap of thickness \( d \ll A^{1/2} \): a “cathode” that emits electrons to vacuum, and an “anode” that absorbs the electrons arriving at its surface. Calculate the dc \( I-V \) curve of the diode, i.e. the stationary relation between the current \( I \) flowing between the electrodes and the voltage \( V \) applied between them, using the following simplifying assumptions:

(i) due to the effect of the negative space charge of the emitted electrons, the current \( I \) is much smaller than the emission ability of the cathode,
(ii) the initial velocity of the emitted electrons is negligible, and
(iii) the direct Coulomb interaction of electrons (besides the space charge effect) is negligible.

4.10. Calculate the space-charge-limited current in a system with the same geometry, and using the same assumptions as in the previous problem, besides that now the emitted charge carriers move not ballistically, but drift in accordance with the Ohm law, with the conductivity given by Eq. (4.13): \( \sigma = q^2 \mu n \), with a constant mobility \( \mu \). \(^{18}\)

*Hint:* In order to get a realistic result, assume that the medium in that the charge carriers move has a certain dielectric constant \( \kappa \), unrelated to the carriers.

4.11. Prove that the distribution of dc currents in a uniform Ohmic conductor, at a fixed voltage applied at its boundaries, corresponds to the minimum of the total power dissipation (“Joule heat”).

---

\(^{18}\) As was mentioned in Sec. 2, the assumption of a constant (charge-density-independent) mobility is most suitable for semiconductors.
Chapter 5. Magnetism

Even though this chapter addresses a completely new type of electric charge interactions, its discussion (for the stationary case) will take not too much time/space, because it recycles many ideas and methods of electrostatics, though with a twist or two.

5.1. Magnetic interaction of currents

DC currents in conductors usually leave them electroneutral, \( \rho(\mathbf{r}) = 0 \), with very good precision, because even a minute misbalance of positive and negative charge density results in extremely strong Coulomb forces that restore their balance by an additional shift of free charge carriers.¹ This is why let us start the discussion of magnetic interactions from the simplest case of two spatially-separated, current-carrying, electroneutral conductors (Fig. 1).

According to the Coulomb law, there is no electrostatic force between them. However, several experiments carried out in 1820² proved that there is a different, magnetic interaction between the currents. In the present-day notation, the results of such experiments may be summarized with just one formula, in SI units expressed as:

\[
\mathbf{F} = -\frac{\mu_0}{4\pi} \int d^3 r \int d^3 r' (\mathbf{j}(\mathbf{r}) \cdot \mathbf{j}'(\mathbf{r}')) \frac{\mathbf{r} - \mathbf{r}'}{|\mathbf{r} - \mathbf{r}'|^3}.
\]

Here the coefficient \( \mu_0/4\pi \) (where \( \mu_0 \) is called either the magnetic constant or the free space permeability) equals to almost exactly \( 10^{-7} \) SI units, with the product \( \varepsilon_0\mu_0 \) equal to exactly \( 1/c^2 \).

Note an almost complete similarity of this expression to the Coulomb law (1.1), written for continuous charge distributions, with the account of the linear superposition principle (1.4):

¹ The most important case when the electroneutrality does not hold is the motion of electrons in vacuum. In this case, the magnetic forces we are going to discuss coexist with (typically, stronger) electrostatic forces – see Eq. (3) below and its discussion. In some semiconductor devices, local violations of electroneutrality also play an important role – see, e.g., SM Chapter 6.
² Most notably, by Hans Christian Ørsted who discovered the effect of an electric current on a magnetic needle, and André-Marie Ampère who has extended this work by finding the magnetic interaction between two currents.
³ See appendix CA: Selected Physical Constants. In the Gaussian units, the coefficient \( \mu_0/4\pi \) is replaced with \( 1/c^2 \) – i.e., implicitly with \( \mu_0\varepsilon_0 \).
Besides the different coefficient and a different sign, the “only” difference of Eq. (1) from Eq. (2) is the scalar product of current densities, evidently necessary because of their vector character. We will see that this difference brings certain complications in applying the approaches discussed in the previous chapters, to magnetostatics.

Before going to their discussion, let us have one more glance at the coefficients in Eqs. (1) and (2). To compare them, let us consider two objects with uncompensated charge distributions \( \rho(r) \) and \( \rho'(r) \), each moving parallel to each other as a whole, with certain velocities \( v \) and \( v' \), as measured in the same inertial (“laboratory”) frame. In this case, \( j(r) = \rho(r)v \), so that \( j(r) \cdot j'(r) = \rho(r)\rho'(r)vv' \), and the integrals in Eqs. (1) and (2) become functionally similar, and differ only by the factor

\[
\frac{F_{\text{magnetic}}}{F_{\text{electric}}} = \frac{-\mu_0 vv'}{4\pi \frac{1}{4\pi\varepsilon_0}} \equiv -\frac{vv'}{\varepsilon_0}. 
\]

(The last expression is valid in any consistent system of units.) We immediately see that the magnetism is an essentially relativistic phenomenon, very weak in comparison with the electrostatic interaction at the human scale velocities, \( v \ll c \), and may dominate only if the latter interaction vanishes – as it does in electroneutral systems. The discovery and initial studies\(^4\) of such a subtle, relativistic phenomenon as magnetism were much facilitated by the relative abundance of natural ferromagnets, materials with a spontaneous magnetic polarization, whose strong magnetic field is due to relativistic effects (such as spin) in the constituent atoms – see Sec. 5 below.

Also, Eq. (3) points at an interesting paradox. Consider two electron beams moving parallel to each other, with the same velocity \( v \) with respect to a lab reference frame. Then, according to Eq. (3), the net force of their total (electric plus magnetic) interaction is proportional to \( (1 - v^2/c^2) \), and tends to zero in the limit \( v \to c \). However, in the reference frame moving together with the electrons, they are not moving at all, i.e. \( v = 0 \). Hence, from the point of view of such a moving observer, the electron beams should interact only electrostatically, with a repulsive force independent of the velocity \( v \). Historically, this had been one of several paradoxes that led to the development of the special relativity; its resolution will be discussed in Chapter 9, devoted to this theory.

Returning to Eq. (1), in some simple cases the double integration in it may be carried out analytically. First of all, let us simplify this expression for the case of two thin, long conductors (“wires”) separated by a distance much larger than their thickness. In this case, we may integrate the products \( j d^3r \) and \( j' d^3r' \) over wires’ cross-sections first, neglecting the corresponding change of the factor \( (r - r') \). Since the integrals of the current density over the cross-sections of the wires are just the currents \( I \) and \( I' \) flowing in the wires, and cannot change along their lengths (say, \( l \) and \( l' \), respectively), they may be taken out of the remaining integrals, reducing Eq. (1) to

\[
F = \frac{-\mu_0 II'}{4\pi} \oint \oint_L (dr \cdot dr') \frac{r - r'}{|r - r'|^3}. 
\]
As the simplest example, consider two straight, parallel wires (Fig. 2), separated by distance $d$, with length $l \gg d$.

In this case, due to symmetry, the vector of the magnetic interaction force has to:

(i) lie in the same plane as the currents, and
(ii) be perpendicular to the wires – see Fig. 2.

Hence we may limit our calculations to just one component of the force, normal to the wires. Using the fact that with the coordinate choice shown in Fig. 2, the scalar product $dr \cdot dr'$ is just $dx dx'$, we get

$$F = -\frac{\mu_0 I'I}{4\pi} \int_{-\infty}^{\infty} dx \int_{-\infty}^{\infty} dx' \frac{\sin \theta}{d^2 + (x-x')^2} = -\frac{\mu_0 I'I}{4\pi} \int_{-\infty}^{\infty} dx \int_{-\infty}^{\infty} dx' \frac{d}{[d^2 + (x-x')^2]^{3/2}}. \quad (5.5)$$

Introducing, instead of $x'$, a new, dimensionless variable $\xi \equiv (x-x')/d$, we may reduce the internal integral to a table integral which we have already met in this course:

$$F = -\frac{\mu_0 I'I}{4\pi d} \int_{-\infty}^{\infty} dx \int_{-\infty}^{\infty} \frac{d\xi}{1 + \xi^2} \equiv -\frac{\mu_0 I'I}{2\pi d} \int_{-\infty}^{\infty} dx. \quad (5.6)$$

The integral over $x$ formally diverges, but it gives a finite interaction force per unit length of the wires:

$$\frac{F}{l} = -\frac{\mu_0 I'}{2\pi d}. \quad (5.7)$$

Note that the force drops rather slowly (only as $1/d$) as the distance $d$ between the wires is increased, and is attractive (rather than repulsive as in the Coulomb law) if the currents are of the same sign.

This is an important result, but again, the problems so simply solvable are few and far between, and it is intuitively clear that we would strongly benefit from the same approach as in electrostatics, i.e., from breaking Eq. (1) into a product of two factors via the introduction of a suitable field. Such decomposition may be done as follows:

$$F = \int_y j(r) \times B(r) d^3r, \quad (5.8)$$

---

5 In particular, until very recently (2018), Eq. (7) was used for the legal definition of the SI unit of current, one ampere (A), via the SI unit of force (the newton, N), with the coefficient $\mu_0$ considered exactly fixed.
where the vector \( \mathbf{B} \) is called the \textit{magnetic field}\(^6\). In our particular case, it is induced by the current \( j' \):

\[
\mathbf{B}(\mathbf{r}) \equiv \frac{\mu_0}{4\pi} \int j'(\mathbf{r}') \times \frac{\mathbf{r} - \mathbf{r}'}{|\mathbf{r} - \mathbf{r}'|^3} d^3r'.
\] (5.9)

The last relation is called the \textit{Biot-Savart law},\(^7\) while the force \( \mathbf{F} \) expressed by Eq. (8) is sometimes called the \textit{Lorentz force}.\(^8\) However, more frequently the latter term is reserved for the full force,

\[
\mathbf{F} = q(\mathbf{E} + \mathbf{v} \times \mathbf{B}),
\] (5.10)

exerted by electric and magnetic fields field on a point charge \( q \), moving with velocity \( \mathbf{v} \).\(^9\)

Now we have to prove that the new formulation, given by Eqs. (8)-(9), is equivalent to Eq. (1). At the first glance, this seems unlikely. Indeed, first of all, Eqs. (8) and (9) involve vector products, while Eq. (1) is based on a scalar product. More profoundly, in contrast to Eq. (1), Eqs. (8) and (9) do not satisfy the 3\(^{rd}\) Newton’s law, if applied to elementary current components \( j d^3r \) and \( j' d^3r' \), if these vectors are not parallel to each other. Indeed, consider the situation shown in Fig. 3.

![Fig. 5.3. The apparent violation of the 3\(^{rd}\) Newton law in magnetism.](image)

Here the vector \( j' \) is perpendicular to the vector \( (\mathbf{r} - \mathbf{r}') \), and hence, according to Eq. (9), produces a non-zero contribution \( dB' \) to the magnetic field, directed (in Fig. 3) normally to the plane of the drawing, i.e. is perpendicular to the vector \( \mathbf{j} \). Hence, according to Eq. (8), this field provides a non-zero contribution to \( \mathbf{F} \). On the other hand, if we calculate the reciprocal force \( \mathbf{F}' \) by swapping the prime indices in Eqs. (8) and (9), the latter equation immediately shows that \( dB'(\mathbf{r}) \propto j(\mathbf{r}' - \mathbf{r}) = 0 \), because the two operand vectors are parallel – see Fig. 3 again. Hence, the current component \( j' d^3r' \) does exert a force on its counterpart, while \( j d^3r \) does not.

---

6. The SI unit of the magnetic field is called \textit{tesla} (T) – after Nikola Tesla, a pioneer of electrical engineering. In the Gaussian units, the already discussed constant \( 1/c^2 \) in Eq. (1) is equally divided between Eqs. (8) and (9), so that in them both, the constant before the integral is \( 1/c \). The resulting Gaussian unit of the field \( \mathbf{B} \) is called \textit{gauss} (G); taking into account the difference of units of electric charge and length, and hence of the current density, 1 G equals exactly \( 10^{-4} \) T. Note also that in some textbooks, especially old ones, \( \mathbf{B} \) is called either the \textit{magnetic induction} or the \textit{magnetic flux density}, while the term “magnetic field” is reserved for the field \( \mathbf{H} \) that will be introduced in Sec. 5 below.

7. Named after Jean-Baptiste Biot and Félix Savart who made several key contributions to the theory of magnetic interactions – in the same notorious 1820.

8. Named after Hendrik Antoon Lorentz, famous mostly for his numerous contributions to the development of special relativity – see Chapter 9 below. To be fair, the magnetic part of the Lorentz force was implicitly described in a much earlier (1865) paper by J. C. Maxwell, and then spelled out by Oliver Heaviside (another genius of electrical engineering – and mathematics!) in 1889, i.e. also before the 1895 work by H. Lorentz.

9. From the magnetic part of Eq. (10), Eq. (8) may be derived by the elementary summation of all forces acting on \( n \gg 1 \) particles in a unit volume, with \( j = qn\mathbf{v} \) – see the footnote on Eq. (4.13a). On the other hand, the reciprocal derivation of Eq. (10) from Eq. (8) with \( j = qn\mathbf{v}(\mathbf{r} - \mathbf{r}_0) \), where \( \mathbf{r}_0 \) is the current particle’s position (so that \( d\mathbf{r}_0/dt = \mathbf{v} \)), requires care, and will be performed in Chapter 9.
Despite this apparent problem, let us still go ahead and plug Eq. (9) into Eq. (8):

\[
F = \frac{\mu_0}{4\pi} \int \int d^3r' \frac{j(r) \times j'(r') \times \frac{r - r'}{|r - r'|^3}}{r'.}
\]

(5.11)

This double vector product may be transformed into two scalar products, using the vector algebraic identity called the \textit{bac minus cab rule}, \(a \times (b \times c) = b(a \cdot c) - c(a \cdot b).\) \(^{10}\) Applying this relation, with \(a = j, b = j',\) and \(c = R \equiv r - r',\) to Eq. (11), we get

\[
F = \frac{\mu_0}{4\pi} \int \int d^3r' j'(r') \left( \int \frac{d^3r \frac{j(r) \cdot R}{R^3}}{r'} \right) - \frac{\mu_0}{4\pi} \int \int d^3r' \frac{j(r) \cdot j'(r')}{R^3} R.
\]

(5.12)

The second term on the right-hand side of this relation coincides with the right-hand side of Eq. (1), while the first term equals zero, because its the internal integral vanishes. Indeed, we may break the volumes \(V\) and \(V'\) into narrow \textit{current tubes} – the stretched elementary volumes whose walls are not crossed by current lines (so that on their walls, \(j_n = 0\)). As a result, the elementary current in each tube, \(dl = jdA = jd^2r,\) is the same along its length, and, just as in a thin wire, \(jd^2r\) may be replaced with \(dldr,\) with the vector \(dr\) directed along \(j.\) Because of this, each tube’s contribution to the internal integral in the first term of Eq. (12) may be represented as

\[
dl \int \frac{d^3r \cdot R}{R^3} = -dl \int \frac{d^3r \cdot \nabla \frac{1}{R}}{R} = -dl \int \frac{d^3r}{R^3} \frac{\partial}{\partial r} \frac{1}{R},
\]

(5.13)

where the operator \(\nabla\) acts in the \(r\) space, and the integral is taken along tube’s length \(l.\) Due to the current continuity, each loop should follow a closed contour, and an integral of a full differential of some scalar function (in our case, \(1/r_{12}\)) along such contour equals zero.

So we have recovered Eq. (1). Returning for a minute to the paradox illustrated with Fig. 3, we may conclude that the apparent violation of the 3rd Newton law was the artifact of our interpretation of Eqs. (8) and (9) as the sums of independent elementary components. In reality, due to the de current continuity expressed by Eq. (4.6), these components are \textit{not} independent. For the whole currents, Eqs. (8)-(9) do obey the 3rd law – as follows from their already proved equivalence to Eq. (1).

Thus we have been able to break the magnetic interaction into the two effects: the induction of the magnetic field \(B\) by one current (in our notation, \(j'\)), and the effect of this field on the other current (\(j\)). Now comes an additional experimental fact: other elementary components \(jd^3r'\) of the current \(j(r)\) also contribute to the magnetic field (9) acting on the component \(jd^3r.\) \(^{11}\) This fact allows us to drop the prime sign after \(j\) in Eq. (9), and rewrite Eqs. (8) and (9) as

\[
B(r) = \frac{\mu_0}{4\pi} \int \frac{j(r') \times \frac{r - r'}{|r - r'|^3}}{r'} d^3r',
\]

(5.14)

\[
F = \int j(r) \times B(r) d^3r,
\]

(5.15)

\(^{10}\) See, e.g., MA Eq. (7.5).

\(^{11}\) Just in electrostatics, one needs to exercise due caution at a transfer from these expressions to the limit of discrete classical particles, and extended wavefunctions in quantum mechanics, to avoid the (non-existing) magnetic interaction of a charged particle with itself.
Again, the field observation point \( \mathbf{r} \) and the field source point \( \mathbf{r}' \) have to be clearly distinguished. We immediately see that these expressions are similar to, but still different from the corresponding relations of the electrostatics, namely Eq. (1.9) and the distributed-charge version of Eq. (1.6):

\[
\mathbf{E}(\mathbf{r}) = \frac{1}{4\pi\varepsilon_0} \oint_{\mathbf{r}'} \rho(\mathbf{r}') \frac{\mathbf{r} - \mathbf{r}'}{|\mathbf{r} - \mathbf{r}'|^3} d^3r', \tag{5.16}
\]

\[
\mathbf{F} = \oint_{\mathbf{r}'} \rho(\mathbf{r}) \mathbf{E}(\mathbf{r}) d^3r. \tag{5.17}
\]

(Note that the sign difference has disappeared, at the cost of the replacement of scalar-by-vector multiplications in electrostatics with cross-products of vectors in magnetostatics.)

For the frequent case of a field of a thin wire of length \( l' \), Eq. (14) may be re-written as

\[
\mathbf{B}(\mathbf{r}) = \frac{\mu_0 I}{4\pi} \oint_{\mathbf{r}'} d\mathbf{r}' \times \frac{\mathbf{r} - \mathbf{r}'}{|\mathbf{r} - \mathbf{r}'|^3}. \tag{5.18}
\]

Let us see how does this formula work for the simplest case of a straight wire (Fig. 4a). The magnetic field contribution \( dB \) due to any small fragment \( d\mathbf{r}' \) of the wire’s length is directed along the same line (perpendicular to both the wire and the normal \( d \) dropped from the observation point to the wire’s line), and its magnitude is

\[
dB = \frac{\mu_0 I}{4\pi} \frac{dx'}{|\mathbf{r} - \mathbf{r}'|} \sin \theta = \frac{\mu_0 I}{4\pi} \frac{dx'}{(d^2 + x'^2)^{3/2}} d. \tag{5.19}
\]

Summing up all such elementary contributions, we get

\[
B = \frac{\mu_0 I \rho}{4\pi} \int_{-\infty}^{\infty} \frac{dx}{(x^2 + d^2)^{3/2}} = \frac{\mu_0 I}{2\pi d}. \tag{5.20}
\]

![Fig. 5.4. Calculating magnetic fields: (a) of a straight current, and (b) of a current loop.](image)

This is a simple but very important result. (Note that it is only valid for very long \( l' \gg d \), straight wires.) It is especially crucial to note the “vortex” character of the field: its lines go around the wire, forming rings with the centers on the current line. This is in the sharp contrast to the electrostatic field lines that can only begin and end on electric charges and never form closed loops (otherwise the Coulomb force \( q\mathbf{E} \) would not be conservative). In the magnetic case, the vortex field may be reconciled with the potential character of the magnetic forces, which is evident from Eq. (1), due to the vector products in Eqs. (14)-(15).
Now we may readily use Eq. (15), or rather its thin-wire version

$$ \mathbf{F} = I \oint \mathbf{dr} \times \mathbf{B}(\mathbf{r}) , $$

(5.21)

to apply Eq. (20) to the two-wire problem (Fig. 2). Since for the second wire vectors $\mathbf{dr}$ and $\mathbf{B}$ are perpendicular to each other, we immediately arrive at our previous result (7), which was obtained directly from Eq. (1).

The next important example of the application of the Biot-Savart law (14) is the magnetic field at the axis of a circular current loop (Fig. 4b). Due to the problem’s symmetry, the net field $\mathbf{B}$ has to be directed along the axis, but each of its components $d\mathbf{B}$ is tilted by the angle $\theta = \tan^{-1}(z/R)$ to this axis, so that its axial component

$$ dB_z = dB \cos \theta = \frac{\mu_0 I}{4\pi} \frac{dr'}{R^2 + z^2} \frac{R}{(R^2 + z^2)^{3/2}} . $$

(5.22)

Since the denominator of this expression remains the same for all wire components $dr'$, the integration over $r'$ is trivial ($\oint dr' = 2\pi R$), giving finally

$$ B = \frac{\mu_0 I}{2} \frac{R^2}{(R^2 + z^2)^{3/2}} . $$

(5.23)

Note that the magnetic field in the loop’s center (i.e., for $z = 0$),

$$ B = \frac{\mu_0 I}{2R} , $$

(5.24)

is $\pi$ times higher than that due to a similar current in a straight wire, at distance $d = R$ from it. This difference is readily understandable, since all elementary components of the loop are at the same distance $R$ from the observation point, while in the case of a straight wire, all its points but one are separated from the observation point by a distance larger than $d$.

Another notable fact is that at large distances ($z^2 >> R^2$), the field (23) is proportional to $z^3$:

$$ B \approx \frac{\mu_0 I}{2} \frac{R^2}{|z|^3} = \frac{\mu_0}{4\pi} \frac{2m}{|z|^3} , \quad \text{with} \quad m \equiv IA , $$

(5.25)

where $A = \pi R^2$ is the loop area. Comparing this expression with Eq. (3.13), for the particular case $\theta = 0$, we see that such field is similar to that of an electric dipole (at least along its direction), with the replacement of the electric dipole moment magnitude $p$ with $m$ (besides the front factor). Indeed such a plane current loop this is the simplest example of a system whose field, at distances much larger than $R$, is that of a magnetic dipole, with the dipole moment $m$ – the notions to be discussed in more detail in Sec. 4 below.

5.2. Vector potential and the Ampère law

The reader can see that the calculations of the magnetic field using Eq. (14) or (18) are still somewhat cumbersome even for the very simple systems we have examined. As we saw in Chapter 1, similar calculations in electrostatics, at least for several important systems of high symmetry, could be
substantially simplified using the Gauss law (1.16). A similar relation exists in magnetostatics as well, but has a different form, due to the vortex character of the magnetic field.

To derive it, let us notice that in an analogy with the scalar case, the vector product under the integral (14) may be transformed as

\[
\frac{j(r') \times (r - r')}{|r - r'|^3} = \nabla \times \frac{j(r')}{|r - r'|},
\]

(5.26)

where the operator \( \nabla \) acts in the \( r \) space. (This equality may be really verified by its Cartesian components, noticing that the current density is a function of \( r' \) and hence its components are independent of \( r \).) Plugging Eq. (26) into Eq. (14), and moving the operator \( \nabla \) out of the integral over \( r' \), we see that the magnetic field may be represented as the curl of another vector field – the so-called vector potential, defined as:\(^{12}\)

\[
B(r) = \nabla \times A(r),
\]

(5.27)  

and in our case equal to

\[
A(r) = \frac{\mu_0}{4\pi} \int \frac{j(r')}{|r - r'|} \, d^3r'.
\]

(5.28)

Please note a beautiful analogy between Eqs. (27)-(28) and, respectively, Eqs. (1.33) and (1.38). This analogy implies that the vector potential \( A \) plays, for the magnetic field, essentially the same role as the scalar potential \( \phi \) plays for the electric field (hence the name “potential”), with due respect to the vortex character of \( B \). This notion will be discussed in more detail below.

Now let us see what equations we may get for the spatial derivatives of the magnetic field. First, vector algebra says that the divergence of any curl is zero.\(^{13}\) In application to Eq. (27), this means that

\[
\nabla \cdot B = 0.
\]

(5.29)

Comparing this equation with Eq. (1.27), we see that Eq. (29) may be interpreted as the absence of a magnetic analog of an electric charge on which magnetic field lines could originate or end. Numerous searches for such hypothetical magnetic charges, called magnetic monopoles, using very sensitive and sophisticated experimental setups, have not given convincing evidence of their existence in Nature.

Proceeding to the alternative, vector derivative of the magnetic field (i.e., its curl), and using Eq. (28), we obtain

\[
\nabla \times B(r) = \frac{\mu_0}{4\pi} \nabla \times \left( \nabla \times \frac{j(r')}{|r - r'|} \, d^3r' \right).
\]

(5.30)

This expression may be simplified by using the following general vector identity:\(^{14}\)

\[
\nabla \times (\nabla \times c) = \nabla (\nabla \cdot c) - \nabla^2 c,
\]

(5.31)

applied to vector \( c(r) \equiv j(r')/|r - r'| \):

\(^{12}\) In the Gaussian units, Eq. (27) remains the same, and hence in Eq. (28), \( \mu_0/4\pi \) is replaced with \( 1/c \).

\(^{13}\) See, e.g., MA Eq. (11.2).

\(^{14}\) See, e.g., MA Eq. (11.3).
\[ \nabla \times \mathbf{B} = \frac{\mu_0}{4\pi} \nabla \int_{V'} \mathbf{j}(\mathbf{r}') \cdot \nabla \frac{1}{|\mathbf{r} - \mathbf{r}'|} d^3 r' - \frac{\mu_0}{4\pi} \int_{V'} \mathbf{j}(\mathbf{r}') \nabla^2 \frac{1}{|\mathbf{r} - \mathbf{r}'|} d^3 r'. \]  

(5.32)

As was already discussed during our study of electrostatics in Sec. 3.1,

\[ \nabla^2 \frac{1}{|\mathbf{r} - \mathbf{r}'|} = -4\pi \delta(\mathbf{r} - \mathbf{r}'), \]

(5.33)

so that the last term of Eq. (32) is just \( \mu_0 \mathbf{j}(\mathbf{r}) \). On the other hand, inside the first integral we can replace \( \nabla \) with \(-\nabla'\), where prime means differentiation in the space of radius-vector \( \mathbf{r}' \). Integrating that term by parts, we get

\[ \nabla \times \mathbf{B} = -\frac{\mu_0}{4\pi} \nabla \int_{S'} \int_{V'} \mathbf{j}(\mathbf{r}') \frac{1}{|\mathbf{r} - \mathbf{r}'|} d^2 r' + \nabla \int_{V'} \mathbf{j}'(\mathbf{r}') \frac{1}{|\mathbf{r} - \mathbf{r}'|} d^3 r' + \mu_0 \mathbf{j}(\mathbf{r}). \]

(5.34)

Applying this equality to the volume \( V' \) limited by a surface \( S' \) either sufficiently distant from the field concentration, or with no current crossing it, we may neglect the first term on the right-hand side of Eq. (34), while the second term always equals zero in statics, due to the dc charge continuity – see Eq. (4.6). As a result, we arrive at a very simple differential equation\(^{15}\)

\[ \nabla \times \mathbf{B} = \mu_0 \mathbf{j}. \]

(5.35)

This is (the dc form of) the inhomogeneous Maxwell equation – which in magnetostatics plays a role similar to Eq. (1.27) in electrostatics. Let me display, for the first time in this course, this fundamental system of equations (at this stage, for statics only), and give the reader a minute to stare, in silence, at their beautiful symmetry – which has inspired so much of the later physics development:

\[
\begin{align*}
\nabla \times \mathbf{E} &= 0, & \nabla \times \mathbf{B} &= \mu_0 \mathbf{j}, \\
\nabla \cdot \mathbf{E} &= \frac{\rho}{\varepsilon_0}, & \nabla \cdot \mathbf{B} &= 0.
\end{align*}
\]

(5.36)

Their only asymmetry, two zeros on the right-hand sides (for the magnetic field’s divergence and electric field’s curl), is due to the absence in Nature of magnetic monopoles and their currents. I will discuss these equations in more detail in Sec. 6.7, after the first two equations (for the fields’ curls) have been generalized to their full, time-dependent versions.

Returning now to our current, more mundane but important task of calculating the magnetic field induced by simple current configurations, we can benefit from an integral form of Eq. (35). For that, let us integrate this equation over an arbitrary surface \( S \) limited by a closed contour \( C \), and apply to the result the Stokes theorem\(^{16}\). The resulting expression,

\[ \oint_C \mathbf{B} \cdot d\mathbf{r} = \mu_0 \oint_S n_s d^2 r \equiv \mu_0 I, \]

(5.37)

where \( I \) is the net electric current crossing surface \( S \), is called the \textit{Ampère law}.

---

\(^{15}\) As in all earlier formulas for the magnetic field, in the Gaussian units the coefficient \( \mu_0 \) in this relation is replaced with \( 4\pi/c \).

\(^{16}\) See, e.g., MA Eq. (12.1) with \( f = \mathbf{B} \).
As the first example of its application, let us return to the current in a straight wire (Fig. 4a). With the Ampère law in our arsenal, we can readily pursue an even more ambitious goal than was achieved in the previous section – calculate the magnetic field both outside and inside of a wire of an arbitrary radius $R$, with an arbitrary (albeit axially-symmetric) current distribution $j(\rho)$ – see Fig. 5.

Selecting the Ampère-law contour $C$ in the form of a ring of some radius $\rho$ in the plane perpendicular to the wire axis $z$, we have $B \cdot d\mathbf{r} = B\rho \, d\varphi$, where $\varphi$ is the azimuthal angle, so that Eq. (37) yields:

$$2 \pi \rho B(\rho) = \mu_0 \times \begin{cases} 2 \pi \int_0^\rho j(\rho')\rho'\,d\rho', & \text{for } \rho \leq R, \\ 2 \pi \int_0^R j(\rho')\rho'\,d\rho' \equiv I, & \text{for } \rho \geq R. \end{cases}$$

Thus we have not only recovered our previous result (20), with the notation replacement $d \rightarrow \rho$, in a much simpler way, but could also find the magnetic field distribution inside the wire. In the most common case when the current is uniformly distributed along its cross-section, $j(\rho) = \text{const}$, the first of Eqs. (38) immediately yields $B \propto \rho$ for $\rho \leq R$.

Another important system is a straight, long solenoid (Fig. 6a), with dense winding: $n^2A >> 1$, where $n$ is the number of wire turns per unit length, and $A$ is the area of the solenoid’s cross-section.

From the symmetry of this problem, the longitudinal (in Fig. 6a, vertical) component $B_z$ of the magnetic field may only depend on the horizontal position $\rho$ of the observation point. First taking a plane Ampère contour $C_1$, with both long sides outside the solenoid, we get $B_z(\rho_2) - B_z(\rho_1) = 0$, because
the total current piercing the contour equals zero. This is only possible if \( B_z = 0 \) at any \( \rho \) outside of the (infinitely long!) solenoid.\(^\text{17}\) With this result on hand, from the Ampère law applied to the contour \( C_2 \) we get the following relation for the only (\( z \)-) component of the internal field:

\[
Bl = \mu_0 NI ,
\]

(5.39)

where \( N \) is the number of wire turns passing through the contour of length \( l \). This means that regardless of the exact position of the internal side of the contour, the result is the same:

\[
B = \mu_0 \frac{N}{l} I = \mu_0 nI .
\]

(5.40)

Thus, the field inside an infinitely long solenoid (with an arbitrary shape of its cross-section) is uniform; in this sense, a long solenoid is a magnetic analog of a wide plane capacitor, explaining why these systems are so widely used in physical experiment.

As should be clear from its derivation, the obtained results, especially that the field outside of the solenoid equals zero, are conditional on the solenoid length being very large in comparison with its lateral size. (From Eq. (25), we may predict that for a solenoid of a finite length \( l \), the close-range external field is only a factor of \(~A/l^2\) lower than the internal one.) A much better suppression of this external (“fringe”) field may be obtained using the toroidal solenoid (Fig. 6b). The application of the Ampère law to this geometry shows that, in the limit of dense winding (\( N >> 1 \)), there is no fringe field at all (for any relation between two radii of the torus), while inside the solenoid, at distance \( \rho \) from the system’s axis,

\[
B = \frac{\mu_0 NI}{2\pi\rho} .
\]

(5.41)

We see that a possible drawback of this system for practical applications is that the internal field does depend on \( \rho \), i.e. is not quite uniform; however, if the torus is thin, this problem is minor.

How should we solve the problems of magnetostatics for systems whose low symmetry does not allow getting easy results from the Ampère law? (The examples are of course too numerous to list; for example, we cannot use this approach even to reproduce Eq. (23) for a round current loop.) From the deep analogy with electrostatics, we may expect that in this case we could recover the field from the solution of a certain boundary problem for the field’s potential – in our current case, the vector potential \( \mathbf{A} \) defined by Eq. (28). However, despite the similarity of this formula and Eq. (1.38) for \( \phi \), which was emphasized above, there are two additional issues we should tackle in the magnetic case.

First, calculating the vector potential distribution means determining three scalar functions (say, \( A_x, A_y \), and \( A_z \)), rather than one (\( \phi \)). To reveal the second, more deep issue, let us plug Eq. (27) into Eq. (35):

\[
\nabla \times (\nabla \times \mathbf{A}) = \mu_0 \mathbf{j} ,
\]

(5.42)

and then apply to the left-hand side of this equation the now-familiar identity (31). The result is

\(^{17}\) Applying the Ampère law to a circular contour of radius \( \rho \), coaxial with the solenoid, we see that the field outside (but not inside!) it has an azimuthal component \( B_{\phi} \) similar to that of the straight wire (see Eq. (38) above) and hence (at \( N >> 1 \)) much weaker than the longitudinal field inside the solenoid – see Eq. (40).
\[ \nabla (\nabla \cdot \mathbf{A}) - \nabla^2 \mathbf{A} = \mu_0 \mathbf{j}. \]  

(5.43)

On the other hand, as we know from electrostatics (please compare Eqs. (1.38) and (1.41)), the vector potential \( \mathbf{A}(\mathbf{r}) \) given by Eq. (28) has to satisfy a simpler (“vector-Poisson”) equation

\[ \nabla^2 \mathbf{A} = -\mu_0 \mathbf{j}, \]  

(5.44)

which is just a set of three usual Poisson equations for each Cartesian component of \( \mathbf{A} \).

To resolve the difference between these results, let us note that Eq. (43) is reduced to Eq. (44) if \( \nabla \cdot \mathbf{A} = 0 \). In this context, let us discuss what discretion do we have in the choice of the potential. In electrostatics, we might add to the scalar function \( \phi' \) that satisfied Eq. (1.33) for the given field \( \mathbf{E} \), not only an arbitrary constant, but also an arbitrary function of time:

\[ -\nabla [\phi' + f(t)] = -\nabla \phi' = \mathbf{E}, \]  

(5.45)

without changing the electric field. Similarly, using the fact that curl of the gradient of any scalar function equals zero, we may add to any vector function \( \mathbf{A}' \) that satisfies Eq. (27) for the given field \( \mathbf{B} \), not only any constant, but even a gradient of an arbitrary scalar function \( \chi(\mathbf{r}, t) \), because

\[ \nabla \times (\mathbf{A}' + \nabla \chi) = \nabla \times \mathbf{A}' + \nabla \times (\nabla \chi) = \nabla \times \mathbf{A}' = \mathbf{B}. \]  

(5.46)

Such additions, which keep the fields intact, are called the gauge transformations. Let us see what such a transformation does to \( \nabla \cdot \mathbf{A}' \):

\[ \nabla \cdot (\mathbf{A'} + \nabla \chi) = \nabla \cdot \mathbf{A'} + \nabla^2 \chi. \]  

(5.47)

For any choice of such a function \( \chi \), we can always choose the function \( \chi \) in such a way that it satisfies the Poisson equation \( \nabla^2 \chi = -\nabla \cdot \mathbf{A}' \), and hence makes the divergence of the transformed vector potential, \( \mathbf{A} = \mathbf{A}' + \nabla \chi \), equal to zero everywhere,

\[ \nabla \cdot \mathbf{A} = 0, \]  

(5.48)

thus reducing Eq. (43) to Eq. (44).

To summarize, the set of distributions \( \mathbf{A}'(\mathbf{r}) \) that satisfy Eq. (27) for a given field \( \mathbf{B}(\mathbf{r}) \), is not limited to the vector potential \( \mathbf{A}(\mathbf{r}) \) given by Eq. (44), but is reduced to it upon the additional Coulomb gauge condition (48). However, as we will see in a minute, even this condition still leaves some degrees of freedom in the choice of the vector potential. To illustrate this fact, and also to get a better gut feeling of the vector potential’s distribution in space, let us calculate \( \mathbf{A}(\mathbf{r}) \) for two very basic cases.

First, let us revisit the straight wire problem shown in Fig. 5. As Eq. (28) shows, in this case the vector potential \( \mathbf{A} \) has just one component (along the axis \( z \)). Moreover, due to the problem’s axial symmetry, its magnitude may only depend on the distance from the axis: \( \mathbf{A} = n_z A(\rho) \). Hence, the gradient of \( \mathbf{A} \) is directed across the \( z \)-axis, so that Eq. (48) is satisfied at all points. For our symmetry (\( \partial/\partial \varphi = \partial/\partial z = 0 \)), the Laplace operator, written in cylindrical coordinates, has just one term, reducing Eq. (44) to

\[ \nabla \cdot \mathbf{A} = 0, \]  

(5.48) Coulomb gauge

18 See, e.g., MA Eq. (11.1).
19 The use of the term “gauge” (originally meaning “a measure” or “a scale”) in this context is purely historic, so the reader should not try to find too much hidden sense in it.
20 See, e.g., MA Eq. (10.3).
\[
\frac{1}{\rho} \frac{d}{d\rho} \left( \rho \frac{dA}{d\rho} \right) = -\mu_0 j(\rho). \quad (5.49)
\]

Multiplying both parts of this equation by \( \rho \) and integrating them over the coordinate once, we get
\[
\rho \frac{dA}{d\rho} = -\mu_0 \int_0^\rho j(\rho')\rho'd\rho' + \text{const}. \quad (5.50)
\]

Since in the cylindrical coordinates, for our symmetry, \( B = -dA/d\rho \), \(21\) Eq. (50) is nothing else than our old result (38) for the magnetic field. \(22\) However, let us continue the integration, at least for the region outside the wire, where the function \( A(\rho) \) depends only on the full current \( I \) rather than on the current distribution. Dividing both parts of Eq. (50) by \( \rho \), and integrating them over it again, we get
\[
A(\rho) = -\frac{\mu_0 I}{2\pi} \ln \rho + \text{const}, \quad \text{where} \quad I = 2\pi \int_0^R j(\rho)\rho d\rho, \quad \text{for} \quad \rho \geq R. \quad (5.51)
\]

As a reminder, we had a similar logarithmic behavior for the electrostatic potential outside a uniformly charged straight line. This is natural, because the Poisson equations for both cases are similar.

Now let us find the vector potential for the long solenoid (Fig. 6a), with its uniform magnetic field. Since Eq. (28) prescribes the vector \( A \) to follow the direction of the inducing current, we may start looking for it in the form \( A = n_\phi A(\rho) \). (This is especially natural if the solenoid’s cross-section is circular.) With this orientation of \( A \), the same general expression for the curl operator in cylindrical coordinates yields \( \nabla \times A = n_\rho (1/\rho) d(\rho A)/d\rho \). According to Eq. (27), this expression should be equal to \( B \), in our current to \( n_\phi B \), with a constant \( B \) – see Eq. (40). Integrating this equality, and selecting such integration constant so that \( A(0) \) is finite, we get
\[
A(\rho) = \frac{B\rho}{2}, \quad \text{i.e.} \quad A = \frac{B\rho}{2} n_\phi. \quad (5.52)
\]

Plugging this result into the general expression for the Laplace operator in the cylindrical coordinates, \(23\) we see that the Poisson equation (44) with \( j = 0 \) (i.e. the Laplace equation), is satisfied again – which is natural since, for this distribution, the Coulomb gauge condition (48) is satisfied: \( \nabla \cdot A = 0 \).

However, Eq. (52) is not the unique (or even the simplest) vector potential that gives the same uniform field \( B = n_\phi B \). Indeed, using the well-known expression for the curl operator in Cartesian coordinates, \(24\) it is straightforward to check that each of the vector functions \( A' = n_\phi Bx \) and \( A'' = -n_\phi By \) also has the same curl, and also satisfies the Coulomb gauge condition (48). \(25\) If such solutions do not look very natural because of their anisotropy in the \([x, y]\) plane, please consider the fact that they represent the uniform magnetic field regardless of its source – for example, regardless of the shape of the long solenoid’s cross-section. Such choices of the vector potential may be very convenient for some

\(21\) See, e.g., MA Eq. (10.5) with \( \partial/\partial \varphi = \partial/\partial z = 0 \).
\(22\) Since the magnetic field at the wire’s axis has to be zero (otherwise, being normal to the axis, where would it be directed?), the integration constant in Eq. (50) has to equal zero.
\(23\) See, e.g., MA Eq. (10.6).
\(24\) See, e.g., MA Eq. (8.5).
\(25\) The axially-symmetric vector potential (52) is just a weighted sum of these two functions: \( A = (A' + A'')/2 \).
problems, for example for the quantum-mechanical analysis of the 2D motion of a charged particle in the perpendicular magnetic field, giving the famous Landau energy levels.\(^{26}\)

### 5.3. Magnetic energy, flux, and inductance

Considering the currents flowing in a system as generalized coordinates, the magnetic forces (1) between them are their unique functions, and in this sense, the energy \( U \) of their magnetic interaction may be considered a potential energy of the system. The apparent (but somewhat deceptive) way to derive an expression for this energy is to use the analogy between Eq. (1) and its electrostatic analog, Eq. (2). Indeed, Eq. (2) may be transformed into Eq. (1) with just three replacements:

1. \( \rho(r) \rho'(r') \) should be replaced with \( [j(r) \cdot j(r')] \),
2. \( \varepsilon_0 \) should be replaced with \( 1/\mu_0 \), and
3. the sign before the double integral has to be replaced with the opposite one.

Hence we may avoid repeating the calculation made in Chapter 1, by making these replacements in Eq. (1.59), which gives the electrostatic potential energy of the system with \( \rho(r) \) and \( \rho'(r') \) describing the same charge distribution, i.e. with \( \rho'(r) = \rho(r) \), to get the following expression for the magnetic potential energy in the system with, similarly, \( j'(r) = j(r) \):\(^{27}\)

\[
U_j = -\frac{\mu_0}{4\pi} \frac{1}{2} \int d^3r \int d^3r' \frac{j(r) \cdot j(r')}{|r - r'|}. \tag{5.53}
\]

However, this is not the unique, and even not the most convenient answer. Actually, Eq. (53) describes the energy that is adequate (i.e. whose minimum corresponds to the stable equilibrium of the system), only in the case when the interacting currents are fixed — just as Eq. (1.59) is adequate when the interacting charges are fixed. Here comes a substantial difference between the electrostatics and the magnetostatics: due to the fundamental fact of charge conservation (already discussed in Secs. 1.1 and 4.1), keeping electric charges fixed does not require external work, while the maintenance of currents generally does. As a result, Eq. (53) describes the energy of the magnetic interaction plus of the system keeping the currents constant — or rather of its part depending on the system under our consideration.\(^{28}\)

Now to exclude from \( U_j \) the contribution due to the interaction with the current-supporting system(s), i.e. calculate the potential energy \( U \) of our system as such, we need to know this contribution. The simplest way to do this is to use the Faraday induction law, which describes this interaction. This is why let me postpone the derivation until the beginning of the next chapter, and for now ask the reader to believe me that its account leads to an addition to \( U_j \) a term of a twice larger magnitude, so that the result is given by an expression similar to Eq. (53), but with the opposite sign:

\[
U = \frac{\mu_0}{4\pi} \frac{1}{2} \int d^3r \int d^3r' \frac{j(r) \cdot j(r')}{|r - r'|}, \tag{5.54}
\]

---

26 See, e.g., QM Sec. 3.2.
27 Just as in electrostatics, for the interaction of two independent current distributions \( j(r) \) and \( j'(r') \), the factor \( \frac{1}{2} \) should be dropped.
28 In the terminology already used in Sec. 3.5 (see also a general discussion in CM Sec. 1.4.), \( U_j \) may be interpreted as the Gibbs potential energy of our magnetic system.
I promise to prove this fact in Sec. 6.2 below.29

Due to the importance of Eq. (54), let us rewrite it in several other forms, convenient for different applications. First of all, just as in electrostatics, it may be recast into a potential-based form. Indeed, using the definition (28) of the vector potential \( A(r) \), Eq. (54) becomes

\[
U = \frac{1}{2} \int \mathbf{j}(r) \cdot A(r) d^3 r. \tag{5.55}
\]

This formula, which is a clear magnetic analog of Eq. (1.60) of electrostatics, is very popular among field theorists, because it is very handy for their manipulations. However, for many calculations, it is more convenient to have a direct expression of energy via the magnetic field. Again, this may be done very similarly to what had been done for electrostatics in Sec. 1.3, i.e. by plugging, into Eq. (55), the current density expressed from Eq. (35), and then transforming it as

\[
U = \frac{1}{2} \int \mathbf{j} \cdot A d^3 r = \frac{1}{2 \mu_0} \int A \cdot (\nabla \times \mathbf{B}) d^3 r = \frac{1}{2 \mu_0} \int \mathbf{B} \cdot (\nabla \times A) d^3 r - \frac{1}{2 \mu_0} \int \nabla \cdot (A \times \mathbf{B}) d^3 r. \tag{5.56}
\]

Now using the divergence theorem, the second integral may be transformed into a surface integral of \((A \times \mathbf{B})_n\). According to Eqs. (27)-(28) if the current distribution \( j(r) \) is localized, this vector product drops, at large distances, faster than \( 1/r^2 \), so that if the integration volume is large enough, the surface integral is negligible. In the remaining first integral in Eq. (56) we may use Eq. (27) to recast \( \nabla \times A \) into the magnetic field. As a result, we get a very simple and fundamental formula.

\[
U = \frac{1}{2 \mu_0} \int B^2 d^3 r. \tag{5.57a}
\]

Just as with the electric field, this expression may be interpreted as a volume integral of the magnetic energy density \( u \):

\[
U = \int u(r) d^3 r, \quad \text{with } u(r) = \frac{1}{2 \mu_0} B^2(r), \tag{5.57b}
\]

clearly similar to Eq. (1.65).32 Again, the conceptual choice between the spatial localization of magnetic energy – either at the location of electric currents only, as implied by Eqs. (54) and (55), or in all regions where the magnetic field exists, as apparent from Eq. (57b), cannot be done within the framework of magnetostatics, and only the electrodynamics gives the decisive preference for the latter choice.

For the practically important case of currents flowing in several thin wires, Eq. (54) may be first integrated over the cross-section of each wire, just as was done at the derivation of Eq. (4). Again, since the integral of the current density over \( k \) wire's cross-section is just the current \( I_k \) in the wire, and cannot change along its length, it may be taken from the remaining integrals, giving

\[\text{Footnotes:}
29 Actually, this sign dichotomy should not be quite surprising to the attentive reader, in the context of Eqs. (3.73) and (3.81) for the electrostatic energy.
30 This relation remains the same in the Gaussian units, because in those units, both Eq. (28) and Eq. (54) should be stripped of their \( \mu_0/4\pi \) coefficients.
31 For that, we may use MA Eq. (11.7) with \( f = A \) and \( g = B \), giving \( A \cdot (\nabla \times B) = B \cdot (\nabla \times A) - \nabla \cdot (A \times B) \).
32 The transfer to the Gaussian units in Eqs. (77)-(78) may be accomplished by the usual replacement \( \mu_0 \rightarrow 4\pi \), thus giving, in particular, \( u = B^2/8\pi \).
where $l$ is the full length of the wire loop. Note that Eq. (58) is valid if the currents $I_k$ are independent of each other, because the double sum counts each current pair twice, compensating the coefficient $\frac{1}{2}$ in front of the sum. It is useful to decompose this relation as

$$U = \frac{1}{2} \sum_{k,k'} I_k I_{k'} L_{kk'},$$  \hspace{1cm} (5.59)$$

where the coefficients $L_{kk'}$ are independent of the currents:

$$L_{kk'} \equiv \frac{\mu_0}{4\pi} \oint \oint \frac{d\mathbf{r}_k \cdot d\mathbf{r}_{k'}}{|\mathbf{r}_k - \mathbf{r}_{k'}|},$$  \hspace{1cm} (5.60)$$

The coefficient $L_{kk'}$ with $k \neq k'$, is called the mutual inductance between current the loops with numbers $k$ and $k'$, while the diagonal coefficient $L_k \equiv L_{kk}$ is called the self-inductance (or just inductance) of the $k^\text{th}$ loop.\footnote{As evident from Eq. (60), these coefficients depend only on the geometry of the system. Moreover, in the Gaussian units, in which Eq. (60) is valid without the factor $\mu_0/4\pi$, the inductance coefficients have the dimension of length (centimeters). The SI unit of inductance is called the henry, abbreviated H – after Joseph Henry, who in particular discovered the effect of electromagnetic induction (see Sec. 6.1) independently of Michael Faraday.} From the symmetry of Eq. (60) with respect to the index swap, $k \leftrightarrow k'$, it evident that the matrix of coefficients $L_{kk'}$ is symmetric:\footnote{Note that the matrix of the mutual inductances $L_{ij}$ is very much similar to the matrix of reciprocal capacitance coefficients $p_{kk'}$ — for example, compare Eq. (62) with Eq. (2.21).}

$$L_{kk'} = L_{k'k},$$  \hspace{1cm} (5.61)$$

so that for the practically important case of two interacting currents $I_1$ and $I_2$, Eq. (59) reads

$$U = \frac{1}{2} L_1 I_1^2 + M I_1 I_2 + \frac{1}{2} L_2 I_2^2,$$  \hspace{1cm} (5.62)$$

where $M \equiv L_{12} = L_{21}$ is the mutual inductance coefficient.

These formulas clearly show the importance of the self- and mutual inductances, so I will demonstrate their calculation for at least a few basic geometries. Before doing that, however, let me recast Eq. (58) into one more form that may facilitate such calculations. Namely, let us notice that for the magnetic field induced by current $I_k$ in a thin wire, Eq. (28) is reduced to

$$\mathbf{A}_k (\mathbf{r}) = \frac{\mu_0}{4\pi} I_k \oint \frac{d\mathbf{r}_k}{|\mathbf{r} - \mathbf{r}_k|},$$  \hspace{1cm} (5.63)$$

so that Eq. (58) may be rewritten as

$$U = \frac{1}{2} \sum_{k,k'} I_k \oint_{\mathbf{r}_k} \mathbf{A}_k (\mathbf{r}_k) \cdot d\mathbf{r}_{k'}.$$  \hspace{1cm} (5.64)$$
But according to the same Stokes theorem that was used earlier in this chapter to derive the Ampère law, and Eq. (27), the integral in Eq. (64) is nothing else than the *magnetic field’s flux* (more frequently called just the *magnetic flux*) through a surface $S$ limited by the contour $l$: \(^{35}\)

\[
\oint_l \mathbf{A}(r) \cdot d\mathbf{r} = \iint_S (\nabla \times \mathbf{A})_n \, d^2r = \iint_S B_n \, d^2r = \Phi .
\]  

As a result, Eq. (64) may be rewritten as

\[
U = \frac{1}{2} \sum_{k,k'} I_k \Phi_{kk'},
\]  

where $\Phi_{kk'}$ is the flux of the field induced by the $k'$-th current through the loop of the $k$-th current. Comparing this expression with Eq. (59), we see that

\[
\Phi_{kk'} = \iint_{S_k} (B_{k'})_n \, d^2r = L_{kk'} I_{k'},
\]  

This expression not only gives us one more means for calculating coefficients $L_{kk'}$, but also shows their physical sense: the mutual inductance characterizes what part of the magnetic field (colloquially, “what fraction of field lines”), induced by the current $I_k$, pierces the $k$-th loop – see Fig. 7.

Due to the linear superposition principle, the total flux piercing $k$-th loop may be represented as

\[
\Phi_k \equiv \sum_{k'} \Phi_{kk'} = \sum_{k'} L_{kk'} I_{k'} .
\]  

For example, for the system of two currents, this expression is reduced to a clear analog of Eqs. (2.19):

\[
\Phi_1 = L_1 I_1 + M I_2 ,
\]

\[
\Phi_2 = M I_1 + L_2 I_2 .
\]  

For the even simpler case of a single current,

\[
\Phi = LI ,
\]  

---

\(^{35}\) The SI unit of magnetic flux is called *weber*, abbreviated Wb – after Wilhelm Edward Weber (1804-1891), who in particular co-invented (with Carl Gauss) the electromagnetic telegraph. More importantly for this course, in 1856 he was the first (together with Rudolf Kohlrausch) to notice that the value of (in modern terms) $1/(\varepsilon_0 \mu_0)^{1/2}$, derived from electrostatic and magnetostatic measurements, coincides with the independently measured speed of light $c$. This observation gave an important motivation for Maxwell’s theory.
so that the magnetic energy of the current may be represented in several equivalent forms:

\[
U = \frac{L}{2} I^2 = \frac{1}{2} \frac{\Phi}{I} = \frac{1}{2L} \Phi^2 .
\] (5.71)

These relations, similar to Eqs. (2.14)-(2.15) of electrostatics, show that the self-inductance \(L\) of a current loop may be considered as a measure of the system’s magnetic energy, but, as we will see in Sec. 6.1 below, this measure is adequate only if the flux \(\Phi\), rather than the current \(I\), is fixed.

Now we are well equipped for the calculation of inductance coefficients for particular systems, having three options. The first one is to use Eq. (60) directly.\(^{36}\) The second one is to calculate the magnetic field energy from Eq. (57) as the function of all currents \(I_k\) in the system, and then use Eq. (59) to find all coefficients \(L_{kk'}\). For example, for a system with just one current, Eq. (71) yields

\[
L = \frac{U}{I^2 / 2} .
\] (5.72)

Finally, if the system consists of thin wires, so that the loop areas \(S_k\) and hence fluxes \(\Phi_{kk'}\) are well defined, we may calculate them from Eq. (65), and then use Eq. (67) to find the inductances.

Actually, the first two options may have technical advantages over the third one even for some system of thin wires, in which the notion of magnetic flux is not quite apparent. As an important example, let us find the self-inductance of a long solenoid – see Fig. 6a again. We have already calculated the magnetic field inside it – see Eq. (40) – so that, due to the field uniformity, the magnetic flux piercing each wire turn is just

\[
\Phi_1 = BA = \mu_0 n IA ,
\] (5.73)

where \(A\) is the area of solenoid’s cross-section – for example \(\pi R^2\) for a round solenoid, though Eq. (40), and hence Eq. (73) are valid for any cross-section. Comparing Eqs. (73) with Eq. (70), one might wrongly conclude that \(L = \Phi_1/I = \mu_0 n A\) (WRONG!), i.e. that the solenoid’s inductance is independent of its length. Actually, the magnetic flux \(\Phi_1\) pierces each wire turn, so that the total flux through the whole current loop, consisting of \(N\) turns, is

\[
\Phi = N \Phi_1 = \mu_0 n^2 l A I ,
\] (5.74)

and the correct expression for the long solenoid’s self-inductance is

\[
L = \frac{\Phi}{I} = \mu_0 n^2 l A ,
\] (5.75)

i.e. the inductance per unit length, at fixed \(n\), does not depend on \(l\): \(L/l = \mu_0 n^2 A\).

Since this reasoning may seem not quite evident, it is prudent to verify it by using Eq. (72), with the full magnetic energy inside the solenoid (neglecting minor fringe field contributions), given by Eq. (57) with \(B = \text{const}\) within the internal volume \(V = lA\), and zero outside of it:

\[
U = \frac{1}{2} \frac{1}{\mu_0} B^2 Al = \frac{1}{2\mu_0} (\mu_0 n I)^2 Al = \mu_0 n^2 l A \frac{I^2}{2} .
\] (5.76)

\(^{36}\) Numerous applications of this Neumann formula to electrical engineering problems may be found, for example, in the classical text F. Grover, *Inductance Calculations*, Dover, 1946.
Plugging this relation into Eq. (72) immediately confirms the result (75).

This approach becomes virtually inevitable for continuously distributed currents. As an example, let us calculate the self-inductance $L$ of a long coaxial cable with the cross-section shown in Fig. 8, with the full current in the outer conductor equal and opposite to that ($I$) in the inner conductor.

\begin{figure}[h]
\centering
\includegraphics[width=0.5\textwidth]{coaxial_cable.png}
\caption{Fig. 5.8. The cross-section of a coaxial cable.}
\end{figure}

Let us assume that the current is uniformly distributed over the cross-sections of both conductors. (As we know from the previous chapter, this is indeed the case if both the internal and external conductors are made of a uniform resistive material.) First, we should calculate the radial distribution of the magnetic field – which, of course, has only one, azimuthal component, because of the axial symmetry of the problem. This distribution may be immediately found from the application of the Ampère law (37) to the circular contours of radii $\rho$ within four different ranges:

\[
2\pi \rho B = \mu_0 I \left[ \begin{array}{ll}
\rho^2/a^2, & \text{for } \rho < a, \\
1, & \text{for } a < \rho < b, \\
\frac{(c^2 - \rho^2)}{(c^2 - b^2)}, & \text{for } b < \rho < c, \\
0, & \text{for } c < \rho. 
\end{array} \right] 
\]

Now, an easy integration yields the magnetic energy per unit length of the cable:

\[
\frac{U}{l} = \frac{1}{2\mu_0} \int B^2 d^2 r = \frac{\pi}{\mu_0} \int_0^\infty B^2 \rho d\rho = \frac{\mu_0 I^2}{4\pi} \left[ \int_a^b \left( \frac{\rho}{a^2} \right)^2 \rho d\rho + \int_b^c \left( \frac{1}{\rho} \right)^2 \rho d\rho + \int_c^{\infty} \left( \frac{c^2 - \rho^2}{\rho(c^2 - b^2)} \right)^2 \rho d\rho \right] 
\]

\[
\frac{U}{l} = \frac{\mu_0}{2\pi} \ln \frac{b}{a} + \frac{c^2}{c^2 - b^2} \left( \frac{c^2}{c^2 - b^2} \ln \frac{c}{b} - \frac{1}{2} \right) l^2. 
\]

From here, and Eq. (72), we get the final answer:

\[
\frac{L}{l} = \frac{\mu_0}{2\pi} \left[ \ln \frac{b}{a} + \frac{c^2}{c^2 - b^2} \left( \frac{c^2}{c^2 - b^2} \ln \frac{c}{b} - \frac{1}{2} \right) \right]. 
\]

Note that for the particular case of a thin outer conductor, $c - b \ll b$, this expression reduces to

\[
\frac{L}{l} \approx \frac{\mu_0}{2\pi} \left( \ln \frac{b}{a} + \frac{1}{4} \right), 
\]

where the first term in the parentheses may be traced back to the contribution of the magnetic field energy in the free space between the conductors. This distinction is important for some applications.

\[37\] As a reminder, the mutual capacitance $C$ between the conductors of such a system was calculated in Sec. 2.3.
because in superconductor cables, as well as the normal-metal cables as high frequencies (to be discussed in the next chapter), the field does not penetrate the conductor’s bulk, so that Eq. (80) is valid without the last term, 1/4, in the parentheses, which is due to the magnetic field energy inside the wire.

As the last example, let us calculate the mutual inductance between a long straight wire and a round wire loop adjacent to it (Fig. 9), neglecting the thickness of both wires.

Here there is no problem with using the last of the approaches discussed above, based on the direct calculation of the magnetic flux. Indeed, as was discussed in Sec. 1, the field $B_1$ induced by the current $I_1$ at any point of the round loop is normal to its plane – e.g., to the plane of drawing of Fig. 9. In the Cartesian coordinates shown in that figure, Eq. (20) reads $B_1 = \mu_0 I_1 / 2\pi y$, giving the following magnetic flux through the loop:

$$\Phi_{21} = \frac{\mu_0 I_1}{2\pi} \left. \int_{-R}^{+R} dx \int_{R - (R^2 - x^2)^{1/2}}^{R + (R^2 - x^2)^{1/2}} dy \frac{1}{y} \right| \begin{array}{c} \ln \frac{R + (R^2 - x^2)^{1/2}}{R - (R^2 - x^2)^{1/2}} \end{array} = \frac{\mu_0 I_1 R}{2\pi} \left. \ln \frac{1 + (1 - \xi^2)^{1/2}}{1 + (1 - \xi^2)^{1/2}} \right|_{\xi = 0} \frac{1}{y} \right. \int_{\xi = 0}^{\xi = 1} d\xi. \quad (5.81)$$

This is a table integral equal to $\pi^{38}$ so that $\Phi_{21} = \mu_0 I_1 R$, and the final answer for the mutual inductance $M = L_{12} = L_{21} = \Phi_{21}/I_1$ is finite (and very simple):

$$M = \mu_0 R, \quad (5.82)$$
despite the magnetic field’s divergence at the lowest point of the loop ($y = 0$).

Note that in contrast with the finite mutual inductance of this system, the self-inductances of both wires are formally infinite in the thin-wire limit – see, e.g., Eq. (80), which in the limit $b/a >> 1$ describes a thin straight wire. However, since this divergence is very weak (logarithmic), it is quenched by any deviation from this perfectly axial geometry. For example, a good estimate of the inductance of a wire of a large but finite length $l$ may be obtained from Eq. (80) via the replacement of $b$ with $l$:

$$L \sim \frac{\mu_0 l}{2\pi} \ln \frac{l}{a}. \quad (5.83)$$

(Note, however, that the exact result depends on where from/to the current flows beyond that segment.) A close estimate, with $l$ replaced with $2\pi R$, and $b$ replaced with $R$, is valid for the self-inductance of the

---

38 See, e.g., MA Eq. (6.13), with $a = 1$. 

---

Chapter 5
round loop. A more exact calculation of this inductance, which would be asymptotically correct in the limit \( a \ll R \), is a very useful exercise, highly recommended to the reader.\(^{39}\)

### 5.4. Magnetic dipole moment, and magnetic dipole media

The most natural way of the magnetic media description parallels that described in Chapter 3 for dielectrics, and is based on properties of \textit{magnetic dipoles} – the notion close (but not identical!) to that of the electric dipoles discussed in Sec. 3.1. To introduce this notion quantitatively, let us consider, just as in Sec. 3.1, a spatially-localized system with a current distribution \( \mathbf{j}(\mathbf{r'}) \), whose magnetic field is measured at relatively large distances \( r >> r' \) (Fig. 10).

![Fig. 5.10. Calculating the magnetic field of localized currents at a distant point (\( r >> a \)).](image)

Applying the truncated Taylor expansion (3.5) of the fraction \( 1/|\mathbf{r} - \mathbf{r}'| \) to the vector potential given by Eq. (28), we get

\[
\mathbf{A}(\mathbf{r}) \approx \frac{\mu_0}{4\pi} \left[ \frac{1}{r'} \int \mathbf{j}(\mathbf{r'})d^3r' + \frac{1}{r'} \int (\mathbf{r} \cdot \mathbf{r}')\mathbf{j}(\mathbf{r'})d^3r' \right].
\]  

(5.84)

Now, due to the vector character of this potential, we have to depart slightly from the approach of Sec. 3.1 and use the following vector algebra identity:40

\[
\oint [f(\mathbf{j} \cdot \nabla g) + g(\mathbf{j} \cdot \nabla f)]d^3r = 0,
\]

(5.85)

that is valid for any pair of smooth (differentiable) scalar functions \( f(\mathbf{r}) \) and \( g(\mathbf{r}) \), and any vector function \( \mathbf{j}(\mathbf{r}) \) that, as the dc current density, satisfies the continuity condition \( \nabla \cdot \mathbf{j} = 0 \) and whose normal component vanishes on the surface of the volume \( V \). First, let us use Eq. (85) with \( f \) equal to 1, and \( g \) equal to any Cartesian component of the radius-vector \( \mathbf{r} \): \( g = r_l (l = 1, 2, 3) \). Then it yields

\[
\int_{V} (\mathbf{j} \cdot \mathbf{n})d^3r = \int_{V} j_{l}d^3r = 0,
\]

(5.86)

so that for the vector as the whole

\[
\int_{V} \mathbf{j}(\mathbf{r})d^3r = 0,
\]

(5.87)

---

39 Its solution may be found, for example, just after Sec. 34 of L. Landau et al., \textit{Electrodynamics of Continuous Media}, 2nd ed., Butterwort Heinemann, 1984.

40 See, e.g., MA Eq. (12.3) with the additional condition \( j_{n}|_{S} = 0 \), pertinent for space-restricted currents.
showing that the first term on the right-hand side of Eq. (84) equals zero. Next, let us use Eq. (85) again, now with \( f = r_l, g = r_{l'} \) \((l, l' = 1, 2, 3)\); then it yields
\[
\int (r_l f + r_{l'} g') \, d^3 r = 0 ,
\]
(5.88)
so that the \( l^{th} \) Cartesian component of the second integral in Eq. (84) may be transformed as
\[
\int (\mathbf{r} \cdot \mathbf{r}') j_i d^3 r' = \frac{1}{2} \sum_{l=1}^{3} r_l \int (r_l f + r_{l'} g') d^3 r' = \frac{1}{2} \left[ \mathbf{r} \times \int (r' \times j) d^3 r' \right]_l.
\]
(5.89)
As a result, Eq. (84) may be rewritten as
\[
\mathbf{A}(\mathbf{r}) = \frac{\mu_0}{4\pi} \frac{\mathbf{m} \times \mathbf{r}}{r^3} ,
\]
(5.90)
where the vector \( \mathbf{m} \), defined as\(^41\)
\[
\mathbf{m} \equiv \frac{1}{2} \int \mathbf{r} \times \mathbf{j}(\mathbf{r}) \, d^3 r ,
\]
(5.91)
is called the magnetic dipole moment of our system – that itself, within the long-rang approximation (90), is called the magnetic dipole.

Note a close analogy between the \( \mathbf{m} \) defined by Eq. (91), and the orbital\(^42\) angular momentum of a non-relativistic particle with mass \( m_k \):
\[
\mathbf{L}_k = \mathbf{r}_k \times \mathbf{p}_k = \mathbf{r}_k \times m_k \mathbf{v}_k ,
\]
(5.92)
where \( \mathbf{p}_k = m_k \mathbf{v}_k \) is its linear momentum. Indeed, for a continuum of such particles with the same electric charge \( q \), with the spatial density \( n \), we have \( \mathbf{j} = q \mathbf{n} \mathbf{v} \), and Eq. (91) yields
\[
\mathbf{m} = \frac{1}{2} \int \mathbf{r} \times \mathbf{j} \, d^3 r = \frac{1}{2} \int q \mathbf{n} \mathbf{v} \times \mathbf{r} \, d^3 r ,
\]
(5.93)
while the total angular momentum of such a system of particles of the same mass \( (m_k = m_0) \) is
\[
\mathbf{L} = \int m_0 \mathbf{r} \times \mathbf{v} \, d^3 r ,
\]
so that we get a very straightforward relation
\[
\mathbf{m} = \frac{q}{2m_0} \mathbf{L} ,
\]
(5.95)
\( \mathbf{m} \) vs. \( \mathbf{L} \)

For the orbital motion, this classical relation survives in quantum mechanics for the linear operators, and hence for the eigenvalues of the observables. Since the orbital angular momentum is quantized in the

\(^41\) In the Gaussian units, the definition (91) is kept valid, so that Eq. (90) is stripped of the factor \( \mu_0/4\pi \).
\(^42\) This adjective is used, especially in quantum mechanics, to distinguish the motion of a particle as a whole (not necessarily along a closed orbit!) from its intrinsic angular momentum, the spin – see, e.g., QM Chapters 3-6.
units of the Planck’s constant $\hbar$, for an electron, the orbital magnetic moment is always a multiple of the so-called **Bohr magneton**

$$\mu_B \equiv \frac{e\hbar}{2m_e},$$

(5.96)

where $m_e$ is the free electron mass.$^{43}$ However, for particles with spin, such a universal relation between the vectors $\mathbf{m}$ and $\mathbf{L}$ is no longer valid. For example, electron’s spin $s = \frac{1}{2}$ gives a contribution of $\hbar/2$ to the mechanical angular momentum, but its contribution to the magnetic moment is still very close to $\mu_B$.

The next important example of a magnetic dipole is a **planar** thin-wire loop, limiting area $A$ (of arbitrary shape), and carrying current $I$, for which $\mathbf{m}$ has a surprisingly simple form,

$$\mathbf{m} = IA,$$

(5.97)

where the modulus of the vector $\mathbf{A}$ equals the loop’s area $A$, and its direction is normal to the loop’s plane. This formula may be readily proved by noticing that if we select the coordinate origin on the plane of the loop (Fig. 11), then the elementary component of the magnitude of the integral (91),

$$dm = \frac{1}{2} \left| \frac{1}{c} \mathbf{r} \times I \mathbf{d}r \right| \equiv \frac{1}{c} \frac{1}{2} \mathbf{r} \times \mathbf{d}r = \frac{1}{c} \frac{1}{2} r^2 d\varphi,$$

(5.98)

is just the elementary area $dA = (1/2)r d(r \varphi) = r^2 d\varphi/2$ – the equality also used in CM Eq. (3.40).

The combination of Eqs. (96) and (97) allows a useful estimate of the scale of atomic currents, by finding what current $I$ should flow in a circular loop of atomic size scale (the Bohr radius) $r_B \approx 0.5 \times 10^{-10}$ m, i.e. of area $A \approx 10^{-20}$ m$^2$, to produce a magnetic moment of the order of $\mu_B$.$^{44}$ The result is surprisingly macroscopic: $I \approx 1$ mA – quite comparable to the currents driving the sound in your phone’s earbuds. Though this estimate should not be taken too literally, due to the quantum-mechanical spread of electron's wavefunctions, it is very useful for getting a feeling of how significant the atomic magnetism is and hence why ferromagnets may provide such a strong field.

After these illustrations, let us return to the discussion of Eq. (90). Plugging it into (also general) Eq. (27), we may calculate the magnetic field of a magnetic dipole.$^{45}$

$^{43}$ In SI units, $m_e \approx 0.91 \times 10^{-30}$ kg, so that $\mu_B \approx 0.93 \times 10^{-23}$ J/T.

$^{44}$ Another way to arrive at the same estimate is to take $I \approx ef = e\omega/2\pi$ with $\omega \approx 10^{16}$ s$^{-1}$ being the typical frequency of radiation due to atomic interlevel quantum transitions.

$^{45}$ Similarly to the situation with the electric dipoles (see Eq. (3.24) and its discussion), it may be shown that the magnetic field of any closed current loop (or any system of such loops) satisfies the following equality:
\[ \mathbf{B}(\mathbf{r}) = \frac{\mu_0}{4\pi} \frac{3\mathbf{r}(\mathbf{r} \cdot \mathbf{m}) - \mathbf{m}r^2}{r^5} . \]  

(5.99)

The structure of this formula exactly replicates that of Eq. (3.13) for the electric dipole field (including the sign). Because of this similarity, the energy of a dipole of a fixed magnitude \( m \) in an external field, and hence the torque and the force exerted on it by a fixed external field, are also absolutely similar to the expressions for an electric dipole – see Eqs. (3.15)-(3.19):\(^{46}\)

\[ U = -\mathbf{m} \cdot \mathbf{B}_{\text{ext}} , \]  

(5.100)

and as a result,

\[ \tau = \mathbf{m} \times \mathbf{B}_{\text{ext}} , \]  

(5.101)

\[ \mathbf{F} = \nabla (\mathbf{m} \cdot \mathbf{B}_{\text{ext}}) . \]  

(5.102)

Now let us consider a system of many magnetic dipoles (e.g., atoms or molecules), distributed in space with a macroscopic (i.e. average) density \( n \). Then we can use Eq. (90) (generalized in an evident way for an arbitrary position, \( \mathbf{r}' \), of a dipole), and the linear superposition principle, to calculate the macroscopic vector potential \( \mathbf{A} \):

\[ \mathbf{A}(\mathbf{r}) = \frac{\mu_0}{4\pi} \int \frac{\mathbf{M}(\mathbf{r}') \times (\mathbf{r} - \mathbf{r}')}{|\mathbf{r} - \mathbf{r}'|^3} d^3r' , \]  

(5.103)

where \( \mathbf{M} \equiv n\mathbf{m} \) is the magnetization, i.e. the average magnetic moment per unit volume. Transforming this integral absolutely similarly to how Eq. (3.27) had been transformed into Eq. (3.29), we get:

\[ \mathbf{A}(\mathbf{r}) = \frac{\mu_0}{4\pi} \int \left\{ \mathbf{V}' \times \mathbf{M}(\mathbf{r'}) \right\} |\mathbf{r} - \mathbf{r}'| d^3r' . \]  

(5.104)

Comparing this result with Eq. (28), we see that \( \mathbf{V} \times \mathbf{M} \) is equivalent, in its effect, to the density \( \mathbf{j}_{\text{ef}} \) of a certain effective “magnetization current”. Just as the electric-polarization charge \( \rho_{\text{ef}} \) discussed in Sec. 3.2 (see Fig. 3.4), the vector \( \mathbf{j}_{\text{ef}} = \mathbf{V} \times \mathbf{M} \) may be interpreted as the uncompensated part of the loop currents representing single magnetic dipoles \( \mathbf{m} \) (Fig. 12). Note, however, that since the atomic dipoles may be due to particles’ spins, rather than the actual electric currents due to the orbital motion, the magnetization current’s nature is not as direct than that of the polarization charge.

\[ \int_{V} \mathbf{B}(\mathbf{r})d^3r = (2/3)\mu_0 \mathbf{m} , \]

where the integral is over any sphere confining all the currents. On the other hand, as we know from Sec. 3.1, for a field with the structure (99), derived from the long-range approximation (90), such an integral vanishes. As a result, to get a course-grain description of the magnetic field of a small system, located at \( r = 0 \), which would give the correct average value of the magnetic field, Eq. (99) should be modified as follows:

\[ \mathbf{B}_{\text{cg}}(\mathbf{r}) = \frac{\mu_0}{4\pi} \left( \frac{3\mathbf{r}(\mathbf{r} \cdot \mathbf{m}) - \mathbf{m}r^2}{r^5} + \frac{8\pi}{3} \mathbf{m} \delta(\mathbf{r}) \right) , \]

in a conceptual (though not quantitative) similarity to Eq. (3.25).

\(^{46}\) Note that the fixation of \( m \) and \( \mathbf{B}_{\text{ext}} \) effectively means that the currents producing them are fixed – please have one more look at Eqs. (35) and (97). As a result, Eq. (100) is a particular case of Eq. (53) rather than (54) – hence the minus sign.
Now, using Eq. (28) to add the possible contribution from “stand-alone” currents $j$, not included into the currents of microscopic magnetic dipoles, we get the general expression for the vector potential of the macroscopic field:

$$A(r) = \frac{\mu_0}{4\pi} \int \frac{\mathbf{j}(r') + \nabla' \times \mathbf{M}(r')}{|r - r'|} \, d^3 r'. \quad (5.105)$$

Repeating the calculations that have led us from Eq. (28) to the Maxwell equation (35), with the account of the magnetization current term, for the macroscopic magnetic field $\mathbf{B}$ we get

$$\nabla \times \mathbf{B} = \mu_0 \left( \mathbf{j} + \nabla \times \mathbf{M} \right). \quad (5.106)$$

Following the same philosophy as in Sec. 3.2, we may recast this equation as

$$\nabla \times \mathbf{H} = \mathbf{j}, \quad (5.107)$$

where the field defined as

$$\mathbf{H} = \frac{\mathbf{B}}{\mu_0} - \mathbf{M}, \quad (5.108)$$

by historic reasons (and very unfortunately) is also called the magnetic field.\footnote{This confusion is exacerbated by the fact that in Gaussian units, Eq. (108) has the form $\mathbf{H} = \mathbf{B} - 4\pi \mathbf{M}$, and hence the fields $\mathbf{B}$ and $\mathbf{H}$ have the same dimensionality (and are formally equal in free space) – though the unit of $\mathbf{H}$ has a different name (oersted, abbreviated as Oe). Mercifully, in the SI units, the dimensionality of $\mathbf{B}$ and $\mathbf{H}$ is different, with the unit of $\mathbf{H}$ called the ampere per meter.}

It is crucial to remember that the physical sense of the field $\mathbf{H}$ is very much different from the field $\mathbf{B}$. In order to understand this difference better, let us use Eq. (107) to bring Eqs. (3.32), (3.36), (29) and (107) together, writing them as the system of the macroscopic Maxwell equations (again, so far for the stationary case $\partial/\partial t = 0$): \footnote{Let me remind the reader once again that in contrast with the system (36) of the Maxwell equations for the genuine (microscopic) fields, the right-hand sides of Eqs. (109) represent only the stand-alone charges and currents, not included into the microscopic electric and magnetic dipoles.}

$$\nabla \times \mathbf{E} = 0, \quad \nabla \times \mathbf{H} = \mathbf{j}, \quad (5.109)$$

$$\nabla \cdot \mathbf{D} = \rho, \quad \nabla \cdot \mathbf{B} = 0.$$
Despite this similarity, let me note an important difference of signs in the relation (3.33) between \( \mathbf{E} \), \( \mathbf{D} \), and \( \mathbf{P} \), on one hand, and the relation (108) between \( \mathbf{B} \), \( \mathbf{H} \), and \( \mathbf{M} \), on the other hand. This is not just a matter of definition. Indeed, due to the similarity of Eqs. (3.15) and (100), including similar signs, the electric and magnetic fields both try to orient the corresponding dipole moments along the field. Hence, in the media that allow such an orientation (and as we will see momentarily, for magnetic media it is not always the case), the induced polarizations \( \mathbf{P} \) and \( \mathbf{M} \) are directed along, respectively, the vectors \( \mathbf{E} \) and \( \mathbf{B} \) of the genuine (though macroscopic, i.e. averaged) fields. According to Eq. (3.33), if the would-be field \( \mathbf{D} \) is fixed – say, by a fixed stand-alone charge distribution \( \rho(\mathbf{r}) \) – such a polarization reduces the electric field \( \mathbf{E} = (\mathbf{D} - \mathbf{P})/\varepsilon_0 \). On the other hand, Eq. (108) shows that in a magnetic media with a fixed would-be field \( \mathbf{H} \), the magnetic polarization with \( \mathbf{M} \) parallel to \( \mathbf{B} \) enhances the magnetic field \( \mathbf{B} = \mu_0(\mathbf{H} + \mathbf{M}) \). This difference may be traced back to the sign difference in the basic relations (1) and (2), i.e. to the fundamental fact that the electric charges of the same sign repulse, while the currents of the same direction attract each other.

5.5. Magnetic materials

In order to form a complete system, the macroscopic Maxwell equations (109) have to be complemented with the constitutive relations describing the medium: \( \mathbf{D} \leftrightarrow \mathbf{E} \), \( \mathbf{j} \leftrightarrow \mathbf{E} \), and \( \mathbf{B} \leftrightarrow \mathbf{H} \). The first two of them were discussed, in brief, in the last two chapters; let us proceed to the last one.

A major difference between the dielectric and magnetic constitutive relations \( \mathbf{D} = \varepsilon \mathbf{E} \) and \( \mathbf{B} = \mu \mathbf{H} \) is that while a dielectric medium always reduces the external field, magnetic media may either reduce or enhance it. To quantify this fact, let us consider the most widespread materials – linear magnetics in which \( \mathbf{M} \) (and hence \( \mathbf{H} \)) are proportional to \( \mathbf{B} \). For isotropic materials, this proportionality is characterized by a scalar – either the magnetic permeability \( \mu \), defined by the following relation:

\[
\mathbf{B} \equiv \mu \mathbf{H},
\]  

or the magnetic susceptibility\footnote{According to Eqs. (110) and (112), i.e. in the SI units, \( \chi_m \) is dimensionless, while \( \mu \) has the same dimensionality as \( \mu_0 \). In the Gaussian units, \( \mu \) is dimensionless: \( (\mu)_{\text{Gaussian}} = (\mu)_{\text{SI}}/\mu_0 \), and \( \chi_m \) is also introduced differently, as \( \mu = 1 + 4\pi\chi_m \). Hence, just as for the electric susceptibilities, these dimensionless coefficients are different in the two systems: \( (\chi_m)_{\text{G}} = 4\pi(\chi_m)_{\text{SI}} \). Note also that \( \chi_m \) is formally called the \emph{volumic} magnetic susceptibility, to distinguish it from the \emph{atomic} (or “molecular”) susceptibility \( \chi \) defined by a similar relation, \( \langle \mathbf{m} \rangle = \chi \mathbf{H} \), where \( \mathbf{m} \) is the induced magnetic moment of a single dipole – e.g., an atom. \( \chi \) is an analog of the electric atomic polarizability \( \alpha \) – see Eq. (3.48) and its discussion.) Evidently, in a dilute medium, i.e. in the absence of a substantial dipole-dipole interaction, \( \chi_m = n\chi \), where \( n \) is the dipole density.} defined as

\[
\mathbf{M} = \chi_m \mathbf{H}.
\]

Plugging these relations into Eq. (108), we see that these two parameters are not independent, but are related as

\[
\mu = (1 + \chi_m)\mu_0.
\]

Note that despite the superficial similarity between Eqs. (110)-(112) and the corresponding relations (3.43)-(3.47) for linear dielectrics:

\[
\mathbf{D} = \varepsilon \mathbf{E}, \quad \mathbf{P} = \chi \varepsilon_0 \mathbf{E}, \quad \varepsilon = (1 + \chi)\varepsilon_0,
\]

\[
\chi_m \text{ vs. } \mu
\]
there is an important conceptual difference between them. Namely, while the vector \( \mathbf{E} \) on the right-hand sides of Eqs. (113) is the actual (though macroscopic) electric field, the vector \( \mathbf{H} \) on the right-hand side of Eqs. (110)-(111) represents a “would-be” magnetic field, in most aspects similar to \( \mathbf{D} \) rather than \( \mathbf{E} \) – see, for example, Eqs. (109). This historic difference in the traditional way to write the constitutive relations for the electric and magnetic fields is not without its physical reasons. Most key experiments with electric and magnetic materials are performed by placing their samples into nearly-uniform electric and magnetic fields, and the simplest systems for their implementation are, respectively, the plane capacitor (Fig. 2.3) and the long solenoid (Fig. 6). The field in the former system may be most conveniently controlled by measuring the voltage \( V \) between its plates, which is proportional to the electric field \( \mathbf{E} \). On the other hand, the field provided by the solenoid may be controlled by the current \( I \) in it. According to Eq. (107), the field proportional to this stand-alone current is \( \mathbf{H} \), rather than \( \mathbf{B} \).

Table 1 lists the values of magnetic susceptibility for several materials. It shows that in contrast to linear dielectrics whose susceptibility \( \chi_e \) is always positive, i.e. the dielectric constant \( \kappa = \chi_e + 1 \) is always larger than 1 (see Table 3.1), linear magnetic materials may be either paramagnets (with \( \chi_m > 0 \), i.e. \( \mu > \mu_0 \)) or diamagnets (with \( \chi_m < 0 \), i.e. \( \mu < \mu_0 \)).

(a) The table does not include bulk superconductors, which may be described, in a so-called coarse-scale approximation, as perfect diamagnets (with \( B = 0 \), i.e. \( \chi_m = -1 \) and \( \mu = 0 \)), though the actual physics of this phenomenon is more intricate – see Sec. 6.3 below.

(b) The exact values of \( \chi_m >> 1 \) for soft ferromagnetic materials (see, e.g., the upper three rows of the table) depend not only on their composition, but also on their thermal processing (“annealing”). Moreover, due to unintentional vibrations, the extremely high values of \( \chi_m \) of such materials may decay with time, though may be restored to the original values by new annealing. The reason for such behavior is discussed in the text below.

The reason for this difference is that in dielectrics, two different polarization mechanisms (schematically illustrated by Fig. 3.7) lead to the same sign of the average polarization – see the discussion in Sec. 3.3. One of these mechanisms, illustrated by Fig. 3.7b, i.e. the ordering of

\(^{50}\) This fact also explains the misleading term “magnetic field” for \( \mathbf{H} \).
spontaneous dipoles by the applied field, is also possible for magnetization – for the atoms and molecules with spontaneous internal magnetic dipoles of magnitude $m_0 \sim \mu_B$, due to their net spins. Again, in the absence of an external magnetic field the spins, and hence the dipole moments $m_0$ may be disordered, but according to Eq. (100), the external magnetic field tends to align the dipoles along its direction. As a result, the average direction of the spontaneous elementary moments $m_0$, and hence the direction of the arising magnetization $\mathbf{M}$, is the same as that of the microscopic field $\mathbf{B}$ at the points of the dipole location (i.e., for a diluted media, of $H \approx B/\mu_0$), resulting in a positive susceptibility $\chi_m$, i.e. in the paramagnetism, such as that of oxygen and aluminum – see Table 1.

However, in contrast to the electric polarization of atoms/molecules with no spontaneous electric dipoles, which gives the same sign of $\chi_e \equiv \kappa - 1$ (see Fig. 3.7a and its discussion), the magnetic materials with no spontaneous atomic magnetic dipole moments have $\chi_m < 0$ – the effect called the orbital (or “Larmor”\(^{51}\)) diamagnetism. As the simplest model of this effect, let us consider the orbital motion of an atomic electron about an atomic nucleus as that of a classical particle of mass $m_0$, with an electric charge $q$, about an immobile attracting center. As the classical mechanics tells us, the central attractive force does not change particle’s angular momentum $\mathbf{L} \equiv m_0 \mathbf{r} \times \mathbf{v}$, but the applied magnetic field $\mathbf{B}$ (that may be taken uniform on the atomic scale) does, due to the torque (101) it exerts on the magnetic moment (95):

$$\frac{d\mathbf{L}}{dt} = \tau = \mathbf{m} \times \mathbf{B} = \frac{q}{2m_0} \mathbf{L} \times \mathbf{B} . \quad (5.114)$$

The diagram in Fig. 13 shows that in the limit of relatively weak field, when the magnitude of the angular momentum $\mathbf{L}$ may be considered constant, this equation describes the rotation (called the torque-induced precession\(^{52}\)) of the vector $\mathbf{L}$ about the direction of the vector $\mathbf{B}$, with the angular frequency $\Omega = -qB/2m_0$, independent of the angle $\theta$. According to Eqs. (91), (114), the resulting additional (field-induced) magnetic moment $\Delta \mathbf{m} \propto q \Omega \propto -q^2 \mathbf{B}/m_0$ has, irrespectively of the sign of $q$, a direction opposite to the field. Hence, according to Eq. (111) with $H \approx B/\mu_0$, $\chi_m \propto \chi \equiv \Delta \mathbf{m}/H$ is indeed negative. (Let me leave its quantitative estimate within this model for the reader’s exercise.) The quantum-mechanical treatment confirms this qualitative picture of the Larmor diamagnetism, while giving quantitative corrections to the classical result for $\chi_m$.\(^{53}\)

\(^{51}\) Named after Sir Joseph Larmor who was the first (in 1897) to describe this effect mathematically.

\(^{52}\) For a detailed discussion of the effect see, e.g., CM Sec. 4.5.

\(^{53}\) See, e.g., QM Sec. 6.4. The quantum mechanics also shows why in the most important s-states, the contribution (95) of the basic angular momentum $\mathbf{L}$ to the average $\mathbf{m}$ vanishes – see, e.g., QM Sec. 3.6.
A simple estimate (also left for the reader’s exercise) shows that in atoms with uncompensated spins, the magnetic dipole orientation mechanism prevails over the orbital diamagnetism, so that the materials incorporating such atoms usually exhibit net paramagnetism – see Table 1. Due to possible strong quantum interaction between the spin dipole moments, the magnetism of such materials is rather complex, with numerous interesting phenomena and elaborated theories. Unfortunately, all this physics is well outside the framework of this course, and I have to refer the interested reader to special literature, but still, need to mention some key notions we will need.

Most importantly, a sufficiently strong dipole-dipole interaction may lead to their spontaneous ordering, even in the absence of the applied field. This ordering may correspond to either parallel alignment of the magnetic dipoles (ferromagnetism) or anti-parallel alignment of the adjacent dipoles (antiferromagnetism). Evidently, the external effects of ferromagnetism are stronger, because such phase corresponds to a substantial spontaneous magnetization \( M \) even in the absence of an external magnetic field. (The corresponding magnitude of \( B = \mu_0 M \) is called the remanence field, \( B_R \).) The direction of the vector \( B_R \) may be switched by the application an external magnetic field, with a magnitude above certain value \( H_C \) called coercivity, leading to the well-known hysteretic loops on the \([B, H]\) plane (see Fig. 14 for a typical example), similar to those in ferroelectrics, already discussed in Sec. 3.3.

Similarly to the ferroelectrics, the ferromagnets may also be hard or soft – in the magnetic sense. In hard ferromagnets (also called permanent magnets), the dipole interaction is so strong that \( B \) stays close to \( B_R \) in all applied fields below \( H_C \), so that the hysteretic loops are virtually rectangular. Correspondingly, the magnetization \( M \) of a permanent magnet may be considered constant, with the magnitude \( B_R/\mu_0 \). Such hard ferromagnetic materials, with high remanence fields (typically, close to 1 T) have numerous practical applications. Let me give just two, perhaps most important examples.

First, the permanent magnets are core components of most electric motors. By the way, this venerable (~150-years-old) technology is currently experiencing a quiet revolution, driven mostly by the electric car development. In the most advanced type of the motors, called permanent-magnet synchronous machines (PMSM), the remanence magnetic field \( B_R \) of a permanent-magnet central part

(called rotor) interacts with ac currents passed through wire windings in the external, static part of the motor (called stator). The resulting torque may drive the rotor to extremely high speeds, exceeding 10,000 rotations per minute, enabling the motor to deliver several kilowatts of mechanical power from each kilogram of its mass.

As the second important example, despite the decades of the exponential (Moore’s-law) progress of semiconductor electronics, most computer data storage systems (e.g., in data centers) are still based on hard disk drives whose active medium is a submicron-thin layer of a hard ferromagnet, with the data bits stored in the form of the direction of the remanent magnetization of small film spots. This technology has reached fantastic sophistication, with the recorded data density of the order of $10^{12}$ bits per square inch. (Only recently it has started to be seriously challenged by the so-called solid-state drives based on the floating-gate semiconductor memories already mentioned in Chapter 3.)

In contrast, in soft ferromagnets, with their lower magnetic dipole interactions, the magnetization is constant only within spontaneously formed magnetic domains, while the volume and shape of the domains are affected by the applied magnetic field. As a result, the hysteresis loop’s shape of soft ferromagnets is dependent on the cycled field’s amplitude and cycling history – see Fig. 14. At high fields, their $B$ (and hence $M$) are driven into saturation, with $B \approx B_R$, but at low cycled fields they behave essentially as linear magnetics with very high values of $\chi_m$ and hence $\mu$ – see the top rows of Table 1. (The magnetic domain interaction, and hence the low-field susceptibility of such soft ferromagnets are highly dependent on the material’s fabrication technology and its post-fabrication thermal and mechanical treatments.) Due to these high values of $\mu$, the soft ferromagnets, especially iron and its alloys (e.g., various special steels), are extensively used in electrical engineering – for example in the cores of transformers – see the next section.

Due to the relative weakness of the magnetic dipole interaction in some materials, their ferromagnetic ordering may be destroyed by thermal fluctuations, if the temperature is increased above some value called the so-called Curie temperature $T_C$. The transition between the ferromagnetic and paramagnetic phase at $T = T_C$ is the classical example of a continuous phase transition, with the average polarization $M$ playing the role of the so-called order parameter that (in the absence of external fields) becomes different from zero only at $T < T_C$, increasing gradually at the further temperature reduction.\[57\]

---

56 High-frequency properties of hard ferromagnets are also very non-trivial. For example, according to Eq. (101), an external magnetic field $B_{\text{ext}}$ exerts torque $\tau = M \times B_{\text{ext}}$ on the spontaneous magnetic moment $M$ of a unit volume of a ferromagnet. In some nearly-isotropic, mechanically fixed ferromagnetic samples, this torque causes the precession around the direction of $B_{\text{ext}}$ (very similar to that illustrated in Fig. 13) of not the sample as such, but of the magnetization $M$ inside it, with a certain frequency $\omega$. If the frequency $\omega$ of an additional ac field becomes very close to $\omega$, its absorption sharply increases – the so-called ferromagnetic resonance. Moreover, if $\omega$ is somewhat higher than $\omega$, the effective magnetic permeability $\mu(\omega)$ of the material for the ac field may become negative, enabling a series of interesting effects and practical applications. Very unfortunately, I do not have time for their discussion, and have to refer the interested reader to literature, for example to the monograph by A. Gurevich and G. Melkov, Magnetization Oscillations and Waves, CRC Press, 1996.

57 In this series, a quantitative discussion of such transitions is given in SM Chapter 4.
5.6. Systems with magnetics

Similarly to the electrostatics of linear dielectrics, the magnetostatics of linear magnetics is very simple in the particular case when the stand-alone currents are embedded into a medium with a constant permeability $\mu$. Indeed, let us assume that we know the solution $B_0(r)$ of the magnetic pair of the genuine (“microscopic”) Maxwell equations (36) in free space, i.e. when the genuine current density $j$ coincides with that of stand-alone currents. Then the macroscopic Maxwell equations (109) and the linear constitutive equation (110) are satisfied with the pair of functions

$$H(r) = \frac{B_0(r)}{\mu_0}, \quad B(r) = \mu H(r) = \frac{\mu}{\mu_0} B_0(r). \quad (5.115)$$

Hence the only effect of the complete filling a system of fixed currents with a uniform, linear magnetic is the change of the magnetic field $B$ at all points by the same constant factor $\mu / \mu_0 \equiv 1 + \chi_m$, which may be either larger or smaller than 1. (As a reminder, a similar filling of a system of fixed stand-alone charges with a uniform, linear dielectric always leads to a reduction of the electric field $E$ by a factor of $\varepsilon / \varepsilon_0 \equiv 1 + \chi_e$ – the difference whose physics was already discussed in the end of Sec. 4.)

However, this simple result is generally invalid in the case of non-uniform (or piece-wise uniform) magnetic samples. To analyze them, let us first integrate the macroscopic Maxwell equation (107) along a closed contour $C$ limiting a smooth surface $S$. Now using the Stokes theorem, we get the macroscopic version of the Ampère law (37):

$$\oint_C \mathbf{H} \cdot d\mathbf{r} = I. \quad (5.116)$$

Let us apply this relation to a sharp boundary between two regions with different magnetics, with no stand-alone currents on the interface, similarly to how this was done for the field $E$ in Sec. 3.4 – see Fig. 3.5. The result is similar as well:

$$H_\tau = \text{const}. \quad (5.117)$$

On the other hand, the integration of the Maxwell equation (29) over a Gaussian pillbox enclosing a border fragment (again just as shown in Fig. 3.5 for the field $D$) yields the result similar to Eq. (3.35):

$$B_n = \text{const}. \quad (5.118)$$

For linear magnetics, with $B = \mu H$, the latter boundary condition is reduced to

$$\mu H_n = \text{const}. \quad (5.119)$$

Let us use these boundary conditions, first of all, to see what happens with a long cylindrical sample of a uniform magnetic material, placed parallel to a uniform external magnetic field $B_0$ – see Fig. 15. Such a sample cannot noticeably disturb the field in the free space outside it, at most of its length: $B_\text{ext} = B_0, \quad H_\text{ext} = \mu_0 B_\text{ext} = \mu_0 B_0$. Now applying Eq. (117) to the dominating, side surfaces of the sample, we get $H_\text{int} = H_0$.\footnote{The constancy of $H$ in this geometry explains why this field’s magnitude is used as the argument in the plots like Fig. 14: such measurements are typically carried out by placing an elongated sample of the material under...} For a linear magnetic, these relations yield $B_\text{int} = \mu H_\text{int} = (\mu / \mu_0) B_0$.\footnote{For the high-$\mu$,...}

---

\[ \text{Macroscopic Ampère law} \]
soft ferromagnetic materials, with this means that $B_{\text{int}} \gg B_0$. This effect may be vividly represented as the concentration of the magnetic field lines in high-$\mu$ samples – see Fig. 15 again. (The concentration affects the external field distribution only at distances of the order of $(\mu/\mu_0) t \ll l$ near the sample’s ends.)

![Fig. 5. 15. Magnetic field concentration in long, high-$\mu$ magnetic samples (schematically).](image)

Such concentration is widely used in such practically important devices as transformers, in which two multi-turn coils are wound on a ring-shaped (e.g., toroidal, see Fig. 6b) core made of a soft ferromagnetic material (such as the transformer steel, see Table 1) with $\mu \gg \mu_0$. This minimizes the number of “stray” field lines, and makes the magnetic flux $\Phi$ piercing each wire turn (of either coil) virtually the same – the equality important for the secondary voltage induction – see the next chapter.

Samples of other geometries may create strong perturbations of the external field, extended to distances of the order of the sample’s dimensions. To analyze such problems, we may benefit from a simple, partial differential equation for a scalar function, e.g., the Laplace equation, because in Chapter 2 we have learned how to solve it for many simple geometries. In magnetostatics, the introduction of a scalar potential is generally impossible due to the vortex-like magnetic field lines. However, if there are no stand-alone currents within the region we are interested in, then the macroscopic Maxwell equation (107) for the field $\mathbf{H}$ is reduced to $\nabla \times \mathbf{H} = 0$, similar to Eq. (1.28) for the electric field, showing that we may introduce the scalar potential of the magnetic field, $\phi_m$, using the relation similar to Eq. (1.33):

$$\mathbf{H} = -\nabla \phi_m.$$  \hspace{1cm} (5.120)

Combining it with the homogenous Maxwell equation (29) for the magnetic field, $\nabla \cdot \mathbf{B} = 0$, and Eq. (110) for a linear magnetic, we arrive at a single differential equation, $\nabla \cdot (\mu \nabla \phi_m) = 0$. For a uniform medium ($\mu(\mathbf{r}) = \text{const}$), it is reduced to our beloved Laplace equation:

$$\nabla^2 \phi_m = 0.$$  \hspace{1cm} (5.121)

Moreover, Eqs. (117) and (119) give us very familiar boundary conditions: the first of them

$$\frac{\partial \phi_m}{\partial \tau} = \text{const},$$  \hspace{1cm} (5.122a)

being equivalent to

$$\phi_m = \text{const},$$  \hspace{1cm} (5.122b)

study into a long solenoid with a controllable current $I$, so that according to Eq. (116), $H_0 = nI$, regardless of the properties of the material.

59 The reader is highly encouraged to carry out a similar analysis of the fields inside narrow gaps cut in a linear magnetic, similar to that carried in Sec. 3.3 out for linear dielectrics – see Fig. 3.6 and its discussion.
while the second one giving
\[
\mu \frac{\partial \phi_m}{\partial n} = \text{const}.
\] (5.123)

Indeed, these boundary conditions are absolutely similar for (3.37) and (3.56) of electrostatics, with the replacement \( \varepsilon \rightarrow \mu \).\(^{60}\)

Let us analyze the geometric effects on magnetization, first using the (too?) familiar structure: a sphere, made of a linear magnetic material, placed into a uniform external field \( \mathbf{H}_0 \equiv \mathbf{B}_0 / \mu_0 \). Since the differential equation and the boundary conditions are similar to those of the corresponding electrostatics problem (see Fig. 3.11 and its discussion), we can use the above analogy to reuse the solution we already have – see Eqs. (3.63). Just as in the electric case, the field outside the sphere, with
\[
(\phi_m)_{r> R} = H_0 \left( -r + \frac{\mu - \mu_0 R^3}{\mu + 2\mu_0 r^2} \right) \cos \theta,
\] (5.124)
is a sum of the uniform external field \( \mathbf{H}_0 \), with the potential \(-H_0 r \cos \theta \equiv -H_0 z\), and the dipole field (99) with the following induced magnetic dipole moment of the sphere:\(^{61}\)
\[
\mathbf{m} = 4\pi \frac{\mu - \mu_0}{\mu + 2\mu_0} R^3 \mathbf{H}_0.
\] (5.125)

On the contrary, the internal field is perfectly uniform, and directed along the external one:
\[
(\phi_m)_{r<R} = -H_0 \frac{3\mu_0}{\mu + 2\mu_0} r \cos \theta,
\]
so that
\[
\frac{H_{\text{int}}}{H_0} = \frac{3\mu_0}{\mu + 2\mu_0}, \quad \frac{B_{\text{int}}}{B_0} = \frac{\mu H_{\text{int}}}{\mu_0 H_0} = \frac{3\mu}{\mu + 2\mu_0}.
\] (5.126)

Note that the field \( \mathbf{H}_{\text{int}} \) inside the sphere is not equal to the applied external field \( \mathbf{H}_0 \). This example shows that the interpretation of \( \mathbf{H} \) as the “would-be” magnetic field generated by external currents \( \mathbf{j} \) should not be exaggerated into saying that its distribution is independent of the magnetic bodies in the system. In the limit \( \mu \gg \mu_0 \), Eqs. (126) yield \( H_{\text{int}}/H_0 \ll 1 \), \( B_{\text{int}}/B_0 = 3\mu_0 \), the factor 3 being specific for the particular geometry of the sphere. If a sample is strongly stretched along the applied field, with its length \( l \) much larger than the thickness scale \( t \), this geometric effect is gradually decreased, and \( B_{\text{int}} \) tends to its value \( \mu \mathbf{H}_0 \gg \mathbf{B}_0 \), as was discussed above – see Fig. 15.

Now let us calculate the field distribution in a similar, but slightly more complex (and practically important) system: a round cylindrical shell, made of a linear magnetic, placed into a uniform external field \( \mathbf{H}_0 \) normal to its axis – see Fig. 16.

---

\(^{60}\) This similarity may seem strange, because earlier we have seen that the parameter \( \mu \) is physically more similar to \( 1/\varepsilon \). The reason for this paradox is that in magnetostatics, the magnetic potential \( \phi_m \) is traditionally used to describe the “would-be field” \( \mathbf{H} \), while in electrostatics, the potential \( \phi \) describes the actual electric field \( \mathbf{E} \). (This tradition persists from the days when \( \mathbf{H} \) was perceived as a genuine magnetic field.)

\(^{61}\) To derive Eq. (125), we may either calculate the gradient of the \( \phi_m \) given by Eq. (124), or use the similarity of Eqs. (3.13) and (99), to derive from Eq. (3.17) a similar expression for the magnetic dipole’s potential
\[
\phi_m = \frac{1}{4\pi} \frac{m \cos \theta}{r^2}.
\]
Now comparing this formula with the second term of Eq. (124), we immediately get Eq. (125).
Since there are no stand-alone currents in the region of our interest, we can again represent the field $\mathbf{H}(r)$ by the gradient of the magnetic potential $\phi_m$ – see Eq. (120). Inside each of three constant-$\mu$ regions, i.e. at $\rho < a$, $a < \rho < b$, and $b < \rho$ (where $\rho$ is the distance from the cylinder's axis), the potential obeys the Laplace equation (121). In the convenient, polar coordinates (see Fig. 16), we may, guided by the general solution (2.112) of the Laplace equation and our experience in its application to axially-symmetric geometries, look for $\phi_m$ in the following form:

$$\phi_m = \begin{cases} 
(-H_0 \rho + b_1' / \rho) \cos \varphi, & \text{for } b \leq \rho, \\
(a_1 \rho + b_1 / \rho) \cos \varphi, & \text{for } a \leq \rho \leq b, \\
-H_{\text{int}} \rho \cos \varphi, & \text{for } \rho \leq a.
\end{cases}$$

Plugging this solution into the boundary conditions (122)-(123) at both interfaces ($\rho = b$ and $\rho = a$), we get the following system of four equations:

$$-H_0 b + b_1' / b = a_1 b + b_1 / b, \quad \mu_0 H_0 = \mu(a_1 - b_1 / b^2), \quad \mu(a_1 - b_1 / a^2) = -\mu_0 H_{\text{int}},$$

for four unknown coefficients $a_1$, $b_1$, $b_1'$, and $H_{\text{int}}$. Solving the system, we get, in particular:

$$\frac{H_{\text{int}}}{H_0} = \frac{\alpha_c - 1}{\alpha_c - (a / b)^2}, \quad \text{with } \alpha_c = \left(\frac{\mu + \mu_0}{\mu - \mu_0}\right)^2.$$  

According to the these formulas, at $\mu > \mu_0$, the field in the free space inside the cylinder is lower than the external field. This fact allows using such structures, made of high-$\mu$ materials such as permalloy (see Table 1), for the passive shielding from unintentional magnetic fields (e.g., the Earth's field) – the task very important for the design of many physical experiments. As Eq. (129) shows, the larger is $\mu$, the closer is $\alpha_c$ to 1, and the smaller is the ratio $H_{\text{int}}/H_0$, i.e. the better is the shielding (for the same $a/b$ ratio). On the other hand, for a given magnetic material, i.e. for a fixed parameter $\alpha_c$, the shielding is improved by making the ratio $a/b < 1$ smaller, i.e. the shield thicker. On the other hand, as Fig. 16 shows, smaller $a$ leaves less space for the shielded samples, calling for a compromise.

Now let us discuss a curious (and practically important) approach to systems with relatively thin, closed magnetic cores made of sections of (possibly, different) high-$\mu$ magnetics, with the cross-section areas $A_k$ much smaller than the squared lengths $l_k$ of the sections – see Fig. 17.

---

62 A complementary approach to the undesirable magnetic fields' reduction is the "active shielding" – the field compensation with the counter-field induced by controlled currents in specially designed wire coils.
If all $\mu_k >> \mu_0$, virtually all field lines are confined to the interior of the core. Then, applying the macroscopic Ampère law (116) to a contour $C$ that follows a magnetic field line inside the core (see, for example, the dashed line in Fig. 17), we get the following approximate expression (exactly valid only in the limit $\mu_k/\mu_0, l_k^2/A_k \rightarrow \infty$):

$$\oint H_j dl \approx \sum_k l_k H_k \equiv \sum_k l_k \frac{B_k}{\mu_k} = NI .$$

(5.130)

However, since the magnetic field lines stay in the core, the magnetic flux $\Phi_k \approx B_kA_k$ should be the same (\(\equiv \Phi\)) for each section, so that $B_k = \Phi/A_k$. Plugging this condition into Eq. (130), we get

$$\Phi = \sum_k N I R_k , \quad \text{where } R_k = \frac{l_k}{\mu_k A_k} .$$

(5.131)

Note a close analogy of the first of these equations with the usual Ohm law for several resistors connected in series, with the magnetic flux playing the role of electric current, while the product NI, the role of the voltage applied to a chain of resistors. This analogy is fortified by the fact that the second of Eqs. (131) is similar to the expression for the resistance $R = l/\sigma A$ of a long, uniform conductor, with the magnetic permeability $\mu$ playing the role of the electric conductivity $\sigma$. (In order to sound similar, but still different from the resistance $R$, the parameter $R$ is called reluctance.) This is why Eq. (131) is called the magnetic Ohm law; it is very useful for approximate analyses of systems like ac transformers, magnetic energy storage systems, etc.

Now let me proceed to a brief discussion of systems with permanent magnets. First of all, using the definition (108) of the field $H$, we may rewrite the Maxwell equation (29) for the field $B$ as

$$\nabla \cdot B \equiv \mu_0 \nabla \cdot (H + M) = 0 , \quad \text{i.e. as } \nabla \cdot H = -\nabla \cdot M ,$$

(5.132)

While this relation is general, it is especially convenient in permanent magnets, where $M$ may be considered field-independent. In this case, Eq. (132) for $H$ is an exact analog of Eq. (1.27) for $E$, with the fixed term $-\nabla \cdot M$ playing the role of the fixed charge density (more exactly, of $\rho/\varepsilon_0$). For the scalar potential $\phi_m$, defined by Eq. (120), this gives the Poisson equation

$$\nabla^2 \phi_m = \nabla \cdot M ,$$

(5.133)

similar to those solved, for many electrostatic situations, in the previous chapters.
In the particular case when the magnetization vector \( \mathbf{M} \) is not only field-independent, but also constant inside a permanent magnet’s volume, then the right-hand sides of Eqs. (132) and (133) vanish both inside the volume and in the surrounding free space, and give a non-zero effective charge only on the magnet’s surface. Integrating Eq. (132) along a short path normal to the surface and crossing it, we get the following boundary conditions:

\[
\Delta H_n \equiv \left( H_n \right)_{\text{in free space}} - \left( H_n \right)_{\text{in magnet}} = M_n \equiv M \cos \theta,
\]

where \( \theta \) is the angle between the magnetization vector and the outer normal to the magnet’s surface. This relation is an exact analog of Eq. (1.24) for the normal component of the field \( \mathbf{E} \), with the effective surface charge density (or rather \( \sigma/\varepsilon_0 \)) equal to \( M \cos \theta \).

This analogy between the magnetic field induced by a fixed, constant magnetization and the electric field induced by surface electric charges enables one to reuse quite a few problems considered in Chapters 1-3. Leaving a few such problems for the reader’s exercise (see Sec. 7), let me demonstrate the power of this analogy on two examples specific for magnetic systems. First, let us calculate the force necessary to detach the flat ends of two long, uniform rod magnets, of length \( l \) and cross-section area \( A \ll l^2 \), with the saturated remanent magnetization \( \mathbf{M}_0 \) directed along their length – see Fig. 18.

Let us assume we have succeeded to detach the magnets by an infinitesimal distance \( t \ll A^{1/2}, l \). Then, according to Eqs. (133)-(134), the distribution of the magnetic field near this small gap should be similar to that of the electric field in a system of two equal by opposite surface charges with the surface density \( \sigma \) proportional to \( M_0 \). From Chapters 1 and 2, we know the properties of such a system very well: within the gap, the electric field is virtually constant, uniform, proportional to \( \sigma \), and independent of \( t \), while outside of the gap, it is negligible. (Due to the condition \( A \ll l^2 \), the effect of the similar effective charges at the "outer" ends of the rods on the field near the gap \( t \) is negligible.) Hence the magnetic field \( H \) inside the gap is proportional to \( M_0 \), and independent of \( A \) and \( t \). Specifically, for its magnitude, Eq. (134) gives simply \( H = M_0 \), and hence \( B = \mu_0 M_0 \).

Now we could calculate \( F_{\text{min}} \) as the force exerted by this field on the effective surface "charges". However, it is even easier to find it from the following energy argument. Since the magnetic field energy localized inside the magnets and near their outer ends cannot depend on \( t \), this small detachment may only alter the energy inside the gap. For this part of the energy, Eq. (57) yields:

\[
\Delta U = \frac{B^2}{2\mu_0} V = \frac{\left( \mu_0 M_0 \right)^2}{2\mu_0} A t \equiv \frac{\mu_0 M_0^2}{2} A t.
\]

The gradient of this potential energy is equal to the attraction force \( \mathbf{F} = -\nabla(\Delta U) \), trying to reduce \( \Delta U \) by decreasing the gap, with the magnitude

\[
|F| = \frac{\partial (\Delta U)}{\partial t} = \frac{\mu_0 M_0^2 A}{2}.
\]
The magnet detachment requires an equal and opposite force.

Now let us consider the situation when similar long permanent magnets (such as the magnetic needles used in magnetic compasses) are separated, in otherwise free space, by a larger distance $d >> A^{1/2}$ – see Fig. 19.

![Diagram](image)

Fig. 5.19. (a) “Magnetic charges” at the ends of a thin permanent-magnet needle and (b) the result of its breaking into two parts (schematically).

For each needle (Fig. 19a), of a length $l >> A^{1/2}$, the right-hand side of Eq. (133) is substantially different from zero only in two relatively small areas at the needle’s ends. Integrating the equation over each end, we see that at distances $r >> A^{1/2}$ from each end, we may reduce Eq. (132) to

$$\nabla \cdot \mathbf{H} = q_m \delta(r - r_+) - q_m \delta(r - r_-),$$

where $r_\pm$ are ends’ positions, and $q_m \equiv M_0 A$, with $A$ being the needle’s cross-section area. This equation is completely similar to Eq. (3.32) for the displacement $\mathbf{D}$, for the particular case of two equal and opposite point charges, i.e. with $\rho = q \delta(r - r_+) - q \delta(r - r_-)$, with the only replacement $q \to q_m$. Since we know the resulting electric field all too well (see, e.g., Eq. (1.7) for $E \equiv \mathbf{D}/\varepsilon_0$), we may immediately write the similar expression for the field $\mathbf{H}$:

$$\mathbf{H}(r) = \frac{1}{4\pi} q_m \begin{pmatrix} \frac{r - r_+}{|r - r_+|^3} - \frac{r - r_-}{|r - r_-|^3} \end{pmatrix}.$$

The resulting magnetic field $\mathbf{B}(r) = \mu_0 \mathbf{H}(r)$ exerts on another “magnetic charge” $q'_m$, located at point $r'$, force $\mathbf{F} = q'_m \mathbf{B}(r')$. Hence if two ends of different needles are separated by an intermediate distance $R$ ($A^{1/2} << R << l$, see Fig. 19b), we may neglect one term in Eq. (138), and get the following “magnetic Coulomb law” for the interaction of the nearest ends:

$$\mathbf{F} = \pm \frac{\mu_0}{4\pi} q_m q'_m \frac{R}{R^3}.$$

The “only” (but conceptually, crucial!) difference of this interaction from that of the electric point charges is that the two “magnetic charges” (quasi-monopoles) of a magnetic needle cannot be fully

---

63 The simplest way to verify this (perhaps, obvious) expression is to check that for a system of two “charges” $\pm q_m$, separated by vector $\mathbf{a}$, placed into a uniform external magnetic field $\mathbf{B}_\text{ext}$, it yields the potential energy (100) with the correct magnetic dipole moment $\mathbf{m} = q_m \mathbf{a}$ – cf. Eq. (3.9) for an electric dipole.
separated. For example, if we break the needle in the middle in an attempt to bring its two ends further apart, two new “charges” appear – see Fig. 19b.

There are several solid-state systems where more flexible structures, similar in their magnetostatics to the needles, may be implemented. First of all, certain (“type-II”) superconductors may sustain so-called *Abrikosov vortices* – superficially, flexible tubes with field-suppressed superconductivity inside, each carrying one magnetic flux quantum \( \Phi_0 = \frac{\pi h}{e} \approx 2 \times 10^{15} \) Wb. Ending on superconductor’s surfaces, these tubes let their magnetic field lines spread into the surrounding free space, essentially forming magnetic monopole analogs – of course, with equal and opposite “magnetic charges” \( q_m \) on each end of the tube. Such flux tubes are not only flexible but readily stretchable, resulting in several peculiar effects – see Sec. 6.4 for more detail. Another, recently found, example of such paired quasi-monopoles is *spin chains* in the so-called *spin ices* – crystals with paramagnetic ions arranged into a specific (pyrochlore) lattice – such as dysprosium titanate \( \text{Dy}_2\text{Ti}_2\text{O}_7 \).\(^{64}\) Let me emphasize again that any reference to magnetic monopoles in such systems should not be taken literally.

In order to complete this section (and this chapter), let me briefly discuss the magnetic field energy \( U \), for the simplest case of systems with linear magnetics. In this case, we still may use Eq. (55), but if we want to operate with the macroscopic fields, and hence the stand-alone currents, we should repeat the manipulations that have led us to Eq. (57), using \( j \) not from Eq. (35), but from Eq. (107). As a result, instead of Eq. (57) we get

\[
U = \int \frac{1}{2} u(\mathbf{r}) d^3r, \quad \text{with} \quad u = \frac{B \cdot \mathbf{H}}{2} = \frac{B^2}{2\mu} = \frac{\mu H^2}{2},
\]

(5.140)

This result is evidently similar to Eq. (3.73) of electrostatics.

As a simple but important example of its application, let us again consider a long solenoid (Fig. 6a), but now filled with a linear magnetic material with permeability \( \mu \). Using the macroscopic Ampère law (116), just as we used Eq. (37) for the derivation of Eq. (40), we get

\[
H = \mu n \mathbf{I}, \quad \text{and hence} \quad B = \mu n \mathbf{I},
\]

(5.141)

where \( n \equiv N/l \), just as in Eq. (40), is the winding density, i.e. the number of wire turns per unit length. (At \( \mu = \mu_0 \), we immediately return to that old result.) Now we may plug Eq. (141) into Eq. (140) to calculate the magnetic energy stored in the solenoid:

\[
U = \frac{1}{2} u V = \frac{1}{2} \frac{\mu H^2}{2} l A = \frac{\mu (n I)^2 l A}{2},
\]

(5.142)

and then use Eq. (72) to calculate its self-inductance:\(^{65}\)

\[
L = \frac{U}{I^2/2} = \mu n^2 l A
\]

(5.143)

\(^{64}\) See, e.g., L. Jaubert and P. Holdworth, *J. Phys. – Cond. Matt.* 23, 164222 (2011), and references therein.

\(^{65}\) Admittedly, we could get the same result simpler, just by arguing that since the magnetic material fills the whole volume of a substantial magnetic field in this system, the filling simply increases the vector \( \mathbf{B} \) at all points, and hence its flux \( \Phi \), and hence \( L \equiv \Phi/I \) by the factor \( \mu/\mu_0 \) in comparison with the free-space value (75).
We see that \( L \propto \mu V \), so that filling a solenoid with a high-\( \mu \) material may allow to make it more compact, while preserving the same value of inductance. In addition, as the discussion of Fig. 15 has shown, such filling reduces the fringe fields near the solenoid's ends, which may be detrimental for some applications, especially in precise physical experiments.

Still, we need to explore the issue of the energy in magnetics beyond Eq. (140), not only to get a general expression for it in materials with an arbitrary dependence \( B(H) \), but also to finally prove Eq. (54) and explore its relation with Eq. (53). I will do this in the beginning of the next chapter.

5.7. Exercise problems

5.1. A circular wire loop, carrying a fixed dc current, has been placed inside a similar but larger loop, carrying a fixed current in the same direction – see the figure on the right. Use semi-quantitative arguments to analyze the mechanical stability of the coaxial, coplanar position of the inner loop with respect to its possible angular, axial, and lateral displacements relative to the outer loop.

5.2. Two straight, plane, parallel, long, thin conducting strips of width \( w \), separated by distance \( d \), carry equal but oppositely directed currents \( I \) – see the figure on the right. Calculate the magnetic field in the plane located in the middle between the strips, assuming that the flowing currents are uniformly distributed across the strip widths.

5.3. For the system studied in the previous problem, but now only in the limit \( d \ll w \), calculate:
   (i) the distribution of the magnetic field (in the simplest possible way),
   (ii) the vector potential of the field,
   (iii) the magnetic force (per unit length) exerted on each strip, and
   (iv) the magnetic energy and self-inductance of the loop formed by the strips (per unit length).

5.4. Calculate the magnetic field distribution near the center of the system of two similar, plane, round, coaxial wire coils, carrying equal but oppositely directed currents – see the figure on the right.
5.5. The two-coil-system considered in the previous problem, now carries equal and similarly directed currents – see the figure on the right. \textsuperscript{66} Calculate what should be the ratio \(d/R\) for the second derivative \(\partial^2 \mathbf{B}_z / \partial z^2\) at \(z = 0\) to vanish.

\begin{figure}[h]
\centering
\includegraphics[width=0.5\textwidth]{two_coil_system.png}
\caption{Two-coil-system with equal and similarly directed currents.}
\end{figure}

5.6. Calculate the magnetic field’s distribution along the axis of a straight solenoid (see Fig. 6a, partly reproduced on the right) with a finite length \(l\), and round cross-section of radius \(R\). Assume that the solenoid has many \((N \gg 1, l/R)\) wire turns, uniformly distributed along its length.

\begin{figure}[h]
\centering
\includegraphics[width=0.5\textwidth]{solenoid.png}
\caption{Solenoid with finite length \(l\) and round cross-section of radius \(R\).}
\end{figure}

5.7. A thin round disk of radius \(R\), carrying electric charge of a constant areal density \(\sigma\), is being rotated around its axis with a constant angular velocity \(\Omega\). Calculate:

(i) the induced magnetic field on the disk’s axis,
(ii) the magnetic moment of the disk,
and relate these results.

5.8. A thin spherical shell of radius \(R\), with charge \(Q\) uniformly distributed over its surface, rotates about its axis with angular velocity \(\omega\). Calculate the distribution of the magnetic field everywhere in space.

5.9. A sphere of radius \(R\), made of an insulating material with a uniform electric charge density \(\rho\), rotates about its diameter with angular velocity \(\omega\). Calculate the magnetic field distribution inside the sphere and outside it.

5.10. The reader is (hopefully :) familiar with the classical Hall effect when it takes place in the usual rectangular \textit{Hall bar} geometry – see the left panel of the figure below. However, the effect takes a different form in the so-called \textit{Corbino disk} – see the right panel of the figure below. (Dark shading shows electrodes, with no appreciable resistance.) Analyze the effect in both geometries, assuming that in both cases the conductors are thin, planar, have a constant Ohmic conductivity \(\sigma\) and charge carrier density \(n\), and that the applied magnetic field \(\mathbf{B}\) is uniform and normal to conductors’ planes.

\begin{figure}[h]
\centering
\includegraphics[width=0.5\textwidth]{hall_effect.png}
\caption{Hall effect in Hall bar and Corbino disk geometries.}
\end{figure}

\textsuperscript{66} This system (called the \textit{Helmholtz coils}), producing a highly uniform field near its center, is broadly used in physics experiment.
5.11. The simplest model of the famous homopolar motor\textsuperscript{67} is a thin, round conducting disk, placed into a uniform magnetic field normal to its plane, and fed by a dc current flowing from disk’s center to a sliding electrode (“brush”) on its rim – see the figure on the right.

(i) Express the torque rotating the disk, via its radius $R$, the magnetic field $B$, and the current $I$.

(ii) If the disk is allowed to rotate about its axis, and the motor is driven by a battery with e.m.f. $\mathcal{V}$, calculate its stationary angular velocity $\omega$, neglecting friction and the electric circuit’s resistance.

(iii) Now assuming that the current circuit (battery + wires + contacts + disk itself) has a non-zero resistance $\mathcal{R}$, derive and solve the equation for the time evolution of $\omega$, and analyze the solution.

5.12. Current $I$ flows in a thin wire bent into a plane, round loop of radius $R$. Calculate the net magnetic flux through the plane in which the loop is located.

5.13. Prove that:

(i) the self-inductance $L$ of a current loop cannot be negative, and

(ii) any inductance coefficient $L_{kk'}$, defined by Eq. (60), cannot be larger than $(L_{kk}L_{k'k'})^{1/2}$.

5.14. Estimate the values of magnetic susceptibility due to

(i) orbital diamagnetism, and

(ii) spin paramagnetism,

for a medium with negligible interaction between the induced molecular dipoles. Compare the results.

*Hints: For Task (i), you may use the classical model described by Eq. (114) – see Fig. 13. For Task (ii), assume the mechanism of ordering of spontaneous magnetic dipoles $\mathbf{m}_0$, with a magnitude $m_0$ of the order of the Bohr magneton $\mu_B$, similar to the one sketched for electric dipoles in Fig. 3.7a.

5.15. Use the classical picture of the orbital (“Larmor”) diamagnetism, discussed in Sec. 5, to calculate its (small) contribution $\Delta B(0)$ to the magnetic field $B$ felt by an atomic nucleus, modeling the electrons of the atom by a spherically-symmetric cloud with an electric charge density $\rho(r)$. Express the result via the value $\Phi(0)$ of the electrostatic potential of electrons’ cloud, and use this expression for a crude numerical estimate of the ratio $\Delta B(0)/B$ for the hydrogen atom.

5.16. Calculate the (self-) inductance of a toroidal solenoid (see Fig. 6b) with the round cross-section of radius $r \sim R$ (see the figure on the right), with many ($N \gg 1$, $R/r$) wire turns uniformly distributed along the perimeter, and filled with a linear magnetic material of a magnetic permeability $\mu$. Check your results by analyzing the limit $r \ll R$.

\textsuperscript{67} It was invented by Michael Faraday in 1821, i.e. well before his celebrated work on electromagnetic induction. The adjective “homopolar” refers to the constant “polarity” (sign) of the current; the alternative term is “unipolar”.
5.17. A long straight, thin wire, carrying current \( I \), passes parallel to the plane boundary between two uniform, linear magnetics – see the figure on the right. Calculate the magnetic field everywhere in the system, and the force (per unit length) exerted on the wire.

5.18. Solve the magnetic shielding problem similar to that discussed in Sec. 5.6 of the lecture notes, but for a spherical, rather than cylindrical shell, with the same central cross-section as shown in Fig. 16. Compare the efficiency of those two shields, for the same shell’s permeability \( \mu \), and the same \( b/a \) ratio.

5.19. Calculate the magnetic field distribution around a spherical permanent magnet with a uniform magnetization \( \mathbf{M}_0 = \text{const} \).

5.20. A limited volume \( V \) is filled with a magnetic material with a fixed (field-independent) magnetization \( \mathbf{M}(\mathbf{r}) \). Write explicit expressions for the magnetic field induced by the magnetization, and its potential, and recast these expressions into the forms more convenient when \( \mathbf{M}(\mathbf{r}) = \mathbf{M}_0 = \text{const} \) inside the volume \( V \).

5.21. Use the results of the previous problem to calculate the distribution of the magnetic field \( \mathbf{H} \) along the axis of a straight permanent magnet of length \( 2l \), with a round cross-section of radius \( R \), and a uniform magnetization \( \mathbf{M}_0 \) parallel to the axis – see the figure on the right.

5.22. A very broad film of thickness \( 2t \) is permanently magnetized normally to its plane, with a periodic checkerboard pattern, with the square of area \( a \times a \):

\[
\mathbf{M}_{|z|<t} = n_z M(x, y), \quad \text{with } M(x, y) = M_0 \times \text{sgn} \left( \cos \frac{\pi x}{a} \cos \frac{\pi y}{a} \right).
\]

Calculate the magnetic field’s distribution in space.\(^{68}\)

5.23.* Based on the discussion of the quadrupole electrostatic lens in Sec. 2.4, suggest the permanent-magnet systems that may similarly focus particles moving close to the system’s axis, and carrying:

(i) an electric charge,
(ii) no net electric charge, but a spontaneous magnetic dipole moment \( \mathbf{m} \).

\(^{68}\) This problem is of an evident relevance for the perpendicular magnetic recording (PMR) technology, which presently dominates the high-density digital magnetic recording.
Chapter 6. Electromagnetism

This chapter discusses two major new effects that arise when the electric and magnetic fields are changing in time: the “electromagnetic induction” of an additional electric field by changing magnetic field, and the reciprocal effect of the “displacement currents”- actually, the induction of an additional magnetic field by changing electric field. These two phenomena, which make time-dependent electric and magnetic fields inseparable (hence the term “electromagnetism”), are reflected in the full system of Maxwell equations, valid for an arbitrary electromagnetic process. On the way toward this system, I will make a pause for a brief review of the electrodynamics of superconductivity, which (besides its own significance), provides a perfect platform for a discussion of the general issue of gauge invariance.

6.1. Electromagnetic induction

As Eqs. (5.36) show, in static situations ($\frac{\partial}{\partial t} = 0$) the Maxwell equations describing the electric and magnetic fields are independent – coupled only implicitly, via the continuity equation (4.5) relating their right-hand sides $\rho$ and $j$. (In statics, this relation imposes a restriction only on $j$.) In dynamics, when the fields change in time, the situation in different.

Historically, the first discovered explicit coupling between the electric and magnetic fields was the effect of electromagnetic induction. The summary of Faraday’s numerous experiments has turned out to be very simple: if the magnetic flux, defined by Eq. (5.65),

$$\Phi \equiv \int S B \cdot dS,$$  

(6.1)

through a surface $S$ limited by contour $C$, changes in time by whatever reason (e.g., either due to a change of the magnetic field $B$ (as in Fig.1), or the contour’s motion, or its deformation, or any combination of the above), it induces an additional, vortex-like electric field $\mathbf{E}_{\text{ind}}$ directed along the contour – see Fig. 1.

![Fig. 6.1. Two simplest ways to observe the Faraday electromagnetic induction.](image)

The exact distribution of $\mathbf{E}_{\text{ind}}$ in space depends on system geometry details, but its integral along the contour $C$, called the inductive electromotive force (e.m.f.), obeys a very simple Faraday induction law:

\[
I = \mathcal{V}_{\text{ind}} / R
\]

---

1 It was coined by H. Ørsted in 1820 in the context of his experiments – see the previous chapter.

2 The induction effect was discovered independently by Joseph Henry, but it was a brilliant series of experiments by Michael Faraday, carried out mostly in 1831, that resulted in the first general formulation of the induction law.
\[ \mathcal{V}_{\text{ind}} = \oint_{C} \mathbf{E}_{\text{ind}} \cdot d\mathbf{r} = -\frac{d\Phi}{dt}. \] (6.2)

(In the Gaussian units, the right-hand side of this formula has the additional coefficient \(1/c\).)

It is straightforward (and hence left for the reader’s exercise) to show that this e.m.f. may be measured, for example, either inserting a voltmeter into a conducting loop following contour \(C\), or by measuring a small current \(I = \mathcal{V}_{\text{ind}}/R\) it induces in a thin wire with a sufficiently large Ohmic resistance \(R\), whose shape follows that contour – see Fig. 1. (Actually, these methods are not entirely different, because a typical voltmeter measures voltage by the small Ohmic current it drives through a known high internal resistance of the device.) In the context of the latter approach, it is easy to formulate the so-called Lenz rule used for the description of the minus sign in Eq. (2): the magnetic field of the induced current \(I\) provides a partial compensation of the change of the original flux \(\Phi(t)\) with time.4

In order to recast Eq. (2) in a differential form, more convenient in many cases, let us apply to the contour integral in it the same Stokes theorem that was repeatedly used in Chapter 5. The result is

\[ \mathcal{V}_{\text{ind}} = \int_{S} \left( \nabla \times \mathbf{E}_{\text{ind}} \right) \cdot d^{2}r. \] (6.3)

Now combining Eqs. (1)-(3), for a contour \(C\) whose shape does not change in time (so that the integration along it is interchangeable with the time derivative), we get

\[ \int_{S} \left( \nabla \times \mathbf{E}_{\text{ind}} + \frac{\partial \mathbf{B}}{\partial t} \right) \cdot d^{2}r = 0. \] (6.4)

Since the induced electric field is an addition to the gradient field (1.33) created by electric charges, for the net field we may write \(\mathbf{E} = \mathbf{E}_{\text{ind}} - \nabla \phi\). However, since the curl of any gradient field is zero, \(\nabla \times (\nabla \phi) = 0\), Eq. (4) remains valid even for the net field \(\mathbf{E}\). Since this equation should be correct for any closed area \(S\), we may conclude that

\[ \nabla \times \mathbf{E} + \frac{\partial \mathbf{B}}{\partial t} = 0 \] (6.5)

at any point. This is the final (time-dependent) form of this Maxwell equation. Superficially, it may look that Eq. (5) is less general than Eq. (2); for example, it does not describe any electric field, and hence any e.m.f. in a moving loop, if the field \(\mathbf{B}\) is constant in time, even if the magnetic flux (1) through the loop does change in time. However, this is not true; in Chapter 9 we will see that in the reference frame moving with the loop such e.m.f. does appear.6

---

3 Such induced current is sometimes called the *eddy current*, though most often this term is reserved for the distributed currents induced by a changing magnetic field in a bulk conductor – see Sec. 3 below.

4 Let me also hope that the reader is familiar with the paradox arising at attempts to measure \(\mathcal{V}_{\text{ind}}\) with a voltmeter without its insertion into the wire loop; if not, I would highly recommend him or her to solve Problem 2.

5 See, e.g., MA Eq. (11.1).

6 I have to admit that from the beginning of the course, I was carefully sweeping under the rug a very important question: in what exactly reference frame(s) all the equations of electrodynamics are valid? I promise to discuss this issue in detail later in the course (in Chapter 9), and for now would like to get away with a very short answer: all the formulas discussed so far are valid in *any inertial* reference frame, as defined in classical mechanics – see, e.g., CM Sec. 1.3. It is crucial, however, to have fields \(\mathbf{E}\) and \(\mathbf{B}\) measured *in the same* reference frame.
Now let us re-formulate Eq. (5) in terms of the vector potential $A$. Since the induction effect does not alter the fundamental relation $\nabla \cdot B = 0$, we still may represent the magnetic field as prescribed by Eq. (5.27), i.e. $B = \nabla \times A$. Plugging this expression into Eq. (5), and changing the order of the temporal and spatial differentiation, we get

$$\nabla \times \left( \mathbf{E} + \frac{\partial \mathbf{A}}{\partial t} \right) = 0.$$  \hspace{1cm} (6.6)

Hence we can use the same argumentation as in Sec. 1.3 (there applied to the vector $\mathbf{E}$ alone) to represent the expression in the parentheses as $-\nabla \phi$, so that we get

$$\mathbf{E} = -\frac{\partial \mathbf{A}}{\partial t} - \nabla \phi, \quad \mathbf{B} = \nabla \times \mathbf{A}.$$  \hspace{1cm} (6.7)

It is very tempting to interpret the first term of the right-hand side of the expression for $\mathbf{E}$ as describing the electromagnetic induction alone, and the second term representing a purely electrostatic field induced by electric charges. However, the separation of these two terms is, to a certain extent, conditional. Indeed, let us consider the gauge transformation already mentioned in Sec. 5.2,

$$A \rightarrow A + \nabla \chi,$$  \hspace{1cm} (6.8)

that, as we already know, does not change the magnetic field. According to Eq. (7), to keep the full electric field intact (gauge-invariant) as well, the scalar electric potential has to be transformed simultaneously, as

$$\phi \rightarrow \phi - \frac{\partial \chi}{\partial t},$$  \hspace{1cm} (6.9)

leaving the choice of a time-independent addition to $\phi$ restricted only by the Laplace equation – since the full $\phi$ should satisfy the Poisson equation (1.41) with a gauge-invariant right-hand side. We will return to the discussion of the gauge invariance in Sec. 4.

### 6.2. Magnetic energy revisited

Now we are sufficiently equipped to return to the issue of the magnetic energy, in particular, to finally prove Eqs. (5.57) and (5.140), and discuss the dichotomy of the signs in Eqs. (5.53) and (5.54). For that, let us consider a sufficiently slow, small magnetic field variation $\partial \mathbf{B}$. If we want to neglect the kinetic energy of the system of electric currents under consideration, as well as the wave radiation effects, we need to prevent its acceleration by the arising induction field $\mathbf{E}_{\text{ind}}$. Let us suppose that we do this by the virtual balancing this field by an external electric field $\mathbf{E}_{\text{ext}} = -\mathbf{E}_{\text{ind}}$. According to Eq. (4.38), the work of that field\(^7\) on the stand-alone currents of the system during time interval $\delta t$, and hence the change of the potential energy of the system, is

$$\delta U = \delta t \int_{\mathcal{V}} \mathbf{j} \cdot \mathbf{E}_{\text{ext}} d^3 r = -\delta t \int_{\mathcal{V}} \mathbf{j} \cdot \mathbf{E}_{\text{ind}} d^3 r,$$  \hspace{1cm} (6.10)

\(^7\) As a reminder, the magnetic component of the Lorentz force (5.10), $\mathbf{v} \times \mathbf{B}$, is always perpendicular to particle’s velocity $\mathbf{v}$, so that the magnetic field $\mathbf{B}$ itself cannot perform any work on moving charges, i.e. on currents.
where the integral is over the volume of the system. Now expressing the current density $j$ from the macroscopic Maxwell equation (5.107), and then applying the vector algebra identity\(^8\)

$$
(\nabla \times \mathbf{H}) \cdot \mathbf{E}_{\text{ind}} = \mathbf{H} \cdot (\nabla \times \mathbf{E}_{\text{ind}}) - \nabla \cdot (\mathbf{E}_{\text{ind}} \times \mathbf{H}),
$$

we get

$$
\delta U = -\delta t \oint \mathbf{H} \cdot (\nabla \times \mathbf{E}) d^3r + \delta t \oint \nabla \cdot (\mathbf{E} \times \mathbf{H}) d^3r.
$$

According to the divergence theorem, the second integral in the right-hand of this equality is equal to the flux of the Poynting vector $\mathbf{S} \equiv \mathbf{E} \times \mathbf{H}$ through the surface limiting the considered volume $V$. Later in the course we will see that this flux represents, in particular, the power of electromagnetic radiation through the surface. If such radiation is negligible (as it always is if the field variation is sufficiently slow), the surface may be selected sufficiently far, so that the flux of $\mathbf{S}$ is negligible. In this case, we may express $\nabla \times \mathbf{E}$ from the Faraday induction law (5) to get

$$
\delta U = -\delta t \oint \left( -\frac{\partial \mathbf{B}}{\partial t} \right) \cdot \mathbf{H} d^3r = \oint \mathbf{H} \cdot \mathbf{B} d^3r.
$$

Just as in the electrostatics (see Eqs. (1.65) and (3.73), and their discussion), this relation may be interpreted as the variation of the magnetic field energy $U$ of the system, and represented in the form

$$
\delta U = \int \delta u(r) d^3r, \quad \text{with } \delta u \equiv \mathbf{H} \cdot \mathbf{B}.
$$

This is a keystone result; let us discuss it in some detail.

First of all, for a system filled with a linear magnetic material, we may use Eq. (14) together with Eq. (5.110): $\mathbf{B} = \mu \mathbf{H}$. Integrating the result over the variation of the field from 0 to a certain final value $\mathbf{B}$, we get Eq. (5.140) – so important that it is worthy of rewriting it again:

$$
U = \int u(r) d^3r, \quad \text{with } u = \frac{B^2}{2\mu}.
$$

In the simplest case of free space (no magnetics at all, so that $\mathbf{j}$ above is the complete current density), we may take $\mu = \mu_0$, and reduce Eq. (15) to Eq. (5.57). Now performing backward the transformations that took us, in Sec. 5.3, to derive that relation from Eq. (5.54), we finally have the latter formula proved – as was promised.

It is very important, however, to understand the limitations of Eq. (15). For example, let us try to apply it to a very simple problem, which was already analyzed in Sec. 5.6 (see Fig. 5.15): a very long cylindrical sample of a linear magnetic material placed into a fixed external field $\mathbf{H}_{\text{ext}}$, parallel to the sample’s axis. It is evident that in this simple geometry, the field $\mathbf{H}$ and hence the field $\mathbf{B} = \mu \mathbf{H}$ have to be uniform inside the sample, besides negligible regions near its ends, so that Eq. (15) is reduced to

$$
U = \frac{B^2}{2\mu} V,
$$

\(^8\) See, e.g., MA Eq. (11.7) with $f = \mathbf{E}_{\text{ind}}$ and $g = \mathbf{H}$.\n
---

Chapter 6  Page 4 of 38
where \( V = Al \) is the cylinder’s volume. Now if we try to calculate the static (equilibrium) value of the field from the minimum of this potential energy, we get evident nonsense: \( \mathbf{B} = 0 \) (WRONG!).

The situation may be readily rectified by using the notion of the Gibbs potential energy, just as it was done for the electric field in Sec. 3.5 (and implicitly in the end of Sec. 1.3). According to Eq. (14), in magnetostatics, the Cartesian components of the field \( \mathbf{H}(\mathbf{r}) \) play the role of the generalized forces, while those of the field \( \mathbf{B}(\mathbf{r}) \), of the generalized coordinates (per unit volume). As the result, the Gibbs potential energy, whose minimum corresponds to the stable equilibrium of the system under the effect of a fixed generalized force (in our current case, of the fixed external field \( \mathbf{H}_{\text{ext}} \)), is

\[
U_G = \int u_G(\mathbf{r})d^3r, \quad \text{with} \quad u_G(\mathbf{r}) = u(\mathbf{r}) - \mathbf{H}_{\text{ext}}(\mathbf{r}) \cdot \mathbf{B}(\mathbf{r}),
\]

- the expression parallel to Eq. (3.78). For a system with linear magnetics, we may use Eq. (15) for \( u \), getting the following Gibbs energy’s density:

\[
u_G(\mathbf{r}) = \frac{1}{2\mu} \mathbf{B} \cdot \mathbf{B} - \mathbf{H}_{\text{ext}} \cdot \mathbf{B} \equiv \frac{1}{2\mu} \left( \mathbf{B} - \frac{\mu}{\mu} \mathbf{H}_{\text{ext}} \right)^2 + \text{const},
\]

where “const” means a term independent of the field \( \mathbf{B} \) inside the sample. For our simple cylindrical system, with its uniform fields, Eqs. (17)-(18) gives the following full Gibbs energy of the sample:

\[
U_G = \frac{\left( \mathbf{B}_{\text{int}} - \frac{\mu}{\mu} \mathbf{H}_{\text{ext}} \right)^2}{2\mu} V + \text{const},
\]

whose minimum immediately gives the correct stationary value \( \mathbf{B}_{\text{int}} = \mu \mathbf{H}_{\text{ext}} \), i.e. \( \mathbf{H}_{\text{int}} \equiv \mathbf{B}_{\text{int}}/\mu = \mathbf{H}_{\text{ext}} \) – which was already obtained in Sec. 5.6 in a different way, from the boundary condition (5.117).

Now notice that with this result on hand, Eq. (18) may be rewritten in a different form:

\[
u_G(\mathbf{r}) = \frac{1}{2\mu} \mathbf{B} \cdot \mathbf{B} - \frac{\mathbf{B}}{\mu} \cdot \mathbf{B} \equiv -\frac{B^2}{2\mu},
\]

similar to Eq. (15) for \( u(\mathbf{r}) \), but with an opposite sign. This sign dichotomy explains that in Eqs. (5.53) and Eq. (5.54); indeed, as was already noted in Sec. 5.3, the former of these expressions gives the potential energy whose minimum corresponds to the equilibrium of a system with fixed currents. (In our current example, this means the external stand-alone currents inducing the field \( \mathbf{H}_{\text{ext}} \).) So, the energy \( U_j \) given by Eq. (5.53) is essentially the Gibbs energy \( U_G \) defined by Eqs. (17) and (for the case of linear magnetics, or no magnetic media at all) by Eq. (20), while Eq. (5.54) is just another form of Eq. (15) – as was explicitly shown in Sec. 5.3.11

---

9 Note that this erroneous result cannot be corrected by just adding the energy (15) of the field outside the cylinder, because in the limit \( t \to 0 \), this field is not affected by the internal field \( \mathbf{B} \).

10 Note that in this respect, the analogy with electrostatics is not quite complete. Indeed, according to Eq. (3.76), in electrostatics the role of a generalized coordinate is played by “would-be” field \( \mathbf{D} \), and that of the generalized force, by the actual electric field \( \mathbf{E} \). This difference may be traced back to the fact that electric field \( \mathbf{E} \) may perform work on a moving charged particle, while the magnetic field cannot. However, this difference does not affect the full analogy of expressions (3.73) and (15) for the field energy density in linear media.

11 As was already noted in Sec. 5.4, one more example of the energy \( U_j \) is given by Eq. (5.100).
Let me complete this section by stating that the difference between the energies \( U \) and \( U_G \) is not properly emphasized (or even left obscure) in some textbooks, so that the reader is advised to seek additional clarity by solving additional simple problems – for example, by spelling out these energies for the simple case of a long straight solenoid (Fig. 5.6a), and then using these formulas to calculate the pressure exerted by the magnetic field on the solenoid’s walls (windings) and the longitudinal forces exerted on its ends.

6.3. Quasistatic approximation and skin effect

Perhaps the most surprising experimental fact concerning the time-dependent electromagnetic phenomena is that unless they are so fast that one more new effect of the displacement currents (to be discussed in Sec. 7 below) becomes noticeable, all formulas of electrostatics and magnetostatics remain valid, with the only exception: the generalization of Eq. (3.36) to Eq. (5), describing the Faraday induction. As a result, the system of macroscopic Maxwell equations (5.109) is generalized to

\[
\nabla \times \mathbf{E} + \frac{\partial \mathbf{B}}{\partial t} = 0, \quad \nabla \times \mathbf{H} = \mathbf{j}, \\
\nabla \cdot \mathbf{D} = \rho, \quad \nabla \cdot \mathbf{B} = 0. 
\]

(As it follows from the discussions in chapters 3 and 5, the corresponding system of microscopic Maxwell equations for genuine, “microscopic” fields \( \mathbf{E} \) and \( \mathbf{B} \) may be obtained from Eq. (21) by the formal substitutions \( \mathbf{D} = \varepsilon_0 \mathbf{E} \) and \( \mathbf{H} = \mathbf{B}/\mu_0 \), and the replacement of the stand-alone charge and current densities \( \rho \) and \( \mathbf{j} \) with their full densities.\(^{12}\) These equations, whose range of validity will be quantified in Sec. 7, define the so-called quasistatic approximation of electromagnetism, and are sufficient for an adequate description of a broad range of physical effects.

Let us use them first of all for an analysis of the so-called skin effect, the phenomenon of self-shielding of the alternating (ac) magnetic field by the eddy currents induced by the field in an Ohmic conductor. In order to form a complete system of equations, Eqs. (21) should be augmented by constituent equations describing the medium. Let us take them, for a conductor, in the simplest (and simultaneously, most common) linear and isotropic forms already discussed in Chapters 4 and 5:

\[
\mathbf{j} = \sigma \mathbf{E}, \quad \mathbf{B} = \mu \mathbf{H}. 
\]

If the conductor is uniform, i.e. the coefficients \( \sigma \) and \( \mu \) are constant inside it, the whole system of Eqs. (21)-(22) may be reduced to just one equation. Indeed, a sequential substitution of these equations into each other, using a well-known vector-algebra identity\(^{13}\) in the middle, yields:

\[
\frac{\partial \mathbf{B}}{\partial t} = -\nabla \times \mathbf{E} = -\frac{1}{\sigma} \nabla \times \mathbf{j} = -\frac{1}{\sigma} \nabla \times (\nabla \times \mathbf{H}) = -\frac{1}{\sigma \mu} \nabla \times (\nabla \times \mathbf{B}) \equiv -\frac{1}{\sigma \mu} \left[ \nabla (\nabla \cdot \mathbf{B}) - \nabla^2 \mathbf{B} \right] \\
= \frac{1}{\sigma \mu} \nabla^2 \mathbf{B}. 
\]

\(^{12}\) Obviously, in free space the last replacement is unnecessary, because all charges and currents may be treated as “stand-alone” ones.

\(^{13}\) See, e.g., MA Eq. (11.3).
Thus we have arrived, without any further assumptions, at a rather simple partial differential equation. Let us use it to analyze the skin effect in the simplest geometry (Fig. 2a) when an external source (which, at this point, does not need to be specified) has produced, near a plane surface of a bulk conductor, a spatially-uniform ac magnetic field $H^{(0)}(t)$ parallel to the surface.\(^{14}\)

Selecting the coordinate system as shown in Fig. 2a, we may express this condition as

$$H \big|_{x=0} = H^{(0)}(t) n_y . \quad (6.24)$$

The translational symmetry of our simple problem within the surface plane $[y, z]$ implies that inside the conductor $\partial/\partial y = \partial/\partial z = 0$ as well, and $H = H(x, t)n_0$ even at $x \geq 0$, so that Eq. (23) for conductor’s interior is reduced to a differential equation for just one scalar function $H(x, t) = B(x, t)/\mu$:

$$\frac{\partial H}{\partial t} = \frac{1}{\sigma \mu} \frac{\partial^2 H}{\partial x^2}, \quad \text{for } x \geq 0 . \quad (6.25)$$

This equation may be further simplified by noticing that due to its linearity, we may use the linear superposition principle for the time dependence of the field,\(^{15}\) via expanding it, as well as the external field (24), into the Fourier series:

$$H(x,t) = \sum_\omega H_\omega(x)e^{-i\omega t}, \quad \text{for } x \geq 0,$$

$$H^{(0)}(t) = \sum_\omega H^{(0)}_\omega e^{-i\omega t}, \quad \text{for } x = -0, \quad (6.26)$$

and arguing that if we know the solution for each frequency component of the series, the whole field may be found through the straightforward summation (26) of these solutions.

For each a single-frequency component, Eq. (25) is immediately reduced to an ordinary differential equation for the complex amplitude $H_\omega(x)$:\(^{16}\)

\(^{14}\) Due to the simple linear relation $B = \mu H$ between the fields $B$ and $H$, it does not matter too much which of them is used for the solution of this problem, with a slight preference for $H$, due to the simplicity of Eq. (5.117) – the only boundary condition relevant for this simple geometry.

\(^{15}\) Another important way to exploit the linearity of Eq. (6.25) is to use the spatial-temporal Green’s function approach to explore the dependence of its solutions on various initial conditions. Unfortunately, because of lack of time, I have to leave an analysis of this opportunity for the reader’s exercise.
\[-i\omega H_\omega = \frac{1}{\sigma \mu} \frac{d^2}{dx^2} H_\omega. \quad (6.27)\]

From the theory of linear ordinary differential equations, we know that Eq. (27) has the following general solution:

\[H_\omega (x) = H_+ e^{\kappa_+ x} + H_- e^{\kappa_- x}, \quad (6.28)\]

where the constants \(\kappa\) are the roots of the characteristic equation that may be obtained by substitution of any of these two exponents into the initial differential equation. For our particular case, the characteristic equation, following from Eq. (27), is

\[-i\omega = \frac{\kappa^2}{\sigma \mu} \quad (6.29)\]

and its roots are complex constants

\[\kappa_\pm = (-i \mu \omega \sigma)^{1/2} \equiv \pm \frac{1 - i}{\sqrt{2}} (\mu \omega \sigma)^{1/2}. \quad (6.30)\]

For our problem, the field cannot grow exponentially at \(x \to +\infty\), so that only one of the coefficients, namely \(H\) corresponding to the decaying exponent, with \(\text{Re } \kappa < 0\) (i.e. \(\kappa = \kappa_-\)), may be different from zero, i.e. \(H_\omega(x) = H_\omega(0) \exp\{\kappa_+ x\}\). In order to find the constant factor \(H_\omega(0)\), we can integrate the macroscopic Maxwell equation \(\nabla \times \mathbf{H} = \mathbf{j}\) along a pre-surface contour – say, the contour \(C_1\) shown in Fig. 2b. The right-hand side’s integral is negligible, because the stand-alone current density \(\mathbf{j}\) does not include the “genuinely-surface” currents responsible for the magnetic permeability \(\mu\) – see Fig. 5.12. As a result, we get the boundary condition similar to Eq. (5.117) for the stationary magnetic field: \(H_\tau = \text{const at } x = 0\), i.e.

\[H(0,t) = H^{(0)}(t) \quad \text{i.e. } H_\omega(0) = H_\omega^{(0)}, \quad (6.31)\]

so that the final solution of our problem may be represented as

\[H_\omega (x) = H_\omega^{(0)} \exp\left\{-\frac{x}{\delta_\omega}\right\} \exp\left\{-i\left(\omega t - \frac{x}{\delta_\omega}\right)\right\}, \quad (6.32)\]

where the constant \(\delta_\omega\), with the dimension of length, is called the skin depth:

\[\delta_\omega \equiv -\frac{1}{\text{Re } \kappa_-} = \left(\frac{2}{\mu \sigma \omega}\right)^{1/2}. \quad (6.33)\]

This solution describes the skin effect: the penetration of the ac magnetic field of frequency \(\omega\), and the eddy currents \(\mathbf{j}\) it induces, into a conductor only to a finite depth of the order of \(\delta_\omega\).\(^{17}\) Let me give

\(^{16}\) Let me hope that the reader is not intimidated by the (very convenient) use of such complex variables for describing real fields; their imaginary parts always disappear at the final summation (26). For example, if the external field is purely sinusoidal, with the actual (positive) frequency \(\omega\), each sum in Eq. (26) has just two terms, with complex amplitudes \(H_\omega\) and \(H_\omega^* = H_\omega^*\), so that their sum is always real. (For a more detailed discussion of this issue, see, e.g., CM Sec. 5.1.)

\(^{17}\) Let me hope that the physical intuition of the reader makes it evident that the ac field penetrates into a sample of any shape only by a distance of the order of \(\delta_s\).
a few of numerical examples of this depth: for copper at room temperature, \( \delta_s \approx 1 \text{ cm} \) at the ac power distribution frequency of 60 Hz, and is of the order of just 1 \( \mu \text{m} \) at a few GHz, i.e. at typical frequencies of cell phone signals and kitchen microwave magnetrons. For lightly salted (say, sea) water, \( \delta_s \) is close to 250 m at just 1 Hz (with big implications for radio communications with submarines), and is of the order of 1 cm at a few GHz (explaining, in particular, nonuniform heating of a soup bowl in a microwave oven).

In order to complete the skin effect discussion, let us consider what happens with the induced eddy currents and the electric field at this effect. When deriving our basic equation (23), we have used, in particular, relations \( j = \nabla \times H = \mu^{-1} \nabla \times B \), and \( E = j/\sigma \). Since a spatial differentiation of an exponent yields a similar exponent, the electric field and current density have the same spatial dependence as the magnetic field, i.e. penetrate inside the conductor only by distances of the order of \( \delta_s(\omega) \), but their vectors are directed perpendicularly to \( B \), while still being parallel to the conductor surface:

\[
\begin{align*}
\begin{align*}
\mathbf{j}_\omega(x) &= \kappa \cdot H_\omega(x) \mathbf{n}_z, \\
\mathbf{E}_\omega(x) &= \frac{\kappa}{\sigma} \cdot H_\omega(x) \mathbf{n}_z .
\end{align*}
\end{align*}
\] (6.34)

We may use these expressions to calculate the time-averaged power density (4.39) of the energy dissipation, for the important case of a sinusoidal (“monochromatic”) field \( H(x, t) = |H_\omega(x)| \cos(\omega t + \phi) \), and hence sinusoidal eddy currents: \( j(x, t) = |j_\omega(x)| \cos(\omega t + \phi') \):

\[
\overline{\mathcal{P}}(x) = \frac{j^2(x, t)}{2\sigma} = \frac{j_\omega(x)^2 \cos^2(\omega t + \phi')}{2\sigma} = \frac{\kappa^2}{2\sigma} \cdot \frac{|H_\omega(x)|^2}{\delta_s^2 \sigma} = \frac{|H_\omega(x)|^2}{\delta_s^2 \sigma} . \quad (6.35)
\]

Now the (elementary) integration of this expression along the \( x \)-axis (through all the skin depth), using the exponential law (6.32), gives us the following average power of the energy loss per unit area:

\[
\frac{d\overline{\mathcal{P}}}{dA} = \int_0^\infty \overline{\mathcal{P}}(x) dx = \frac{1}{2\delta_s \sigma} \cdot |H_\omega(0)|^2 = \frac{\mu \omega \delta_s}{4} \cdot |H_\omega(0)|^2 . \quad (6.36)
\]

We will extensively use this expression in the next chapter to calculate the energy losses in microwave waveguides and resonators with conducting (practically, metallic) walls, and for now I just note that according to Eqs. (33) and (36), at fixed applied field amplitude, the losses grow with frequency as \( \omega^{1/2} \).

One more important remark concerning Eqs. (34): integrating the first of them over \( x \), with the help of Eq. (32), we may readily prove that the linear density \( J \) of the surface currents (measured in A/m), is simply and fundamentally related to the applied magnetic field:

\[
J_\omega \equiv \int_0^\infty j_\omega(x) dx = H_\omega(0) \mathbf{n}_z . \quad (6.37)
\]

Since this relation does not have any frequency-dependent factors, we may sum it up for all frequency components, and get a universal relation

\[
J(t) = H^{(0)}(t) \mathbf{n}_z \equiv H^{(0)}(t)(-\mathbf{n}_x \times \mathbf{n}_z) = H^{(0)}(t) \times (-\mathbf{n}_z) = H^{(0)}(t) \times \mathbf{n} , \quad (6.38a)
\]

(where \( \mathbf{n} = -\mathbf{n}_z \) is the outer normal to the surface – see Fig. 2b) or, in a different form,

\[18\] The loop (vortex) character of the induced current lines, responsible for the term “eddy”, is not very apparent in the 1D geometry explored above, with the near-surface currents (Fig. 2b) looping only implicitly, at \( z \to \pm \infty \).
\[ \Delta \mathbf{H}(t) = \mathbf{n} \times \mathbf{J}(t), \]  
\hspace{1cm} (6.38b)

where \( \Delta \mathbf{H} \) is the full change of the field through the skin layer. This simple coarse-grain relation (whose last form is independent of the choice of coordinate axes), is independent of the used constituent relations (22), and is by no means occasional. Indeed, it may be readily obtained from the macroscopic Ampère law (5.116), applied to a contour drawn around a fragment of the surface, extending under it substantially deeper than the skin depth – see the contour \( C_2 \) in Fig. 2b, regardless of the exact law of the field penetration.

For the skin effect, this fundamental relation between the linear current density and the external magnetic field implies that the skin effect’s implementation does not necessarily require a dedicated ac magnetic field source. For example, the effect takes place in any wire that carries an ac current, leading to a current concentration in a surface sheet of thickness \( \sim \delta_s \). (Of course, the quantitative analysis of this problem in a wire with an arbitrary cross-section may be technically complicated, because it requires to solve Eq. (23) for a 2D geometry; even for the round cross-section, the solution involves the Bessel functions – see Problem 9.) In this case, the ac magnetic field outside the conductor, which still obeys Eq. (38), is better interpreted as the effect, rather than the reason, of the ac current flow.

Finally, the reader should mind the validity limits of all the above results. First, in order for the quasistatic approximation to be valid, the field frequency \( \omega \) should not be too high, so that the displacement current effects are negligible. (Again, this condition will be quantified in Sec. 7 below; it will show that for usual metals, the condition is violated only at extremely high frequencies above \( \sim 10^{18} \) s\(^{-1} \).) A more practical upper limit on \( \omega \) is that the skin depth \( \delta_s \) should stay much larger than the mean free path \( l \) of charge carriers,\(^{19} \) because beyond this point, the relation between the vectors \( \mathbf{j}(\mathbf{r}) \) and \( \mathbf{E}(\mathbf{r}) \) becomes essentially non-local. Both theory and experiment show that at \( \delta_s \) below \( l \), the skin effect still persists, but acquires a frequency dependence slightly different from Eq. (33), \( \delta_s \propto \omega^{1/3} \) rather than \( \omega^{-1/2} \). This so-called anomalous skin effect has useful applications, for example, for experimental measurements of the Fermi surface of metals.\(^{20} \)

6.4. Electrodynamics of superconductivity and gauge invariance

The effect of superconductivity\(^{21} \) takes place (in certain materials only, mostly metals) when temperature \( T \) is reduced below a certain critical temperature \( T_c \), specific for each material. For most metallic superconductors, \( T_c \) is of the order of typically a few kelvins, though several compounds (the so-called high-temperature superconductors) with \( T_c \) above 100 K have been found since 1987. The most notable property of superconductors is the absence, at \( T < T_c \), of measurable resistance to (not very high) dc currents. However, the electromagnetic properties of superconductors cannot be described by just taking \( \sigma = \infty \) in our previous results. Indeed, for this case, Eq. (33) would give \( \delta_s = 0 \), i.e., no ac magnetic field penetration at all, while for the dc field we would have the uncertainty \( \sigma \omega \rightarrow ? \). Experiment shows something substantially different: weak magnetic fields do penetrate into superconductors by a material-specific distance \( \delta_s \sim 10^{-7} \)-10\(^{-6} \) m, the so-called London’s penetration

\(^{19} \) A brief discussion of the mean free path may be found, for example, in SM Chapter 6. In very clean metals at very low temperatures, \( \delta_s \) may approach \( l \) at frequencies as low as \( \sim 1 \) GHz, but at room temperature, the crossover from the normal to the anomalous skin effect takes place only at \( \sim 100 \) GHz.

\(^{21} \) Discovered experimentally in 1911 by Heike Kamerlingh Onnes.
which is virtually frequency-independent until the skin depth $\delta_s$, measured in the same material in its “normal” state, i.e. the absence of superconductivity, becomes less than $\delta_L$. (This crossover happens typically at frequencies $\omega \sim 10^{13}-10^{14} \text s^{-1}$.) The smallness of $\delta_L$ on the human scale means that the magnetic field is pushed out of macroscopic samples at their transition into the superconducting state.

This Meissner-Ochsenfeld effect, discovered experimentally in 1933,\textsuperscript{23} may be partly understood using the following classical reasoning. The discussion of the Ohm law in Sec. 4.2 implied that the current’s (and hence the electric field’s) frequency $\omega$ is either zero or sufficiently low. In the classical Drude reasoning, this is acceptable while $\omega \tau << 1$, where $\tau$ is the effective carrier scattering time participating in Eqs. (4.12)-(4.13). If this condition is not satisfied, we should take into account the charge carrier inertia; moreover, in the opposite limit $\omega \tau >> 1$, we may neglect the scattering at all. Classically, we can describe the charge carriers in such a “perfect conductor” as particles with a non-zero mass $m$, which are accelerated by the electric field, following the 2nd Newton law (4.11),

$$m \ddot{\mathbf{v}} = \mathbf{F} = q \mathbf{E}, \quad (6.39)$$

so that the current density $\mathbf{j} = qn\mathbf{v}$ they create changes in time as

$$\dot{\mathbf{j}} = qn\ddot{\mathbf{v}} = \frac{q^2 n}{m} \mathbf{E}. \quad (6.40)$$

In terms of the Fourier amplitudes of the functions $\mathbf{j}(t)$ and $\mathbf{E}(t)$, this means

$$-i\omega \mathbf{j}_\omega = \frac{q^2 n}{m} \mathbf{E}_\omega. \quad (6.41)$$

Comparing this formula with the relation $\mathbf{j}_\omega = \sigma \mathbf{E}_\omega$ implied in the last section, we see that we can use all its results with the following replacement:

$$\sigma \rightarrow i \frac{q^2 n}{m \omega}. \quad (6.42)$$

This change replaces the characteristic equation (29) with

$$-i\omega = \frac{\kappa^2 m \omega}{iq^2 n \mu}, \quad \text{i.e.} \quad \kappa^2 = \frac{\mu q^2 n}{m}, \quad (6.43)$$

i.e. replaces the skin effect with the field penetration by the following frequency-independent depth:

$$\delta \equiv \frac{1}{\kappa} = \left( \frac{m}{\mu q^2 n} \right)^{1/2}. \quad (6.44)$$

Superficially, this means that the field decay into the superconductor does not depend on frequency:

$$H(x,t) = H(0,t)e^{-x/\delta}, \quad (6.45)$$

\textsuperscript{22} Named to acknowledge the pioneering theoretical work of brothers Fritz and Heinz London – see below.

\textsuperscript{23} It is hardly fair to shorten the name to just the “Meissner effect”, as it is frequently done, because of the reportedly crucial contribution by Robert Ochsenfeld, then a Walther Meissner’s student, into the discovery.
thus explaining the Meissner-Ochsenfeld effect.

However, there are two problems with this result. First, for the parameters typical for good metals \((q = -e, n \sim 10^{29} \text{ m}^{-3}, m \sim m_e, \mu \approx \mu_0)\), Eq. (44) gives \(\delta \sim 10^{-8} \text{ m}\), a factor of \(\sim 10\) to \(\sim 10^2\) lower than the typical experimental values of \(\delta\). Experiment also shows that the penetration depth diverges at \(T \to T_c\), which is not predicted by Eq. (44). Another, much more fundamental problem with Eq. (44) is that it has been derived for \(\omega \tau >> 1\). Even if we assume that somehow there is no scattering at all, i.e. \(\tau = \infty\), at \(\omega \to 0\) both parts of the characteristic equation (43) vanish, and we cannot make any conclusion about \(\kappa\). This is not just a mathematical artifact we could ignore. For example, let us place a non-magnetic metal into a static external magnetic field at \(T > T_c\). The field would completely penetrate the sample. Now let us cool it. As soon as the temperature is decreased below \(T_c\), the above calculations would become valid, forbidding the penetration into the superconductor of any change of the field, so that the initial field would be “frozen” inside the sample. The experiment shows something completely different: as \(T\) is lowered below \(T_c\), the initial field is being pushed out of the sample.

The resolution of these contradictions has been provided by quantum mechanics. As was explained in 1957 in a seminal work by J. Bardeen, L. Cooper, and J. Schrieffer (commonly referred to as the BSC theory), the superconductivity is due to the correlated motion of electron pairs, with opposite spins and nearly opposite momenta. Such Cooper pairs, each with the electric charge \(q = -2e\) and zero spin, may form only in a narrow energy layer near the Fermi surface, of certain thickness \(\Delta(T)\). This parameter \(\Delta(T)\), which may also be considered as the binding energy of the pair, tends to zero at \(T \to T_c\), while at \(T << T_c\) it has a virtually constant value \(\Delta(0) \approx 3.5 k_B T_c\), of the order of a few meV for most superconductors. This fact readily explains the relatively low spatial density of the Cooper pairs: \(n_p \sim n\Delta(T) / \varepsilon_F \sim 10^{26} \text{ m}^{-3}\). With the correction \(n \to n_p\), Eq. (44) for the penetration depth becomes

\[
\delta \rightarrow \delta_L = \left( \frac{m}{\mu q^2 n_p} \right)^{1/2}.
\]

This expression diverges at \(T \to T_c\), and generally fits the experimental data reasonably well, at least for the so-called “clean” superconductors (with the mean free path \(l = v_F \tau\), where \(v_F \sim (2m \varepsilon_F)^{1/2}\) is the r.m.s. velocity of electrons on the Fermi surface, much longer than the Cooper pair size \(\xi\) – see below).

The smallness of the coupling energy \(\Delta(T)\) is also a key factor in the explanation of the Meissner-Ochsenfeld effect, as well as several macroscopic quantum phenomena in superconductors. Because of the Heisenberg’s quantum uncertainty relation \(\delta r \delta \phi \sim \hbar\), the spatial extension of the Cooper-pair’s wavefunction (the so-called coherence length of the superconductor) is relatively large: \(\xi \sim \delta r \sim \hbar / \delta \phi \sim h v_F / \Delta(T) \sim 10^{-6} \text{ m}\). As a result, \(n_p \xi^3 >> 1\), meaning that the wavefunctions of the pairs are strongly overlapped in space. Now, due to their integer spin, Cooper pairs behave like bosons, which means in particular that at low temperatures they exhibit the so-called Bose-Einstein condensation onto the same ground energy level \(\varepsilon_g\).\(^{24}\) This means that the frequency \(\omega = \varepsilon_g / \hbar\) of the time evolution of each pair’s

\(^{24}\) A qualitative discussion of the Bose-Einstein condensation of bosons may be found in SM Sec. 3.4, though the full theory of superconductivity is more complex, because it describes the condensation taking place simultaneously with the formation of effective bosons (Cooper pairs) from fermions (single electrons). For more detailed, but very readable coverage of physics of superconductors, I would refer the reader to the monograph by M. Tinkham, *Introduction to Superconductivity*, 2nd ed., McGraw-Hill, 1996.
wavefunction $\Psi = \psi \exp\{-i\omega t\}$ is the same, i.e. that the phases $\varphi$ of the wavefunctions, defined by the relation

$$\psi = |\psi| e^{i\varphi},$$

(6.47)
become equal, so that the electric current is carried not by individual Cooper pairs but rather their Bose-Einstein condensate described by a single wavefunction. Due to this coherence, the quantum effects (which are, in the usual Fermi-gases of single electrons, masked by the statistical spread of their energies, and hence of their phases), become very explicit – “macroscopic”.

To illustrate this, let us write the well-known quantum-mechanical formula for the probability current density of a free, non-relativistic particle,\(^\text{25}\)

$$j_w = \frac{i\hbar}{2m} \left( \psi \nabla \psi^* - \text{c.c.} \right) \equiv \frac{1}{2m} \left[ \psi^* (-i\hbar \nabla) \psi - \text{c.c.} \right],$$

(6.48)

where c.c. means the complex conjugate of the previous expression. Now let me borrow one result that will be proved later in this course (in Sec. 9.7) when we discuss the analytical mechanics of a charged particle moving in an electromagnetic field. Namely, to account for the magnetic field effects, the particle’s kinetic momentum $p \equiv mv$ (where $v = dr/dt$ is particle’s velocity) has to be distinguished from its canonical momentum,\(^\text{26}\)

$$P \equiv p + qA.$$  

(6.49)

where $A$ is the vector potential of the field, defined by Eq. (5.27). In contrast with the Cartesian components $p_j = mv_j$ of the kinetic momentum $p$, the canonical momentum’s components are the generalized momenta corresponding to the Cartesian components $r_j$ of the radius-vector $r$, considered as generalized coordinates of the particle: $P_j = \partial L/\partial \dot{r}_j$, where $L$ is the particle’s Lagrangian function. According to the general rules of transfer from classical to quantum mechanics,\(^\text{27}\) it is the vector $P$ whose operator (in the coordinate representation) equals $-i\hbar \nabla$, so that the operator of the kinetic momentum $p = P - qA$ is equal to $-i\hbar \nabla - qA$. Hence, the in order to account for the magnetic field effects, we should make the following replacement,

$$-i\hbar \nabla \rightarrow -i\hbar \nabla - qA,$$

(6.50)
in all field-free quantum-mechanical relations. In particular, Eq. (48) has to be generalized as

$$j_w = \frac{1}{2m} \left[ \psi^* (-i\hbar \nabla - qA) \psi - \text{c.c.} \right].$$

(6.51)

This expression becomes more transparent if we take the wavefunction in form (47):

\(^\text{25}\) See, e.g., QM Sec. 1.4, in particular Eq. (1.47).
\(^\text{26}\) I am sorry to use traditional notations $p$ and $P$ for the momenta – the same symbols which were used for the electric dipole moment and polarization in Chapter 3. I hope there will be no confusion, because the latter notions are not used in this section.
\(^\text{27}\) See, e.g., CM Sec. 10.1, in particular Eq. (10.26).
\(^\text{28}\) The account of the electric field is easier, because the related energy $q\phi$ of the particle may be directly included into the potential energy operator – not participating in our current discussion.
This relation means, in particular, that in order to keep \( j_w \) gauge-invariant, the transformation (8)-(9) has to be accompanied by a simultaneous transformation of the wavefunction’s phase:

\[
\varphi \to \varphi + \frac{q}{\hbar} \chi .
\]  

(6.53)

It is fascinating that the quantum-mechanical wavefunction (or more exactly, its phase) is not gauge-invariant, meaning that you may change it in your mind – at your free will! Again, this does not change any observable (such as \( j_w \) or the probability density \( \psi \psi^* \)), i.e. any experimental results.

Now for the electric current density of the whole superconducting condensate, Eq. (52) yields the following constitutive relation:

\[
j \equiv j_w q n_p = \frac{\hbar q n_p}{m} |\psi|^2 \left( \nabla \varphi - \frac{q}{\hbar} A \right),
\]  

(6.54)

This equation shows that this supercurrent may be induced by the dc magnetic field alone and does not require any electric field. Indeed, for the simplest, 1D geometry shown in Fig. 2a, \( j(r) = j(x)n_z, \ A(r) = A(x) n_z, \) and \( \partial / \partial z = 0, \) so that the Coulomb gauge condition (5.48) is satisfied for any choice of the gauge function \( \chi(x), \) and for the sake of simplicity we can choose it to provide \( \varphi(r) \equiv \text{const}, \) so that

\[
j = - \frac{q^2 n_p}{m} A \equiv - \frac{1}{\mu \delta_L^2} A .
\]  

(6.55)

where \( \delta_L \) is given by Eq. (46), and the field is assumed to be small, and hence not affecting the probability \( |\psi|^2 \) (normalized to 1 in the absence of the field). This is the so-called London equation, proposed (in a different form) by F. and H. London in 1935 for the Meissner-Ochsenfeld effect’s explanation. Combining it with Eq. (5.44), generalized for a linear magnetic medium by the replacement \( \mu_0 \to \mu, \) we get

\[
\nabla^2 A = \frac{1}{\delta_L^2} A ,
\]  

(6.56)

This simple differential equation, similar Eq. (23), for our 1D geometry has an exponential solution similar to Eq. (32):

\[
A(x) = A(0) \exp\left\{ - \frac{x}{\delta_L} \right\}, \quad B(x) = B(0) \exp\left\{ - \frac{x}{\delta_L} \right\}, \quad j(x) = j(0) \exp\left\{ - \frac{x}{\delta_L} \right\},
\]  

(6.57)

which shows that the magnetic field and the supercurrent penetrate into a superconductor only by London’s penetration depth \( \delta_L, \) regardless of frequency.\(^{30}\) By the way, integrating the last result through

\(^{29}\) This is the so-called London gauge; for our simple geometry, it is also the Coulomb gauge (5.48).

\(^{30}\) Since at \( T > 0 \) not all electrons in a superconductor form Cooper pairs, at any frequency \( \omega \neq 0 \) the unpaired electrons provide energy-dissipating Ohmic currents, which are not described by Eq. (54). These losses become very substantial when the frequency \( \omega \) becomes so high that the skin-effect length \( \delta_s \) of the material (as measured with superconductivity suppressed, say by high magnetic field) becomes less than \( \delta_L. \) For typical metallic superconductors, this crossover takes place at frequencies of a few hundred GHz, so that even for microwaves, Eq. (57) still gives a fairly accurate description of the field penetration.
the penetration layer, and using the vector potential’s definition, $\mathbf{B} = \nabla \times \mathbf{A}$ (for our geometry, giving $B(x) = dA(x)/dx = -\delta_x A(x)$) we may readily check that the linear density $\mathbf{J}$ of the surface supercurrent still satisfies the universal coarse-grain relation (38).

This universality should bring to our attention the following common feature of the skin effect (in “normal” conductors) and the Meissner-Ochsenfeld effect (in superconductors): if the linear size of a bulk sample is much larger than, respectively, $\delta_0$ or $\delta_s$, than $\mathbf{B} = 0$ in the dominating part of its interior. According to Eq. (5.110), a formal description of such conductors (valid only on a coarse-grain scale much larger than either $\delta_0$ or $\delta_s$), may be achieved by formally treating the sample as an ideal diamagnet, with $\mu = 0$. In particular, we can use this description and Eq. (5.124) to immediately obtain the magnetic field’s distribution outside of a bulk sphere:

$$\mathbf{B} = \mu_0 \mathbf{H} = -\mu_0 \nabla \phi_m, \quad \text{with} \quad \phi_m = H_0 \left( -r - \frac{R^3}{2r^2} \right) \cos \theta, \quad \text{for} \quad r \geq R . \quad (6.58)$$

Figure 3 shows the corresponding surfaces of equal potential $\phi_m$. It is evident that the magnetic field lines (which are normal to the equipotential surfaces) bend to become parallel to the surface near it.

This pattern also helps to answer the question that might arise at making the assumption (24): what happens to bulk conductors placed into in a normal ac magnetic field – and to superconductors in a normal dc magnetic field as well? The answer is: the field is deformed outside the conductor to sustain the following coarse-grain boundary condition:

$$B_n \bigg|_{\text{surface}} = 0 , \quad (6.59)$$

which follows from Eq. (5.118) and the coarse-grain requirement $B|_{\text{inside}} = 0$.

This answer should be taken with reservations. For normal conductors it is only valid at sufficiently high frequencies, so that the skin depth (33) is sufficiently small: $\delta_0 \ll a$, where $a$ is the scale of the conductor’s linear size – for a sphere, $a \sim R$. In superconductors, this simple picture is valid

31 Sometimes this boundary condition, as well as the (compatible) Eq. (38), are called “macroscopic”. However, this term may lead to confusion with the genuine macroscopic boundary conditions (5.117)-(5.118), which also ignore the atomic-scale microstructure of the “effective currents” $\mathbf{j}_e = \nabla \times \mathbf{M}$, but (as was shown earlier in this section) still allow explicit, detailed accounts of the skin-current (34) and supercurrent (55) distributions.
not only if \( \delta_s \ll a \), but also only in sufficiently low magnetic fields, because strong fields do penetrate into superconductors, destroying superconductivity (completely or partly), thus violating the Meissner-Ochsenfeld effect – see the next section.

6.5. Electrodynamics of macroscopic quantum phenomena\(^{32}\)

Despite the superficial similarity of the skin effect and the Meissner-Ochsenfeld effect, the electrodynamics of superconductors is much richer. For example, let us use Eq. (54) to describe the fascinating effect of magnetic flux quantization. Consider a closed ring/loop (of any particular shape) made of a superconducting “wire” with a cross-section much larger than \( \delta_s^2 \) (Fig. 4a).

From the last section’s discussion, we know that deep inside the wire the supercurrent is exponentially small. Integrating Eq. (54) along any closed contour \( C \) that does not approach the surface closer than a few \( \delta_s \) at any point (see the dashed line in Fig. 4), so that with \( \mathbf{j} = 0 \) at all its points, we get

\[
0 = \oint_C \mathbf{A} \cdot d\mathbf{r}. \quad (6.60)
\]

The first integral, i.e. the difference of \( \varphi \) in the initial and final points, has to be equal to either zero or an integer number of \( 2\pi \), because the change \( \varphi \to \varphi + 2\pi n \) does not change the Cooper pair’s condensate’s wavefunction:

\[
\psi' \equiv |\psi| e^{i(\varphi+2\pi n)} = |\psi| e^{i\varphi} \equiv \psi. \quad (6.61)
\]

On the other hand, according to Eq. (5.65), the second integral in Eq. (60) is just the magnetic flux \( \Phi \) through the contour.\(^{33}\) As a result, we get a wonderful result:

\[\text{Fig. 6.4. (a) A closed, flux-quantizing superconducting ring, (b) a ring with a narrow slit, and (c) a Superconducting QUantum Interference Device (SQUID).}\]

---

\(^{32}\) The material of this section is not covered in most E&M textbooks, and will not be used in later sections of this course. Thus the “only” loss from the reader’s skipping this section would be the lack of familiarity with one of the most fascinating fields of physics. Note also that we already have virtually all the tools necessary for its discussion, so that reading this section should not require much effort.

\(^{33}\) Due to the Meissner-Ochsenfeld effect, the exact path of the contour is not important, and we may discuss \( \Phi \) just as the magnetic flux through the ring.
saying that the magnetic flux inside any superconducting loop can only take values multiple of the flux quantum $\Phi_0$. This effect, predicted in 1950 by the same Fritz London (who expected $q$ to be equal to the electron charge $-e$), was confirmed experimentally in 1961,\textsuperscript{34} but with $|q| = 2e$ – so that $\Phi_0 \approx 2.07 \times 10^{-15}$ Wb. Historically, this observation gave decisive support to the BSC theory of superconductivity based on Cooper pairs, with charge $q = -2e$, which had been put forward just four years before.

Note the truly macroscopic character of this quantum effect: it has been repeatedly observed in human-scale superconducting loops, and from what is known about superconductors, there is no doubt that if we have made a giant superconducting wire loop extending, say, over the Earth’s equator, the magnetic flux through it would still be quantized – though with a very large flux quanta number $n$. This means that the quantum coherence of Bose-Einstein condensates may extend over, using H. Casimir’s famous expression, “miles of dirty lead wire”. (Lead is a typical superconductor, with $T_c \approx 7.2$ K, and indeed retains its superconductivity even being highly contaminated by impurities.)

Moreover, hollow rings are not entirely necessary for flux quantization. In 1957, A. Abrikosov explained the counter-intuitive high-field behavior of superconductors with $\delta_L > \xi \sqrt{2}$, known experimentally as their mixed (or “Shubnikov”) phase since the 1930s. He showed that a sufficiently high magnetic field may penetrate such superconductors in the form of self-formed magnetic field “threads” (or “tubes”) surrounded by vortex-shaped supercurrents – the so-called Abrikosov vortices. In the simplest case, the core of such a vortex is a straight line, on which the superconductivity is completely suppressed ($|\psi| = 0$), surrounded by circular, axially-symmetric, persistent supercurrents $j(\rho)$, where $\rho$ is the distance from the vortex axis – see Fig. 5a. At the axis, the current vanishes, and with the growth of $\rho$, it first rises and then falls (with $j(\infty) = 0$), reaching its maximum at $\rho \sim \xi$, while the magnetic field $B(\rho)$, directed along the vortex axis, is largest at $\rho = 0$, and drops monotonically at distances of the order of $\delta_L$ (Fig. 5b).

\[
\Phi = n\Phi_0, \quad \text{where} \quad \Phi_0 = \frac{2\pi\hbar}{|q|}, \quad \text{with} \quad n = 0, \pm 1, \pm 2, \ldots, \quad (6.62)
\]

The total flux of the field equals exactly one flux quantum $\Phi_0$, given by Eq. (62). Correspondingly, the wavefunction’s phase $\varphi$ performs just one $\pm 2\pi$ revolution along any contour drawn around the vortex’s axis, so that $\nabla \varphi = \pm n_\varphi / \rho$, where $n_\varphi$ is the azimuthal unit vector.\textsuperscript{35} This topological feature of the wavefunction’s phase is sometimes called the fluxoid quantization – to

\textsuperscript{34} Independently and virtually simultaneously by two groups: B. Deaver and W. Fairbank, and R. Doll and M. Nääbauer; their reports were published back-to-back in the same issue of the *Physical Review Letters.*

\textsuperscript{35} The last (perhaps, evident) expression formally follows from MA Eq. (10.2) with $f = \pm \varphi + \text{const.}$
distinguish is from the flux quantization, which is valid only for relatively large contours, not approaching the axis by distances \( \sim \delta \).

A quantitative analysis of an Abrikosov vortex requires, besides the equations we have discussed, one more constituent equation that would describe the changes of the number of Cooper pairs (quantified by \(|\psi|^2\)) by the magnetic field – or rather by the field-induced supercurrent. In his original work, Abrikosov used for this purpose the famous Ginzburg-Landau equation\(^{36}\), which is qualitatively valid only at \( T \approx T_c \). The equation which may be conveniently represented using either of the following forms:

\[
\frac{1}{2m}(-i\hbar \nabla - q A)^2 \psi = a \psi - b |\psi|^2, \quad \xi^2 \psi \* \left( \nabla - i \frac{q}{\hbar} A \right)^2 \psi = \left( 1 - |\psi|^2 \right) |\psi|^2, \tag{6.63}
\]

where \( a \) and \( b \) are certain temperature-dependent coefficients, with \( a \to 0 \) at \( T \to T_c \). The first of these forms clearly shows that the Ginzburg-Landau equation (together with the similar Gross-Pitaevskii equation describing uncharged Bose-Einstein condensates) belongs to a broader class of nonlinear Schrödinger equations, differing only by the additional nonlinear term from the usual Schrödinger equation, which is linear in \( \psi \). The equivalent, second form of Eq. (63) is more convenient for applications, and shows more clearly that if the superconductor’s condensate density, proportional to \( |\psi|^2 \), is suppressed only locally, it restores to its unperturbed value (with \( |\psi|^2 = 1 \)) at the distances of the order of the coherence length \( \xi \equiv \hbar/(2ma)^{1/2} \).

This fact enables a simple quantitative analysis of the Abrikosov vortex in the most important limit \( \xi \ll \delta \). Indeed, in this case (see Fig. 5) \( |\psi|^2 = 1 \) at most distances \( (\rho \approx \delta) \) where the field and current are distributed, so that these distributions may be readily calculated without any further involvement of Eq. (63), just from Eq. (54) with \( \nabla \varphi = \pm n_\varphi / \rho \) and the Maxwell equations (21) for the magnetic field, giving \( \nabla \times \mathbf{B} = \mu j \), and \( \nabla \cdot \mathbf{B} = 0 \). Indeed, combining these equations just as this was done at the derivation of Eq. (23), for the only Cartesian component of the vector \( \mathbf{B}(\mathbf{r}) = B(\rho) \hat{\mathbf{n}}_z \) (where the \( z \)-axis is directed along the vortex axis), we get a simple equation

\[
\delta_2^2 \nabla^2 B - B = -\frac{\hbar}{\mu} \nabla \times (\nabla \times \varphi) \equiv \mp \Phi_0 \delta_2(\rho), \quad \text{at } \rho \gg \xi, \tag{6.64}
\]

which coincides with Eq. (56) at all regular points \( \rho \neq 0 \). Spelling out the Laplace operator for our current case of axial symmetry,\(^{37}\) we get an ordinary differential equation,

\[
\delta_2^2 \frac{1}{\rho} \frac{d}{d\rho} \left( \rho \frac{d \Phi}{d\rho} \right) = -B, \quad \text{for } \rho \neq 0. \tag{6.65}
\]

Comparing this equation with Eq. (2.155) with \( \nu = 0 \), and taking into account that we need the solution decreasing at \( \rho \to \infty \), making any contribution proportional to the function \( l_0 \) unacceptable, we get

\[\text{36 This equation was derived by Vitaly Lazarevich Ginzburg and Lev Davidovich Landau from phenomenological arguments in 1950, i.e. before the advent of the “microscopic” BSC theory, and may be used for simple analyses of a broad range of nonlinear effects in superconductors. The Ginzburg-Landau and Gross-Pitaevskii equations will be further discussed in SM Sec. 4.3.}

\[\text{37 See, e.g., MA Eq. (10.3) with } \partial / \partial \varphi = \partial / \partial z = 0.\]
\[ B = CK_0 \left( \frac{\rho}{\delta_L} \right) \]  
(6.66)

- see the plot of this function (black line) on the right panel of Fig. 2.22. The constant \( C \) should be calculated from fitting the 2D delta-function on the right-hand side of Eq. (64), i.e. by requiring

\[ \int_{\text{vortex}} B(\rho)d^2 \rho = 2\pi \int_0^\infty B(\rho)\rho d\rho = 2\pi\delta_L^2 C \int_0^\infty K_0(\zeta)d\zeta = \mp \Phi_0. \]  
(6.67)

The last, dimensionless integral equals 1,\(^\text{38}\) so that finally

\[ B(\rho) = \frac{\Phi_0}{2\pi\delta_L^2} K_0 \left( \frac{\rho}{\delta_L} \right), \quad \text{at } \rho \gg \xi. \]  
(6.68)

The function \( K_0 \) (the modified Bessel function of the second kind), drops exponentially as its argument becomes larger than 1 (i.e., in our problem, at distances \( \rho \) much larger than \( \delta_L \)), and diverges as its argument tends to zero – see, e.g., the second of Eqs. (2.157). However, this divergence is very slow (logarithmic), and, as was repeatedly discussed in this series, is avoided by the account of virtually any other factor. In our current case, this factor is the decrease of \( |\psi|^2 \) to zero at \( \rho \sim \xi \) (see Fig. 5), not taken into account in Eq. (68). As a result, we may estimate the field on the axis of the vortex as

\[ B(0) \approx \frac{\Phi_0}{2\pi\delta_L^2} \ln \frac{\delta_L}{\xi}; \]  
(6.69)

the exact (much more involved) solution of the problem confirms this estimate with a minor correction: \( \ln(\delta_L/\xi) \to [\ln(\delta_L/\xi) - 0.28] \).

The current density distribution may be now calculated the Maxwell equation \( \nabla \times \mathbf{B} = \mu \mathbf{j} \), giving \( \mathbf{j} = j(\rho) \mathbf{n}_\phi \), with\(^\text{39}\)

\[ j(\rho) = -\frac{1}{\mu} \frac{\partial B}{\partial \rho} = -\frac{\Phi_0}{2\pi\mu\delta_L^2} \frac{\partial}{\partial \rho} K_0 \left( \frac{\rho}{\delta_L} \right) = \frac{\Phi_0}{2\pi\mu\delta_L^2} K_1 \left( \frac{\rho}{\delta_L} \right), \quad \text{at } \rho \gg \xi, \]  
(6.70)

where the same identity (2.158), with \( J_n \to K_n \), and \( n = 1 \), was used. Now looking at Eqs. (2.157) and (2.158), with \( n = 1 \), we see that the supercurrent is exponentially small at \( \rho \gg \delta_L \) (thus outlining the vortex’ periphery), and is proportional to \( 1/\rho \) within the broad range \( \xi \ll \rho \ll \delta_L \). This rise of the current at \( \rho \to 0 \) (which could be readily predicted directly from Eq. (54) with \( \nabla \varphi = \pm \mathbf{n}_\phi / \rho \), and the A-term negligible at \( \rho \ll \delta_L \)) is quenched at \( \rho \sim \xi \) by a rapid drop of the factor \( |\psi|^2 \) in the same Eq. (54), i.e. by the suppression of the superconductivity near the axis (by the same supercurrent!) – see Fig. 5 again.

This vortex structure may be used to calculate, in a straightforward way, its energy per unit length (i.e. its linear tension)

\(^{38}\) This fact follows, for example, from the integration of both sides of Eq. (2.143) (which is valid for any Bessel functions, including \( K_n \)) with \( n = 1 \), from 0 to \( \infty \), and then using the asymptotic values given by Eqs. (2.157)-(2.158): \( K_1(\infty) = 0 \), and \( K_1(\zeta) \to 1/\zeta \) at \( \zeta \to 0 \).

\(^{39}\) See, e.g., MA Eq. (10.5), with \( f_\rho = f_\varphi = 0 \), and \( f_z = B(\rho) \).
\[ T \equiv \frac{U}{l} \approx \frac{\Phi_0^2}{4\pi\mu_0 \delta_c^2} \ln \frac{\delta_c}{\xi}, \]  

(6.71)

and hence the “first critical“ value \( H_{c1} \) of the external magnetic field,\(^{40}\) at which the vortex formation becomes possible (in a long cylindrical sample parallel to the field):

\[ H_{c1} = \frac{T}{\Phi_0} \approx \frac{\Phi_0}{4\pi\mu_0 \delta_c^2} \ln \frac{\delta_c}{\xi}. \]  

(6.72)

Let me leave the proof of these two formulas for the reader’s exercise.

The flux quantization and the Abrikosov vortices discussed above are just two of several macroscopic quantum effects in superconductivity. Let me discuss just one more, but perhaps the most interesting of such effects. Let us consider a superconducting ring/loop interrupted with a very narrow slit (Fig. 4b). Integrating Eq. (54) along any current-free path from point 1 to point 2 (see, e.g., dashed line in Fig. 4b), we get

\[ 0 = \int_1^2 \left( \nabla \varphi - \frac{q}{\hbar} A \right) \cdot dr = \varphi_2 - \varphi_1 - \frac{q}{\hbar} \Phi. \]  

(6.73)

Using the flux quantum definition (62), this result may be rewritten as

\[ \varphi \equiv \varphi_1 - \varphi_2 = \frac{2\pi}{\Phi_0} \Phi, \]  

(6.74)

where \( \varphi \) is called the Josephson phase difference. Note that in contrast to each of the phases \( \varphi_{1,2} \), their difference \( \varphi \) is gauge-invariant, because it is directly related to the gauge-invariant magnetic flux \( \Phi \).

Can this \( \varphi \) be measured? Yes, using the Josephson effect.\(^{41}\) Let us consider two (for the argument simplicity, similar) superconductors, connected with some sort of weak link, for example either a tunnel barrier, or a point contact, or a narrow thin-film bridge, through that a weak Cooper-pair supercurrent can flow. (Such a system of two weakly coupled superconductors is called a Josephson junction.) Let us think about what this supercurrent \( I \) may be a function of. For that, the reverse thinking is helpful: let us imagine that we change the current; what parameter of the superconducting condensate can it affect? If the current is weak, it cannot perturb the superconducting condensate’s density, proportional to \( |\psi|^2 \); hence it may only change the Cooper condensate phases \( \varphi_{1,2} \). However, according to Eq. (53), the phases are not gauge-invariant, while the current should be. Hence the current may affect (or, if you like, may be a function of) only the phase difference \( \varphi \) defined by Eq. (74). Moreover, just has already been argued during the flux quantization discussion, a change of any of \( \varphi_{1,2} \) (and hence of \( \varphi \)) by \( 2\pi \) or any of its multiples should not change the current. Also, if the wavefunction is the same in both superconductors \( (\varphi = 0) \), the supercurrent should vanish due to the system’s symmetry. Hence the function \( I(\varphi) \) should satisfy the following conditions:

\(^{40}\) This term is used to distinguish \( H_{c1} \) from the higher “second critical field” \( H_{c2} \), at which the Abrikosov vortices are pressed to each other so tightly (to distances \( d \sim \xi \)) that they merge, and the remains of superconductivity vanish: \( \psi \to 0 \). Unfortunately, I do not have time/space to discuss these effects; the interested reader may be referred, for example, to Chapter 5 of the M. Tinkham’s monograph cited above.

\(^{41}\) It was predicted in 1961 by Brian David Josephson (then a PhD student!), and observed experimentally by several groups soon after that.
\[ I(0) = 0, \quad I(\varphi + 2\pi) = I(\varphi). \quad (6.75) \]

With these conditions on hand, we should not be terribly surprised by the following Josephson’s result that for the weak link provided by tunneling,\(^{42}\)

\[
I(\varphi) = I_c \sin \varphi, \quad (6.76)
\]

where constant \( I_c \), which depends on the weak link’s strength and temperature, is called the critical current. Actually, Eqs. (54) and (63) enable not only a straightforward calculation of this relation, but even obtaining a simple expression of the critical current \( I_c \) via the link’s normal-state resistance – the task left for the (creative :-)) reader’s exercise.

Now let us see what happens if a Josephson junction is placed into the gap in a superconductor loop – see Fig. 4c. In this case, we may combine Eqs. (74) and (76), getting

\[
I = I_c \sin \left( 2\pi \frac{\Phi}{\Phi_0} \right). \quad (6.77)
\]

This effect of a periodic dependence of the current on the magnetic flux is called the macroscopic quantum interference,\(^{43}\) while the system shown in Fig. 4c, the superconducting quantum interference device – SQUID (with all letters capital, please :-). The low value of the magnetic flux quantum \( \Phi_0 \), and hence the high sensitivity of \( \varphi \) to external magnetic fields, allows using such SQUIDs as ultrasensitive magnetometers. Indeed, for a superconducting ring of area \( \sim 1 \text{ cm}^2 \), one period of the change of the supercurrent (77) is produced by a magnetic filed change of the order of \( 10^{-11} \text{ T} \) \( (10^{-7} \text{ Gs}) \), while sensitive electronics allows measuring a tiny fraction of this period – limited by thermal noise at a level of the order of a few fT. Such sensitivity allows measurements, for example, of the magnetic fields induced outside of the body by the beating human heart, and even by the brain activity.\(^{44}\)

An important aspect of the quantum interference is the so-called Aharonov-Bohm (AB) effect (which actually takes place for single quantum particles as well).\(^{45}\) Let the magnetic field lines be limited to the central part of the SQUID ring, so that no appreciable magnetic field ever touches the superconducting ring material. (This may be done experimentally with very good accuracy, for example using high-\(\mu\) magnetic cores – see their discussion in Sec. 5.6.) As predicted by Eq. (77), and confirmed by several careful experiments carried out in the mid-1960s,\(^{46}\) this restriction does not matter – the

\(^{42}\) For some other types of weak links, the function \( I(\varphi) \) may deviate from the sinusoidal form Eq. (76) rather considerably, while still satisfying the general conditions (75).

\(^{43}\) The name is due to the deep analogy between this phenomenon and the interference between two coherent waves, to be discussed in detail in Sec. 8.4.

\(^{44}\) Other practical uses of SQUIDs include MRI signal detectors, high-sensitive measurements of magnetic properties of materials, and weak field detection in a broad variety of physical experiments – see, e.g., J. Clarke and A. Braginski (eds.), The SQUID Handbook, vol. II, Wiley, 2006. For a comparison of these devices with other sensitive magnetometers see, e.g., the review collection by A. Grosz et al. (eds.), High Sensitivity Magnetometers, Springer, 2017.

\(^{45}\) For a more detailed discussion of the AB effect see, e.g., QM Sec. 3.2.

\(^{46}\) Similar experiments have been carried out with single (unpaired) electrons – moving either ballistically, in vacuum, or in “normal” (non-superconducting) conducting rings. In the last case, the effect is much harder to observe that in SQUIDs, because the ring size has to be very small, and temperature very low, to avoid the so-
interference is observed anyway. This means that not only the magnetic field \( \mathbf{B} \), but also the vector potential \( \mathbf{A} \) represents physical reality, albeit in a quite peculiar way – remember the gauge transformation (5.46), which you may carry out in the top of your head, without changing any physical reality? (Fortunately, this transformation does not change the contour integral participating in Eq. (5.65), and hence the magnetic flux \( \Phi \), and hence the interference pattern.)

Actually, the magnetic flux quantization (62) and the macroscopic quantum interference (77) are not completely different effects, but just two manifestations of the inter-related macroscopic quantum phenomena. To show that, one should note that if the critical current \( I_c \) (or rather its product by the loop’s self-inductance \( L \)) is high enough, the flux \( \Phi \) in the SQUID loop is due not only to the external magnetic field flux \( \Phi_{\text{ext}} \), but also has a self-field component – cf. Eq. (5.68):

\[
\Phi = \Phi_{\text{ext}} - LI, \quad \text{where } \Phi_{\text{ext}} \equiv \oint_{S} (B_{\text{ext}})_{n} \, d^{2}r.
\]

Now the relation between \( \Phi \) and \( \Phi_{\text{ext}} \) may be readily found by solving this equation together with Eq. (77). Figure 6 shows this relation for several values of the dimensionless parameter \( \lambda \equiv 2\pi LI_c/\Phi_0 \).

These plots show that if the critical current (and/or the inductance) is low, \( \lambda \ll 1 \), the self-field effects are negligible, and the total flux follows the external field (i.e., \( \Phi_{\text{ext}} \)) faithfully. However, at \( \lambda > 1 \), the function \( \Phi(\Phi_{\text{ext}}) \) becomes hysteretic, and at \( \lambda \gg 1 \) the stable (positive-slope) branches of this function are nearly flat, with the total flux values corresponding to Eq. (62). Thus, a superconducting ring closed by a high-\( I_c \) Josephson junction exhibits a nearly-perfect flux quantization.

The self-field effects described by Eq. (78) create certain technical problems for SQUID magnetometry, but they are the basis for one more application of these devices: ultrafast computing. called *dephasing effects* due to unavoidable interactions of the electrons with their environment – see, e.g., QM Chapter 7.

47 The sign before \( LI \) would be positive, as in Eq. (5.70), if \( I \) was the current flowing *into* the inductance. However, in order to keep the sign in Eq. (76) intact, \( I \) should mean the current flowing into the Josephson junction, i.e. *from* the inductance, thus changing the sign of the \( LI \) term in Eq. (78).
Indeed, Fig. 6 shows that at the values of $\lambda$ modestly above 1 (e.g., $\lambda \approx 3$), and within a certain range of applied field, the SQUID has two stable flux states that differ by $\Delta \Phi \approx \Phi_0$ and may be used for coding binary 0 and 1. For practical superconductors (like Nb), the time of switching between these states (see dashed arrows in Fig. 4) are of the order of a picosecond, while the energy dissipated at such event may be as low as $\sim 10^{-19}$ J. (This bound is determined not by device’s physics, by the fundamental requirement for the energy barrier between the two states to be much higher than the thermal fluctuation energy scale $k_B T$, ensuring a sufficiently long information retention time.) While the picosecond switching speed may be also achieved with some semiconductor devices, the power consumption of the SQUID-based digital devices may be 5 to 6 orders of magnitude lower, enabling VLSI integrated circuits with 100-GHz-scale clock frequencies. Unfortunately, the range of practical application of these Rapid Single-Flux-Quantum (RSFQ) digital circuits is still very narrow, due to the inconvenience of their deep refrigeration to temperatures below $T_c$.\[48\]

Since we have already got the basic relations (74) and (76) describing the macroscopic quantum phenomena in superconductivity, let me mention in brief two other members of this group, called the \textit{dc} and \textit{ac} Josephson effects. Differentiating Eq. (74) over time, and using the Faraday induction law (2), we get\[49\]

\[\frac{d\phi}{dt} = \frac{2e}{h} V. \tag{6.79}\]

This famous \textit{Josephson phase-to-voltage relation} should be valid regardless of the way how the voltage $V$ has been created,\[50\] so let us apply Eqs. (76) and (79) to the simplest circuit with a non-superconducting source of dc voltage – see Fig. 7.

If the current’s magnitude is below the critical value, Eq. (76) allows the phase $\phi$ to have a time-independent value

\[\phi = \sin^{-1} \frac{I}{I_c}, \quad \text{if } -I_c < I < +I_c, \tag{6.80}\]

and hence, according to Eq. (79), a vanishing voltage drop across the junction: $V = 0$. This \textit{dc Josephson effect} is not quite surprising – indeed, we have postulated from the very beginning that the Josephson junction may pass a certain supercurrent. Much more fascinating is the so-called \textit{ac Josephson effect} that occurs if the voltage across the junction has a non-vanishing average (dc) component $V_0$. For simplicity,

---

48 For more on that technology, see, e.g., the review paper by P. Bunyk \textit{et al.}, \textit{Int. J. High Speed Electron. Syst.} \textbf{11}, 257 (2001), and references therein.

49 Since the induced e.m.f. $\psi_{\text{ind}}$ cannot drop on the superconducting path between the Josephson junction electrodes 1 and 2 (see Fig. 4c), it should be equal to (-$V$), where $V$ is the voltage across the junction.

50 Indeed, it may be also obtained from simple Schrödinger equation arguments – see, e.g., QM Sec. 1.6.
let us assume that this is the *only* voltage component: \( V(t) = V_0 = \text{const} \); then Eq. (79) may be easily integrated to give \( \varphi = \omega_0 t + \varphi_0 \), where

\[
\omega_0 = \frac{2e}{\hbar} V_0.
\] (6.81)

This result, plugged into Eq. (76), shows that the supercurrent oscillates,

\[
I = I_c \sin(\omega_0 t + \varphi_0),
\] (6.82)

with the so-called *Josephson frequency* \( \omega_0 \) (81) proportional to the applied dc voltage. For practicable voltages (above the typical noise level), the frequency \( f_J = \omega_0 / 2\pi \) corresponds to the GHz or even THz ranges, because the proportionality coefficient in Eq. (81) is very high: \( f_J / V_0 = e / \pi \hbar \approx 483 \text{ MHz}/\mu\text{V}. \)

An important experimental fact is the universality of this coefficient. For example, in the mid-1980s, a Stony Brook group led by J. Lukens proved that this factor is material-independent with the relative accuracy of at least \( 10^{-15} \). Very few experiments, especially in solid-state physics, have ever reached such precision. This fundamental nature of the Josephson voltage-to-frequency relation (81) allows an important application of the ac Josephson effect in metrology. Namely, phase-locking\(^{53}\) the Josephson oscillations with an external microwave signal from an atomic frequency standard, one can get a more precise dc voltage than from any other source. In NIST, and in other metrological institutions around the globe, this effect is used for calibration of simpler “secondary” voltage standards that can operate at room temperature.

### 6.6. Inductors, transformers, and ac Kirchhoff laws

Let a *wire coil* (meaning either a single loop illustrated in Fig. 5.4b, or a series of such loops, such as one of the solenoids shown in Fig. 5.6) have a self-inductance \( L \) much larger than that of the wires connecting it to other components of our system: ac voltage sources, voltmeters, etc. (Since, according to Eq. (5.75), \( L \) scales as the number \( N \) of wire turns squared, this condition is easier to satisfy at \( N >> 1 \).) Then in a quasistatic system consisting of such lumped induction coils and external wires (and other circuit elements such as resistors, capacitances, etc.), we may neglect the electromagnetic induction effects everywhere outside the coil, so that the electric field in those external regions is potential. Then the voltage \( V \) between coil’s terminals may be defined (as in electrostatics) as the difference of values of scalar potential \( \varphi \) between the terminals, i.e. as the integral

\[
V = \int \mathbf{E} \cdot d\mathbf{r}
\] (6.83)

between the coil terminals along any path outside the coil. This voltage has to be balanced by the induction e.m.f. (2) in the coil, so that if the Ohmic resistance of the coil is negligible, we may write

---

\(^{51}\) In experiment, this condition is hard to implement, due to relatively high inductance of the current leads providing the dc voltage supply. However, this technical complication does not change the main conclusion of the simple analysis described here.

\(^{52}\) This 1962 prediction (by the same B. Josephson) was confirmed experimentally – first implicitly, by phase-locking of the oscillations with an external oscillator in 1963, and then explicitly, by the direct detection of the emitted microwave radiation in 1967.

\(^{53}\) For a discussion of this very important (and general) effect, see, e.g., CM Sec. 5.4.
\[ V = \frac{d\Phi}{dt}, \quad (6.84) \]

where \( \Phi \) is the magnetic flux in the coil.\(^{54} \) If the flux is due to the current \( I \) in the same coil only (i.e. if it is magnetically uncoupled from other coils), we may use Eq. (5.70) to get the well-known relation

\[ V = L \frac{dI}{dt}, \quad (6.85) \]

where the compliance with the Lenz sign rule is achieved by selecting the relations between the assumed voltage polarity and the current direction as shown in Fig. 8a.

\[ \Phi(t) \]

\[ V \]

\[ L \]

\[ M \]

\[ N_1 \]

\[ N_2 \]

\[ \frac{dI_1}{dt} \]

\[ \frac{dI_2}{dt} \]

\[ \frac{dI_1}{dt} \]

\[ \frac{dI_2}{dt} \]

\[ N_1 \]

\[ N_2 \]

\[ V_1 \]

\[ V_2 \]

\[ V_1 \approx N_1 \frac{d\Phi}{dt}, \quad V_2 \approx N_2 \frac{d\Phi}{dt}, \quad (6.87) \]

so that the voltage ratio is completely determined by the ratio \( N_1/N_2 \) of the number of wire turns.

If similar conditions are satisfied for two magnetically coupled coils (Fig. 8b), then, in Eq. (84), we need to use Eqs. (5.69) instead, getting

\[ V_1 = L_1 \frac{dI_1}{dt} + M \frac{dI_2}{dt}, \quad V_2 = L_2 \frac{dI_2}{dt} + M \frac{dI_1}{dt}. \quad (6.86) \]

Such systems of inductively coupled coils have numerous applications in electrical engineering and physical experiment. Perhaps the most important of them is the \textit{ac transformer}, in which the coils share a common soft-ferromagnetic core with the toroidal (“doughnut”) topology – see Fig. 8c.\(^{55} \) As we already know from the discussion in Sec. 5.6, such cores, with \( \mu >> \mu_0 \), “try” to suck in all magnetic field lines, so that the magnetic flux \( \Phi(t) \) in the core is nearly the same in each of its cross-sections. With this, Eq. (84) yields

\[ V_1 \approx N_1 \frac{d\Phi}{dt}, \quad V_2 \approx N_2 \frac{d\Phi}{dt}, \quad (6.87) \]

so that the voltage ratio is completely determined by the ratio \( N_1/N_2 \) of the number of wire turns.

Now we may generalize, to the ac current case, the Kirchhoff laws already discussed in Chapter 4 – see Fig. 4.3, reproduced in Fig. 9a below. Let not only inductances but also capacitances and resistances of the wires be negligible in comparison with those of the lumped (compact) circuit elements, whose list now would include not only resistors and current sources (as in the dc case), but also the induction coils (including magnetically coupled ones) and capacitors – see Fig. 9b. In the quasistatic limit, the current flowing in each wire is conserved, so that the “node rule”, i.e. the 1\(^{st} \) Kirchhoff law (4.7a),

\(^{54} \) If the resistance is substantial, it may be represented by a separate lumped circuit element (resistor) connected in series with the coil.

\(^{55} \) The first practically-acceptable form of this device, called the \textit{Stanley transformer}, in which multi-turn windings could be easily mounted onto a toroidal ferromagnetic (at that time, silicon-steel-plate) core, was invented in 1886.
remains valid. Also, if the electromagnetic induction effect is restricted to the interior of lumped induction coils as discussed above, the voltage drops $V_k$ across each circuit element may be still represented, just as in dc circuits, with differences of potentials of the adjacent nodes. As a result, the “loop rule”, i.e. 2nd Kirchhoff law (4.7b),

$$\sum_k V_k = 0,$$  \hspace{1cm} (6.88b)

is also valid. In contrast to the dc case, Eqs. (88) are now the (ordinary) differential equations. However, if all circuit elements are linear (as in the examples presented in Fig. 9b), these equations may be readily reduced to linear algebraic equations, using the Fourier expansion. (In the common case of sinusoidal ac sources, the final stage of the Fourier series summation is unnecessary.)

My experience shows that the potential readers of these notes are well familiar with the application of Eqs. (88) to such problems from their undergraduate studies, so I would like to save time/space by skipping discussions of even the simplest examples of such circuits, such as $LC$, $LR$, $RC$, and $LRC$ loops and periodic structures.\(^{56}\) However, since these problems are very important for practice, my sincere advice to the reader is to carry out a self-test by solving a few problems of this type, provided at the end of this chapter, and if they cause any difficulty, go after some remedial reading.

6.7. Displacement currents

The electromagnetic induction is not the only new effect arising in non-stationary electrodynamics. Indeed, though Eqs. (21) are adequate for the description of quasistatic phenomena, a deeper analysis shows that one of these equations, namely $\nabla \times \mathbf{H} = \mathbf{j}$, cannot be exact. To see that, let us take the divergence of both sides:

$$\nabla \cdot (\nabla \times \mathbf{H}) = \nabla \cdot \mathbf{j}.$$  \hspace{1cm} (6.89)

But, as the divergence of any curl,\(^{57}\) the left-hand side should equal zero. Hence we get

---

\(^{56}\) Curiously enough, these effects include wave propagation in periodic $LC$ circuits, even within the quasistatic approximation! However, the speed $1/(LC)^{1/2}$ of these waves in lumped circuits is much lower than the speed $1/(\varepsilon \mu)^{1/2}$ of electromagnetic waves in the surrounding medium – see Sec. 8 below.

\(^{57}\) Again, see MA Eq. (11.2) – if you need it.
\[ \nabla \cdot \mathbf{j} = 0. \quad (6.90) \]

This is fine in statics, but in dynamics, this equation forbids any charge accumulation, because according to the continuity relation (4.5),

\[ \nabla \cdot \mathbf{j} = -\frac{\partial \rho}{\partial t}. \quad (6.91) \]

This discrepancy had been recognized by James Clerk Maxwell who suggested, in the 1860s, a way out of this contradiction. If we generalize the equation for \( \nabla \times \mathbf{H} \) by adding to the term \( \mathbf{j} \) (that describes the density of real electric currents) the so-called displacement current density term,

\[ \mathbf{j}_d = \frac{\partial \mathbf{D}}{\partial t}, \quad (6.92) \]

(which of course vanishes in statics), then the equation takes the form

\[ \nabla \times \mathbf{H} = \mathbf{j} + \mathbf{j}_d = \mathbf{j} + \frac{\partial \mathbf{D}}{\partial t}. \quad (6.93) \]

In this case, due to the equation (3.22), \( \nabla \cdot \mathbf{D} = \rho \), the divergence of the right-hand side equals zero due to the continuity equation (92), and the discrepancy is removed. This incredible theoretical feat,\(^58\) confirmed by the 1886 experiments carried out by Heinrich Hertz (see below) was perhaps the main triumph of theoretical physics of the 19th century.

The Maxwell’s displacement current concept, expressed by Eq. (93), is so important that it is worthwhile to have one more look at its derivation using a particular model shown in Fig. 10.\(^59\)

![Fig. 6.10. The Ampère law applied to capacitor recharging.](image)

Neglecting the fringe field effects, we may use Eq. (4.1) to describe the relation between the current \( I \) flowing through the wires and the electric charge \( Q \) of the capacitor:\(^60\)

\[ \frac{dQ}{dt} = I. \quad (6.94) \]

---

\(^{58}\) It looks deceivingly simple now – after the fact, and with the current mathematical tools (especially the del operator), much superior to those that were available to J. Maxwell.

\(^{59}\) No physicist should be ashamed of doing this. For example, J. Maxwell’ main book, *A Treatise of Electricity and Magnetism*, is full of drawings of plane capacitors, inductance coils, and voltmeters. More generally, the whole history of science teaches us that snobbishness toward particular examples and practical systems is a virtually certain path toward producing nothing of either practical value or fundamental importance.

\(^{60}\) This is of course just the integral form of the continuity equation (91).
Now let us consider a closed contour \( C \) drawn around the wire. (Solid points in Fig. 10 show the places where the contour intercepts the plane of the drawing.) This contour may be seen as the line limiting either the surface \( S_1 \) (crossed by the wire) or the surface \( S_2 \) (avoiding such crossing by passing through the capacitor’s gap). Applying the macroscopic Ampère law (5.116) to the former surface, we get

\[
\oint_C \mathbf{H} \cdot d\mathbf{r} = \int_{S_1} j_n d^2r = I, \quad (6.95)
\]

while for the latter surface the same law gives a different result,

\[
\oint_C \mathbf{H} \cdot d\mathbf{r} = \int_{S_2} j_n d^2r = 0, \quad \text{[WRONG!]} \quad (6.96)
\]

for the same integral. This is just an integral-form manifestation of the discrepancy outlined above, but it shows clearly how serious the problem is (or rather it was – before Maxwell).

Now let us see how the introduction of the displacement currents saves the day, considering for the sake of simplicity a plane capacitor of area \( A \), with a constant electrode spacing. In this case, as we already know, the field inside it is uniform, with \( D = \sigma \), so that the total capacitor’s charge \( Q = A\sigma = AD \), and the current (94) may be represented as

\[
I = \frac{dQ}{dt} = A \frac{dD}{dt}. \quad (6.97)
\]

So, instead of the wrong Eq. (96), the Ampère law modified following Eq. (93), gives

\[
\oint_C \mathbf{H} \cdot d\mathbf{r} = \int_{S_1} (j_d)_n d^2r = \int_{S_1} \frac{\partial D}{\partial t} d^2r = \frac{dD}{dt} A = I, \quad (6.98)
\]

i.e. the Ampère integral becomes independent of the choice of the surface limited by the contour \( C \) – as it has to, because the surface exists only in our imagination.

### 6.8. Finally, the full Maxwell equation system

This is a very special moment in this course: with the displacement current inclusion, i.e. with the replacement of Eq. (5.107) with Eq. (93), we have finally arrived at the full set of macroscopic Maxwell equations for time-dependent fields,\(^{61}\)

\[
\begin{align*}
\nabla \times \mathbf{E} + \frac{\partial \mathbf{B}}{\partial t} &= 0, & \nabla \times \mathbf{H} - \frac{\partial \mathbf{D}}{\partial t} &= \mathbf{j}, \\
\nabla \cdot \mathbf{D} &= \rho, & \nabla \cdot \mathbf{B} &= 0,
\end{align*}
\]

\((6.99a) \quad (6.99b)\)

whose validity has been confirmed in by an enormous body of experimental data. Indeed, despite numerous efforts, no other corrections (e.g., additional terms) to the Maxwell equations have been ever found, and these equations are still considered exact within the range of their validity, i.e. while the electric and magnetic fields may be considered classically. Moreover, even in quantum theory, these

---

\(^{61}\) This vector form of the equations, magnificent in its symmetry and simplicity, was developed in 1884-85 by Oliver Heaviside, with substantial contributions by H. Lorentz. (The original Maxwell’s result circa 1864 looked like a system of 20 equations for Cartesian components of the vector and scalar potentials.)
equations are believed to be *strictly* valid as relations between the Heisenberg operators of the electric and magnetic fields.\(^\text{62}\) (Note that the *microscopic* Maxwell equations for the genuine fields \( \mathbf{E} \) and \( \mathbf{B} \) may be formally obtained from Eqs. (99) by the substitutions \( \mathbf{D} = \varepsilon_0 \mathbf{E} \) and \( \mathbf{H} = \mathbf{B}/\mu_0 \), and the simultaneous replacement of the stand-alone charge and current densities on their right-hand sides with the full ones.)

The most striking feature of these equations is that, even in the absence of stand-alone charges and currents inside the region of our interest, when all equations become homogeneous,

\[
\nabla \times \mathbf{E} = -\frac{\partial \mathbf{B}}{\partial t}, \quad \nabla \times \mathbf{H} = \frac{\partial \mathbf{D}}{\partial t}, \quad (6.100a)
\]

\[
\nabla \cdot \mathbf{D} = 0, \quad \nabla \cdot \mathbf{B} = 0, \quad (6.100b)
\]

they still describe something very non-trivial: *electromagnetic waves*, including light. The physics of the waves may be clearly seen from Eqs. (100a): according to the first of them, the change of the magnetic field in time creates a vortex-like (divergence-free) electric field. On the other hand, the second of Eqs. (100a) describes how the changing electric field, in turn, creates a vortex-like magnetic field. Thus exchanging energy, the coupled electric and magnetic fields may propagate as waves – even very far from their sources.

We will carry out a detailed quantitative analysis of the waves in the next chapter, and here I will only use this notion to fulfill the promise given in Sec. 3, namely to establish the condition of validity of the quasistatic approximation (21). For simplicity, let us consider an electromagnetic wave with a time period \( \tau \), velocity \( v \), and hence the wavelength \( \lambda = v \tau \) in a linear medium with \( \mathbf{D} = \varepsilon \mathbf{E} \), \( \mathbf{B} = \mu \mathbf{H} \), and \( \mathbf{j} = 0 \) and \( \rho = 0 \). Then the magnitude of the left-hand side of the first of Eqs. (100a) is of the order of \( E/\lambda = E/v \tau \), while that of its right-hand side may be estimated as \( B/\tau \sim \mu H/\tau \). Using similar estimates for the second of Eqs. (100a), we arrive at the following two (approximate) requirements:\(^\text{63}\)

\[
\frac{E}{H} \sim \mu v \sim \frac{1}{\varepsilon v}, \quad (6.101)
\]

To insure the compatibility of these two relations, the waves’ speed should satisfy the estimate

\[
\nu \sim \frac{1}{(\varepsilon \mu)^{1/2}}, \quad (6.102)
\]

reduced to \( \nu \sim 1/(\varepsilon_0 \mu_0)^{1/2} \equiv c \) in free space, while the ratio of the electric and magnetic field amplitudes should be of the following order:

\[
\frac{E}{H} \sim \mu v \sim \mu \frac{1}{(\varepsilon \mu)^{1/2}} = \left( \frac{\mu}{\varepsilon} \right)^{1/2} \quad (6.103)
\]

(In the next chapter we will see that these are indeed the *exact* results for a plane electromagnetic wave.)

Now, let a system of size \( \sim a \) carry currents producing a certain magnetic field \( H \). Then, according to Eqs. (100a), their magnetic field Faraday-induces the electric field of magnitude \( E \sim \mu Ha/\tau \), whose displacement currents, in turn, produce an additional magnetic field with magnitude

\[^{62}\text{See, e.g., QM Chapter 9.}\]

\[^{63}\text{The fact that } \tau \text{ has canceled, shows that these estimates are valid for waves of arbitrary frequency.}\]
\[ H' \sim \frac{a e}{\mathcal{T}} E \sim \frac{a e}{\mathcal{T}} \frac{\mu a}{\mathcal{T}} H \sim \left( \frac{a \lambda}{\sqrt{\mathcal{T} \lambda}} \right)^2 H = \left( \frac{a}{\lambda} \right)^2 H. \] (6.104)

Hence, the displacement current effects are negligible for a system of size \( a \ll \lambda \).64

In particular, the quasistatic picture of the skin effect, which was discussed in Sec. 3, is valid while the skin depth (33) remains much smaller than the corresponding wavelength,

\[ \lambda = v \mathcal{T} = \frac{2 \pi v}{\omega} = \left( \frac{4 \pi^2}{\epsilon \mu \sigma^2} \right)^{1/2}. \] (6.105)

The wavelength decreases with the frequency as \( 1/\omega \), i.e. faster than \( \delta_s \propto 1/\omega^{1/2} \), so that they become comparable at the crossover frequency

\[ \omega_c = \frac{\omega}{\kappa \epsilon_0}, \] (6.106)

which is nothing else than the reciprocal charge relaxation time (4.10). As was discussed in Sec. 4.2, for good metals this frequency is extremely high (about \( 10^{18} \text{ s}^{-1} \)), so the validity of Eq. (33) is typically limited by the anomalous skin effect (which was briefly discussed in Sec. 3), rather than the wave effects.

Before going after the analysis of the full Maxwell equations for particular situations (that will be the main goal of all the next chapters of this course), let us have a look at the energy balance they yield for a certain volume \( V \), which may include both charged particles and the electromagnetic field. Since, according to Eq. (5.10), the magnetic field does no work on charged particles even if they move, the total power \( \mathcal{P} \) being transferred from the field to the particles inside the volume is due to the electric field alone – see Eq. (4.38):

\[ \mathcal{P} = \int_V J \cdot d^3r, \quad \text{with} \quad J = \mathbf{j} \cdot \mathbf{E}, \] (6.107)

Expressing \( \mathbf{j} \) from the corresponding Maxwell equation of the system (99), we get

\[ \mathcal{P} = \int_V \left[ \mathbf{E} \cdot (\nabla \times \mathbf{H}) - \mathbf{E} \cdot \frac{\partial \mathbf{D}}{\partial t} \right] d^3r. \] (6.108)

Let us pause here for a second, and transform the divergence of vector \( \mathbf{E} \times \mathbf{H} \), using the well-known vector algebra identity:65

\[ \nabla \cdot (\mathbf{E} \times \mathbf{H}) = \mathbf{H} \cdot (\nabla \times \mathbf{E}) - \mathbf{E} \cdot (\nabla \times \mathbf{H}). \] (6.109)

The last term on the right-hand side of this equality is exactly the first term in the square brackets of Eq. (108), so that we may rewrite that formula as

\[ \mathcal{P} = \int_V \left[ -\nabla \cdot (\mathbf{E} \times \mathbf{H}) + \mathbf{H} \cdot (\nabla \times \mathbf{E}) - \mathbf{E} \cdot \frac{\partial \mathbf{D}}{\partial t} \right] d^3r. \] (6.110)

---

64 Let me emphasize that if this condition is not fulfilled, the lumped-circuit representation of the system (see Fig. 9 and its discussion) is typically inadequate – besides some special cases, to be discussed in Chapter 7.

65 See, e.g., MA Eq. (11.7) with \( \mathbf{f} = \mathbf{E} \) and \( \mathbf{g} = \mathbf{H} \).
However, according to the Maxwell equation for $\nabla \times E$, this curl is equal to $-\partial B/\partial t$, so that the second term in the square brackets of Eq. (110) equals $-H \cdot \partial B/\partial t$ and, according to Eq. (14), is just the (minus) time derivative of the magnetic energy per unit volume. Similarly, according to Eq. (3.76), the third term under the integral is the minus time derivative of the electric energy per unit volume. Finally, we can use the divergence theorem to transform the integral of the first term in the square brackets to a 2D integral over the surface $S$ limiting the volume $V$. As the result, we get the so-called Poynting theorem\textsuperscript{66} for the power balance in the system:

$$\int_V \left( \rho + \frac{\partial u}{\partial t} \right) d^3 r + \int_S n d^2 r = 0.$$  

(6.111)

Here $u$ is the density of the total (electric plus magnetic) energy of the electromagnetic field, with

$$\delta u \equiv E \cdot \delta D + H \cdot \delta B,$$  

(6.112)

so that for an isotropic, linear, and dispersion-free medium, with $D(t) = \varepsilon E(t)$, $B(t) = \mu H(t)$,

$$u = \frac{E \cdot D}{2} + \frac{H \cdot B}{2} = \frac{\varepsilon E^2}{2} + \frac{B^2}{2\mu},$$  

(6.113)

and $S$ is the Poynting vector defined as\textsuperscript{67}

$$S \equiv E \times H.$$  

(6.114)

The first integral in Eq. (111) is evidently the net change of the energy of the system (particles + field) per unit time, so that the second (surface) integral has to be the power flowing out from the system through the surface. As a result, it is tempting to interpret the Poynting vector $S$ locally, as the power flow density at the given point. In many cases, such a local interpretation of vector $S$ is legitimate; however, in other cases, it may lead to wrong conclusions. Indeed, let us consider a simple system shown in Fig. 11: a charged plane capacitor placed into a static and uniform external magnetic field, so that the electric and magnetic fields are mutually perpendicular.

In this static situation, with no charges moving, both $\rho$ and $\partial /\partial t$ are equal to zero, and there should be no power flow in the system. However, Eq. (114) shows that the Poynting vector is not equal

\textsuperscript{66} Called after John Henry Poynting for his work published in 1884, though this fact was independently discovered by O. Heaviside in 1885 in a simpler form, while a similar expression for the intensity of mechanical elastic waves had been derived earlier (in 1874) by Nikolay Alekseevich Umov – see, e.g., CM Sec. 7.7.

\textsuperscript{67} Actually, an addition to $S$ of the curl of an arbitrary vector function $f(r, t)$ does not change Eq. (111). Indeed, we may use the divergence theorem to transform the corresponding change of the surface integral in Eq. (111) to a volume integral of scalar function $\nabla \cdot (\nabla \times f)$ that equals zero at any point – see, e.g., MA Eq. (11.2).
to zero inside the capacitor, being directed as the red arrows in Fig. 11 show. From the point of view of the only unambiguous corollary of the Maxwell equations, Eq. (111), there is no contradiction here, because the fluxes of the vector $\mathbf{S}$ through the side boundaries of the volume shaded in Fig. 11 are equal and opposite (and they are zero for other faces of this rectilinear volume), so that the total flux of the Poynting vector through the volume boundary equals zero, as it should. It is, however, useful to recall this example each time before giving a local interpretation of the vector $\mathbf{S}$.

The paradox illustrated in Fig. 11 is closely related to the radiation recoil effects, due to the electromagnetic field’s momentum – more exactly, it linear momentum. Indeed, acting as at the Poynting theorem derivation, it is straightforward to use the *microscopic* Maxwell equations$^{68}$ to prove that, neglecting the boundary effects, the vector sum of the mechanical linear momentum of the particles in an arbitrary volume, and the integral of the following vector,

$$\mathbf{g} = \frac{\mathbf{S}}{c^2}, \quad (6.115)$$

over the same volume, is conserved, allowing us to interpret $\mathbf{g}$ as the density of the linear momentum of the electromagnetic field. (It will be more convenient for me to prove this relation, and discuss the related issues, in Sec. 9.8, using the 4-vector formalism of the special relativity.) Due to this conservation, if some static fields coupled to mechanical bodies are suddenly decoupled from them and are allowed to propagate in space, i.e. change their local integral of $\mathbf{g}$, they give the bodies an opposite the equal and opposite impulse of force.

Finally, to complete our initial discussion of the Maxwell equations,$^{69}$ let us rewrite them in terms of potentials $\mathbf{A}$ and $\phi$, because this is more convenient for the solution of some (though not all!) problems. Even when dealing with the system (99) of the more general Maxwell equations than discussed before, Eqs. (7) are still used for the definition of the potentials. It is straightforward to verify that with these definitions, the two homogeneous Maxwell equations (99b) are satisfied automatically. Plugging Eqs. (7) into the inhomogeneous equations (99a), and considering, for simplicity, a linear, uniform medium with frequency-independent $\varepsilon$ and $\mu$, we get

$$\nabla^2 \phi + \frac{\partial}{\partial t}(\nabla \cdot \mathbf{A}) = -\frac{\rho}{\varepsilon}, \quad \nabla^2 \mathbf{A} - \varepsilon \mu \frac{\partial^2 \mathbf{A}}{\partial t^2} - \nabla \left( \nabla \cdot \mathbf{A} + \varepsilon \mu \frac{\partial \phi}{\partial t} \right) = -\mu \mathbf{j}. \quad (6.116)$$

This is a more complex result than what we would like to get. However, let us select a special gauge, which is frequently called (especially for the free space case, when $v = c$) the *Lorenz gauge condition*$^{70}$

$$\nabla \cdot \mathbf{A} + \varepsilon \mu \frac{\partial \phi}{\partial t} = 0, \quad (6.117)$$

$^{68}$ The situation with the *macroscopic* Maxwell equations is more complex, and is still a subject of some lingering discussions (usually called the Abraham-Minkowski controversy, despite contributions by many other scientists including A. Einstein), because of the ambiguity of momentum’s division between its field and particle components – see, e.g., the recent review paper by R. Pfeiffer et al., *Rev. Mod. Phys.* 79, 1197 (2007).

$^{69}$ We will return to their general discussion (in particular, to the analytical mechanics of the electromagnetic field, and its stress tensor) in Sec. 9.8, after we have got equipped with the special relativity theory.

$^{70}$ This condition, named after Ludwig Lorenz, should not be confused with the so-called *Lorentz invariance condition* of the relativity theory, due to H. Lorentz (note the last names’ spelling), to be discussed in Sec. 9.4.
which is a natural generalization of the Coulomb gauge (5.48) to time-dependent phenomena. With this condition, Eqs. (107) are reduced to a simpler, beautifully symmetric form:

$$\nabla^2 \phi - \frac{1}{v^2} \frac{\partial^2 \phi}{\partial t^2} = -\frac{\rho}{\varepsilon}, \quad \nabla^2 \mathbf{A} - \frac{1}{v^2} \frac{\partial^2 \mathbf{A}}{\partial t^2} = -\mu \mathbf{j},$$  

(6.118)

where $v^2 \equiv 1/\varepsilon \mu$. Note that these equations are essentially a set of 4 similar equations for 4 scalar functions (namely, $\phi$ and three Cartesian components of $\mathbf{A}$) and thus clearly invite the 4-component vector formalism of the relativity theory; it will be discussed in Chapter 9.

If $\phi$ and $\mathbf{A}$ depend on just one spatial coordinate, say $z$, in a region without field sources: $\rho = 0$, $\mathbf{j} = 0$, Eqs. (118) are reduced to the well-known 1D wave equations

$$\frac{\partial^2 \phi}{\partial z^2} - \frac{1}{v^2} \frac{\partial^2 \phi}{\partial t^2} = 0, \quad \frac{\partial^2 \mathbf{A}}{\partial z^2} - \frac{1}{v^2} \frac{\partial^2 \mathbf{A}}{\partial t^2} = 0.$$

(6.119)

In is well known that these equations describe waves, with arbitrary waveforms (including sinusoidal waves of any frequency), propagating with the same speed $v$ in either of directions of the $z$-axis. According to the definitions of the constants $\varepsilon_0$ and $\mu_0$, in the free space $v$ is just the speed of light:

$$v = \frac{1}{\sqrt{\varepsilon_0 \mu_0}} \equiv c.$$  

(6.120)

Historically, the experimental observation of relatively low-frequency (GHz-scale) electromagnetic waves, with their speed equal to that of light, was the decisive proof (and a real triumph!) of the Maxwell theory and his prediction of such waves. This was first accomplished in 1886 by Heinrich Rudolf Hertz, using the electronic circuits and antennas he had invented for this purpose.

Before proceeding to the detailed analysis of these waves in the following chapters, let me mention that the invariance of Eqs. (119) with respect to the wave propagation direction is not occasional; it is just a manifestation of one more general property of the Maxwell equations (99), called the Lorentz reciprocity. We have already met its simplest example, for time-independent electrostatic fields, in one of the problems of Chapter 1. Let us now consider a much more general case when two time-dependent electromagnetic fields, say \{\mathbf{E}_1(\mathbf{r}, t), \mathbf{H}_1(\mathbf{r}, t)\} and \{\mathbf{E}_2(\mathbf{r}, t), \mathbf{H}_2(\mathbf{r}, t)\} are induced,
respectively, by spatially-localized stand-alone currents $j_1(\mathbf{r}, t)$ and $j_2(\mathbf{r}, t)$. Then it may be proved\textsuperscript{74} that if the medium is linear, and either isotropic or even anisotropic, but with symmetric tensors $\varepsilon_{ij'}$ and $\mu_{ij'}$, then for any volume $V$, limited by a closed surface $S$,

$$
\int_V (\mathbf{j}_1 \cdot \mathbf{E}_2 - \mathbf{j}_2 \cdot \mathbf{E}_1) d^3r = \oint_S (\mathbf{E}_1 \times \mathbf{H}_2 - \mathbf{E}_2 \times \mathbf{H}_1) d^2r .
$$

(6.121)

This property implies, in particular, that the waves propagate similarly in two reciprocal directions even in situations much more general than the 1D case described by Eqs. (119). For some important practical applications (e.g., for low-noise amplifiers and detectors) such reciprocity is rather inconvenient. Fortunately, Eq. (121) may be violated in anisotropic media with asymmetric tensors $\varepsilon_{ij'}$ and/or $\mu_{ij'}$. The simplest, and most important case of such an anisotropy, the Faraday rotation of the wave polarization in plasma, will be discussed in the next chapter.

6.9. Exercise problems

6.1. Prove that the electromagnetic induction e.m.f. $\mathcal{V}_{\text{ind}}$ in a conducting loop may be measured as shown on two panels of Fig. 1:

(i) by measuring the current $I = \mathcal{V}_{\text{ind}}/R$ induced in the loop closed with an Ohmic resistor $R$, or

(ii) using a voltmeter inserted into the loop.

6.2. The flux $\Phi$ of the magnetic field that pierces a resistive ring is being changed in time, while the magnetic field outside of the ring is negligibly low. A voltmeter is connected to a part of the ring, as shown in the figure on the right. What would the voltmeter show?

6.3. A weak, uniform magnetic field $\mathbf{B}$ is applied to an axially-symmetric permanent magnet, with the dipole magnetic moment $\mathbf{m}$ directed along the symmetry axis, rapidly rotating about the same axis, with an angular momentum $\mathbf{L}$. Calculate the electric field resulting from the magnetic field’s application, and formulate the conditions of your result’s validity.

6.4. The similarity of Eq. (5.53), obtained in Sec. 5.3 without any use of the Faraday induction law, and Eq. (5.54), proved in Sec. 2 of this chapter using the law, implies that the law may be derived from magnetostatics. Prove that this is indeed true for a particular case of a current loop, being slowly deformed in a fixed magnetic field $\mathbf{B}$.

6.5. Could Problem 5.1 (i.e. the analysis of the mechanical stability of the system shown in the figure on the right) be solved using potential energy arguments?

\textsuperscript{74} A warning: the proofs of Eq. (121), given in many textbooks and online sites, are deficient.
6.6. Use energy arguments to calculate the pressure exerted by the magnetic field $B$ inside a long uniform solenoid of length $l$, and a cross-section of area $A << \ell^2$, with $N >> l/A^{1/2} >> 1$ turns, on its “walls” (windings), and the forces exerted by the field on the solenoid’s ends, for two cases:

(i) the current through the solenoid is fixed by an external source, and
(ii) after the initial current setting, the ends of the solenoid’s wire, with a negligible resistance, are connected, so that it continues to carry a non-zero current.

Compare the results, and give a physical interpretation of the direction of these forces.

6.7. The **electromagnetic railgun** is a projectile launch system consisting of two long, parallel conducting rails and a sliding conducting projectile, shorting the current $I$ fed into the system by a powerful source – see panel (a) in the figure on the right. Calculate the force exerted on the projectile, using two approaches:

(i) by a direct calculation, assuming that the cross-section of the system has the simple shape shown on panel (b) of the figure above, with $t << w, l$, and
(ii) using the energy balance (for simplicity, neglecting the Ohmic resistances in the system), and compare the results.

6.8. A uniform, static magnetic field $B$ is applied along the axis of a long round pipe of a radius $R$, and a very small thickness $\tau$, made of a material with Ohmic conductivity $\sigma$. A sphere of mass $M$ and radius $R' < R$, made of a linear magnetic with permeability $\mu >> \mu_0$, is launched, with an initial velocity $v_0$, to fly ballistically along the pipe’s axis – see the figure on the right. Use the quasistatic approximation to calculate the distance the sphere would pass before it stops. Formulate the conditions of validity of your result.

6.9. AC current of frequency $\omega$ is being passed through a long uniform wire with a round cross-section of radius $R$ comparable with the skin depth $\delta_s$. In the quasistatic approximation, find the current’s distribution across the cross-section, and analyze it in the limits $R >> \delta_s$ and $\delta_s << R$. Calculate the effective ac resistance of the wire (per unit length) in these two limits.

6.10. A very long, round cylinder of radius $R$, made of a uniform conductor with an Ohmic conductivity $\sigma$ and magnetic permeability $\mu$, has been placed into a uniform ac magnetic field $H_{ext}(t) = H_0 \cos \omega t$, directed along its symmetry axis. Calculate the spatial distribution of the magnetic field’s amplitude, and in particular its value on the cylinder’s axis. Spell out the last result in the limits of relatively small and large $R$.

6.11.* Define and calculate an appropriate spatial-temporal Green’s function for Eq. (25), and then use this function to analyze the dynamics of propagation of the external magnetic field that is suddenly turned on at $t = 0$ and then kept constant:
\[ H(x < 0, t) = \begin{cases} 0, & \text{at } t < 0, \\ H_0, & \text{at } t > 0, \end{cases} \]

into an Ohmic conductor occupying the semi-space \( x > 0 \) – see Fig. 2.

**Hint:** Try to use a function proportional to \( \exp\left\{-(x-x')^2/2(\delta x)^2\right\} \), with a suitable time dependence of the parameter \( \delta x \), and a properly selected pre-exponential factor.

6.12. Solve the previous problem using the variable separation method, and compare the results.

6.13. A small, planar wire loop, carrying current \( I \), is located far from a plane surface of a superconductor. Within the “coarse-grain” (ideal-diamagnetic) description of the Meissner-Ochsenfeld effect, calculate:

(i) the energy of the loop-superconductor interaction,
(ii) the force and torque acting on the loop,
(iii) the distribution of supercurrents on the superconductor surface.

6.14. A straight, uniform magnet of length 2\( l \), cross-section area \( A \ll l^2 \), and mass \( m \), with a permanent longitudinal magnetization \( M_0 \), is placed over a horizontal surface of a superconductor – see the figure on the right. Within the ideal-diamagnet description of the Meissner-Ochsenfeld effect, find the stable equilibrium position of the magnet.

6.15. A plane superconducting wire loop, of area \( A \) and inductance \( L \), may rotate, without friction, about a horizontal axis 0 (in the figure on the right, perpendicular to the plane of the drawing) passing through its center of mass. Initially, the loop was horizontal (with \( \theta = 0 \)), and carried supercurrent \( I_0 \) in such direction that its magnetic dipole vector was directed down. Then a uniform magnetic field \( B \), directed vertically up, was applied. Using the ideal-diamagnet description of the Meissner-Ochsenfeld effect, find all possible equilibrium positions of the loop, analyze their stability, and give a physical interpretation of the results.

6.16. Use the London equation to analyze the penetration of a uniform external magnetic field into a thin (\( t \sim \delta_L \)), planar superconducting film, whose plane is parallel to the field.

6.17. Use the London equation to calculate the distribution of supercurrent density \( j \) inside a long, straight superconducting wire, with a circular cross-section of radius \( R \sim \delta_L \), carrying dc current \( I \).

6.18. Use the London equation to calculate the inductance (per unit length) of a long, uniform superconducting strip placed close to the surface of a similar superconductor – see the figure on the right, which shows the structure’s cross-section.
6.19. Calculate the inductance (per unit length) of a superconducting cable with a round cross-section, shown in the figure on the right, in the following limits:

(i) \( \delta_L \ll a, b, c - b \), and
(ii) \( a \ll \delta_L \ll b, c - b \).

6.20. Use the London equation to analyze the magnetic field shielding by a superconducting thin film of thickness \( t \ll \delta_L \), by calculating the penetration of the field induced by the current \( I \) flowing in a thin wire that runs parallel to a wide, plane, thin film, at distance \( d \gg t \) from it, into the space behind the film.

6.21. Use the Ginzburg-Landau equations (54) and (63) to calculate the largest (“critical”) value of supercurrent in a uniform, long superconducting wire of a small cross-section \( A_w \ll \delta_L^2 \).

6.22. Use the discussion of a long, straight Abricosov vortex, in the limit \( \xi \ll \delta_L \), in Sec. 5 to prove Eqs. (71)-(72) for its energy per unit length, and the first critical field.

6.23. Use the Ginzburg-Landau equations (54) and (63) to prove the Josephson’s relation (76) for a small superconducting weak link, and express its critical current \( I_c \) of via the Ohmic resistance \( R_n \) of the same weak link in its normal state.

6.24. Use Eqs. (76) and (79) to calculate the coupling energy of a Josephson junction, and the full potential energy of the SQUID shown in Fig. 4c.

6.25. Analyze the possibility of wave propagation in a long, uniform chain of lumped inductances and capacitances – see the figure on the right.

Hint: Readers without prior experience with electromagnetic wave analysis may like to use a substantial analogy between this effect and mechanical waves in a 1D chain of elastically coupled particles.\(^75\)

6.26. A sinusoidal e.m.f. of amplitude \( V_0 \) and frequency \( \omega \) is applied to an end of a long chain of similar, lumped resistors and capacitors, shown in the figure on the right. Calculate the law of decay of the ac oscillation amplitude along the chain.

6.27. As was discussed in Sec. 7, the displacement current concept allows one to generalize the Ampère law to time-dependent processes as

\[
\oint C \mathbf{H} \cdot d\mathbf{r} = I_s + \frac{\partial}{\partial t} \int D_n d^3r.
\]

\(^{75}\) See, e.g., CM Sec. 6.3.
We also have seen that such generalization makes the integral $\int \mathbf{H} \cdot d\mathbf{r}$ over an external contour, such as the one shown in Fig. 6.10, independent of the choice of the surface $S$ limited by the contour. However, it may look like the situation is different for a contour drawn inside the capacitor – see the figure on the right. Indeed, if the contour’s size is much larger than the capacitor’s thickness, the magnetic field $\mathbf{H}$, created by the linear current $I$ on the contour’s line is virtually the same as that of a continuous wire, and hence the integral $\int \mathbf{H} \cdot d\mathbf{r}$ along the contour apparently does not depend on its area, while the magnetic flux $\int \mathbf{D} \cdot d^2r$ does, so that the equation displayed above seems invalid. (The current $I_S$ piercing this contour evidently equals zero.) Resolve the paradox, for simplicity considering an axially-symmetric system.

6.28. A straight, uniform, long wire with circular cross-section of radius $R$, is made of an Ohmic conductor with conductivity $\sigma$, and carries dc current $I$. Calculate the flux of the Poynting vector through its surface, and compare it with the Joule energy losses.
Chapter 7. Electromagnetic Wave Propagation

This (rather long) chapter focuses on the most important effect that follows from the time-dependent Maxwell equations, namely the electromagnetic waves, at this stage avoiding a discussion of their origin, i.e. radiation – which will the subject of Chapters 8 and 10. The discussion starts from the simplest, plane waves in a uniform and isotropic media, and then proceeds to non-uniform systems, in particular those with sharp boundaries between different materials, bringing up such effects as reflection and refraction. Then we will discuss the so-called guided waves, propagating along various long transmission lines – such as coaxial cables, waveguides, and optical fibers. Finally, the end of the chapter is devoted to final-length fragments of such lines, serving as resonators, and to the effects of energy dissipation in transmission lines and resonators.

7.1. Plane waves

Let us start from considering a spatial region that does not contain field sources \((\rho = 0, \mathbf{j} = 0)\), and is filled with a linear, uniform, isotropic medium, which obeys Eqs. (3.46) and (5.110):

\[
\mathbf{D} = \varepsilon \mathbf{E}, \quad \mathbf{B} = \mu \mathbf{H}.
\]  

(7.1)

Moreover, let us assume, for a while, that these constitutive equations hold for all frequencies of interest. (Of course, these relations are exactly valid for the very important particular case of free space, where we may formally use the macroscopic Maxwell equations (6.100), but with \(\varepsilon = \varepsilon_0\) and \(\mu = \mu_0\)) As was already shown in Sec. 6.8, in this case, the Lorenz gauge condition (6.117) allows the Maxwell equations to be recast into the wave equations (6.118) for the vector and scalar potentials. However, for most purposes, it is more convenient to use the homogeneous Maxwell equations (6.100) for the electric and magnetic fields – which are independent of the gauge choice. After the elementary elimination of \(\mathbf{D}\) and \(\mathbf{B}\) using Eqs. (1),\(^1\) these equations take a simple, symmetric form

\[
\begin{align*}
\nabla \times \mathbf{E} + \mu \frac{\partial \mathbf{H}}{\partial t} = 0, & \quad \nabla \times \mathbf{H} - \varepsilon \frac{\partial \mathbf{E}}{\partial t} = 0, \\
\nabla \cdot \mathbf{E} = 0, & \quad \nabla \cdot \mathbf{H} = 0.
\end{align*}
\]  

(7.2a)

(7.2b)

Now, acting by operator \(\nabla \times\) on each of Eqs. (2a), i.e. taking their curl, and then using the vector algebra identity (5.31), whose first term, for both \(\mathbf{E}\) and \(\mathbf{H}\), vanishes due to Eqs. (2b), we get similar wave equations for the electric and magnetic fields:

\[
\left(\nabla^2 - \frac{1}{v^2} \frac{\partial^2}{\partial t^2}\right) \mathbf{E} = 0, \quad \left(\nabla^2 - \frac{1}{v^2} \frac{\partial^2}{\partial t^2}\right) \mathbf{H} = 0,
\]  

(7.3)

where the parameter \(v\) is defined as

\(\underline{1}\) Though \(\mathbf{B}\) rather then \(\mathbf{H}\) is the actual magnetic field, mathematically it is a bit more convenient (just as it was in Sec. 6.2) to use the latter vector in the following discussion, because at sharp media boundaries, \(\mathbf{H}\) obeys the boundary condition (5.117) similar to that for \(\mathbf{E}\) – cf. Eq. (3.37).

© K. Likharev
with $v^2 = 1/\varepsilon_0\mu_0 \equiv c^2$ in free space – see Eq. (6.120) again. (The two vector equations (3) are of course just a shorthand for six similar equations for three Cartesian components of $\mathbf{E}$ and $\mathbf{H}$, and hence for their magnitudes $E$ and $H$.)

These equations allow, in particular, the following solution,

$$E \propto H \propto f(z- vt),$$

where $z$ is the Cartesian coordinate along a certain (arbitrary) direction $\mathbf{n}$, and $f$ is an arbitrary function of one argument. This solution describes a specific type of a wave, i.e. a certain field pattern moving, without deformation, along axis $z$, with velocity $v$. According to Eq. (5), both $\mathbf{E}$ and $\mathbf{H}$ have the same values in each plane perpendicular to the direction $\mathbf{n}$ of wave propagation, hence the name – plane wave.

According to Eqs. (2), the independence of the wave equations (3) for vectors $\mathbf{E}$ and $\mathbf{H}$ does not mean that their plane-wave solutions are independent. Indeed, plugging the solutions of the type (5) into Eqs. (2a), we get

$$\mathbf{H} = \frac{\mathbf{n} \times \mathbf{E}}{Z}, \quad \text{i.e. } \mathbf{E} = Z \mathbf{H} \times \mathbf{n},$$

where

$$Z \equiv \frac{E}{H} = \left( \frac{\mu}{\varepsilon} \right)^{1/2}.$$

The vector relation (6) means, first of all, that the vectors $\mathbf{E}$ and $\mathbf{H}$ are perpendicular not only to vector $\mathbf{n}$ (such waves are called transverse), but also to each other (Fig. 1) – at any point of space and at any time instant. Second, this relation does not depend on the function $f$, meaning that the electric and magnetic fields increase and decrease simultaneously.

Finally, the field magnitudes are related by the constant $Z$, called the wave impedance of the medium. Very soon we will see that the impedance plays a pivotal role in many problems, in particular at the wave reflection from the interface between two media. Since the dimensionality of $E$, in SI units, is V/m, and that of $H$ is A/m, Eq. (7) shows that $Z$ has the dimensionality of V/A, i.e. ohms ($\Omega$).\(^2\) In particular, in free space,

\(^2\) In the Gaussian units, $E$ and $H$ have a similar dimensionality (in particular, in a free-space wave, $E = H$), making the (very useful) notion of the wave impedance less manifestly exposed – so that in some older physics textbooks it is not mentioned at all!
\[ Z = \frac{\mu_0}{\epsilon_0}^{1/2} = 4\pi \times 10^{-7} \times c \approx 377 \, \Omega. \quad (7.8) \]

Next, plugging Eq. (6) into Eqs. (6.113) and (6.114), we get:

\[ u = \varepsilon E^2 = \mu H^2, \quad (7.9\text{a}) \]

\[ S \equiv \mathbf{E} \times \mathbf{H} = n \frac{E^2}{Z} = n Z H^2, \quad (7.9\text{b}) \]

so that, according to Eqs. (4) and (7), the wave’s energy and power densities are universally related as

\[ S = n u v. \quad (7.9\text{c}) \]

In the view of the Poynting vector paradox discussed in Sec. 6.8 (see Fig. 6.11), one may wonder whether this expression may be interpreted as the actual density of power flow. In contrast to the static situation shown in Fig. 6.11, that limits the electric and magnetic fields to vicinity of their sources, waves may travel far from them. As a result, they can form wave packets of a finite length in free space – see Fig. 2.

Let us apply the Poynting theorem (6.111) to the cylinder shown with dashed lines in Fig. 2, with one lid inside the wave packet, and another lid in the region already passed by the wave. Then, according to Eq. (6.111), the rate of change of the full field energy \( \varepsilon \) inside the volume is \( d\varepsilon /dt = -SA \) (where \( A \) is the lid area), so that \( S \) may be indeed interpreted as the power flow (per unit area) from the volume. Making a reasonable assumption that the finite length of a sufficiently long wave packet does not affect the physics inside it, we may indeed interpret the \( S \) given by Eqs. (9b-c) as the power flow density inside a plane electromagnetic wave.

As we will see later in this chapter, the free-space value \( Z_0 \) of the wave impedance, given by Eq. (8), establishes the scale of \( Z \) of virtually all wave transmission lines, so we may use it, together with Eq. (9), to get a better feeling of how different are the electric and magnetic field amplitudes in the waves, on the scale of typical electrostatics and magnetostatics experiments. For example, according to Eqs. (9), a wave of a modest intensity \( S = 1 \, \text{W/m}^2 \) (this is what we get from a usual electric bulb a few meters away from it) has \( E \sim (SZ_0)^{1/2} \sim 20 \, \text{V/m}, \) quite comparable with the dc field created by a standard AA battery right outside it. On the other hand, the wave’s magnetic field \( H = (S/Z_0)^{1/2} \approx 0.05 \, \text{A/m}. \) For this particular case, the relation following from Eqs. (1), (4), and (7),
\[ B = \mu H = \frac{\mu E}{Z} = \mu \frac{E}{(\mu/\varepsilon)^{1/2}} = (\varepsilon\mu)^{1/2} E = \frac{E}{v}, \quad (7.10) \]
gives \( B = \mu_0 H = E/c \approx 7 \times 10^{-8} \text{T}, \) i.e. a magnetic field thousand times lower than the Earth’s field, and about 7 orders of magnitude lower than the field of a typical permanent magnet. This huge difference may be interpreted as follows: the scale of magnetic fields \( B \approx E/c \) in the waves is “normal” for electromagnetism, while the permanent magnet fields are abnormally high, because they are due to the ferromagnetic alignment of electron spins, essentially relativistic objects – see the discussion in Sec. 5.5.

The fact that Eq. (5) is valid for an arbitrary function \( f \) means, in plain English, that a medium with frequency-independent \( \varepsilon \) and \( \mu \) supports propagation of plane waves with an arbitrary waveform – without either decay (attenuation) or deformation (dispersion). However, for any real medium but pure vacuum, this approximation is valid only within limited frequency intervals. We will discuss the effects of attenuation and dispersion in the next section and will see that all our prior formulas remain valid even for an arbitrary linear medium, provided that we limit them to single-frequency (i.e. sinusoidal, frequently called monochromatic) waves. Such waves may be most conveniently represented as

\[ f = \text{Re}\left[f_0 e^{i(kz - \omega t)}\right], \quad (7.11) \]

where \( f_0 \) is the complex amplitude of the wave, and \( k \) is its wave number (the magnitude of the wave vector \( \mathbf{k} \equiv \mathbf{n}k \)), sometimes also called the spatial frequency. The last term is justified by the fact, evident from Eq. (11), that \( k \) is related to the wavelength \( \lambda \) exactly as the usual (“temporal”) frequency \( \omega \) is related to the time period \( \tau \):

\[ k = \frac{2\pi}{\lambda}, \quad \omega = \frac{2\pi}{\tau}. \quad (7.12) \]

Requiring Eq. (11) to be a particular form of Eq. (5), i.e. the argument \((kz - \omega t) \equiv k[z - (\omega/k)t]\) to be proportional to \((z - vt)\), so that \( \omega/k = v \), we see that the wave number should equal

\[ k = \frac{\omega}{v} \equiv (\varepsilon\mu)^{1/2} \omega, \quad (7.13) \]
showing that in this “dispersion-free” case the dispersion relation \( \omega(k) \) is linear.

Now note that Eq. (6) does not mean that the vectors \( \mathbf{E} \) and \( \mathbf{H} \) retain their direction in space. (The wave in that they do is called linearly-polarized.\(^4\)) Indeed, nothing in the Maxwell equations prevents, for example, a joint rotation of this pair of vectors around the fixed vector \( \mathbf{n} \), while still keeping all these three vectors perpendicular to each other at any instant – see Fig. 1. However, an arbitrary rotation law, or even an arbitrary constant frequency of such rotation would violate the single-frequency (monochromatic) character of the elementary sinusoidal wave (11). To understand what is the most general type of polarization the wave may have without violating that condition, let us represent

---

\(^3\) As we have already seen in the previous chapter (see also CM Sec. 1), such complex-exponential representation of sinusoidally-changing variables is more convenient for mathematical manipulation with that using sine and cosine functions, especially because in all linear relations, the operator \( \text{Re} \) may be omitted (implied) until the very end of the calculation. Note, however, that this is not valid for the quadratic forms such as Eqs. (9a-b).

\(^4\) The possibility of different polarizations of electromagnetic waves was discovered (for light) in 1699 by Rasmus Bartholin (a.k.a. Erasmus Bartholinus).
two Cartesian components of one of these vectors (say, \(E\)) along any two fixed axes \(x\) and \(y\), perpendicular to each other and to the \(z\)-axis (i.e. to the vector \(n\)), in the same form as used in Eq. (11):

\[
E_x = \text{Re}\left[E_{\omega x}e^{i(kz - \omega t)}\right], \quad E_y = \text{Re}\left[E_{\omega y}e^{i(kz - \omega t)}\right].
\]

In order to keep the wave monochromatic, the complex amplitudes \(E_{\omega x}\) and \(E_{\omega y}\) must be constant in time; however, they may have different magnitudes and an arbitrary phase shift between them.

In the simplest case when the arguments of the complex amplitudes are equal,

\[
E_{\omega x,y} = |E_{\omega x,y}| e^{i\varphi}.
\]

the real field components have the same phase:

\[
E_x = |E_{\omega x}| \cos(kz - \omega t + \varphi), \quad E_y = |E_{\omega y}| \cos(kz - \omega t + \varphi),
\]

so that their ratio is constant in time – see Fig. 3a. This means that the wave is linearly polarized, with the polarization plane defined by the relation

\[
\tan \theta = \frac{|E_{\omega y}|}{|E_{\omega x}|}.
\]

![Fig. 7.3. Time evolution of the electric field vector in monochromatic waves with: (a) a linear polarization, (b) the circular polarization, and (c) an elliptical polarization.](image)

Another simple case is when the moduli of the complex amplitudes \(E_{\omega x}\) and \(E_{\omega y}\) are equal, but their phases are shifted by \(+\pi/2\) or \(-\pi/2\):

\[
E_{\omega x} = |E_{\omega}|e^{i\varphi}, \quad E_{\omega y} = |E_{\omega}|e^{i(\varphi \pm \pi/2)}.
\]

In this case

\[
E_x = |E_{\omega}| \cos(kz - \omega t + \varphi), \quad E_y = |E_{\omega}| \cos\left(kz - \omega t + \varphi \pm \frac{\pi}{2}\right) \equiv \mp |E_{\omega}| \sin(kz - \omega t + \varphi).
\]

This means that on the wave’s plane (normal to \(n\)), the end of the vector \(E\) moves, with the wave’s frequency \(\omega\), either clockwise or counterclockwise around a circle – see Fig. 3b:

\[
\theta(t) = \mp(\omega t - \varphi).
\]
Such waves are called circularly-polarized. In the dominant convention, the wave is called right-polarized (RP) if it is described by the lower sign in Eqs. (18)-(20), i.e. if the vector \( \mathbf{\omega} \) of the angular frequency of the field vector’s rotation coincides with the wave propagation’s direction \( \mathbf{n} \), and left-polarized (LP) in the opposite case. These particular solutions of the Maxwell equations are very convenient for quantum electrodynamics, because single electromagnetic field quanta with a certain (positive or negative) spin direction may be considered as elementary excitations of the corresponding circularly-polarized wave.\(^5\) (This fact does not exclude, from the quantization scheme, waves of other polarizations, because any monochromatic wave may be presented as a linear combination of two opposite circularly-polarized waves – just as Eqs. (14) represent it as a linear combination of two linearly-polarized waves.)

Finally, in the general case of arbitrary complex amplitudes \( E_{\omega x} \) and \( E_{\omega y} \), the field vector’s end moves along an ellipse (Fig. 3c); such wave is called elliptically polarized. The elongation (“eccentricity”) and orientation of the ellipse are completely described by one complex number, the ratio \( E_{\omega x}/E_{\omega y} \), i.e. by two real numbers, for example \(|E_{\omega x}/E_{\omega y}|\) and \( \varphi = \arg(E_{\omega x}/E_{\omega y}) \).\(^6\)

### 7.2. Attenuation and dispersion

Let me start the discussion of the dispersion and attenuation effects by considering a particular case of the time evolution of the electric polarization of a dilute, non-polar medium, with negligible interaction between its elementary dipoles \( \mathbf{p}(t) \). As was discussed in Sec. 3.3, in this case, the local electric field acting on each elementary dipole, equals to the macroscopic field \( \mathbf{E}(t) \). Then, the polarization \( \mathbf{p}(t) \neq 0 \) may be caused only by the values of the field \( \mathbf{E} \) at the same moment of time \( t \), or at the earlier moments of time, \( t < t' \). Due to the linear superposition principle, the macroscopic polarization \( \mathbf{P}(t) = n\mathbf{p}(t) \) should be a linear sum (integral) of the values of \( \mathbf{E}(t') \) at all previous moments of time, \( t' < t \), weighed by some function of \( t \) and \( t' \):\(^7\)

\[
P(t) = \int_{-\infty}^{t} E(t')G(t,t')dt'.
\]

---

\(^5\) This issue is closely related to that of the radiation’s angular momentum; it will be more convenient for me to discuss it later in this chapter (in Sec. 7).

\(^6\) Note that the same information may be expressed via four so-called Stokes parameters \( s_0, s_1, s_2, s_3 \), which are popular in practical optics, because they may be used for the description of not only completely coherent waves that are discussed here, but also of partly coherent or even fully incoherent waves – including the natural light emitted by thermal sources such as our Sun. (In contrast to the coherent waves (14), whose complex amplitudes are deterministic numbers, the amplitudes of incoherent waves should be treated as random variables.) For more on the Stokes parameters, as well as about many other optics topics I will not have time to cover, I can recommend the classical text by M. Born et al., *Principles of Optics*, 7th ed., Cambridge U. Press, 1999.

\(^7\) In an isotropic media, the vectors \( \mathbf{E}, \mathbf{P} \), and hence \( \mathbf{D} = \varepsilon_0 \mathbf{E} + \mathbf{P} \), are all parallel, and for the notation simplicity I will drop the vector sign in the following formulas. I am also assuming that \( \mathbf{P} \) at any point \( \mathbf{r} \) is only dependent on the electric field at the same point, and hence drop the factor \( \exp{ikz} \), the same for all variables. This last assumption is valid if the wavelength \( \lambda \) is much larger than the elementary media dipole’s size \( a \). In most systems of interest, the scale of \( a \) is atomic (~10\(^{-10}\)m), so that the approximation is valid up to very high frequencies, \( \omega \sim c/a \sim 10^{18} \text{ s}^{-1} \), corresponding to hard X-rays.
The condition \( t' < t \), which is implied by this relation, expresses a key principle of physics, the \textit{causal relation} between a cause (in our case, the electric field applied to each dipole) and its effect (the polarization it creates). The function \( G(t, t') \) is called the \textit{temporal Green's function} for the electric polarization.\(^8\) To understand its physical sense, let us consider the case when the applied field \( E(t) \) is a very short pulse at the moment \( t_0 < t \), that may be approximated with the Dirac’s delta-function:

\[
E(t) = \delta(t - t_0) .
\]

Then Eq. (21) yields just \( P(t) = G(t, t_0) \), showing that the Green’s function \( G(t, t') \) is just the polarization at moment \( t \), created by a unit \( \delta \)-functional pulse of the applied field at moment \( t' \) (Fig. 4).

What are the general properties of the temporal Green’s function? First, the function is evidently real, since the dipole moment \( p \) and hence polarization \( P = np \) are real by the definition – see Eq. (3.6). Next, for systems without infinite internal “memory”, \( G \) should tend to zero at \( t - t' \to \infty \), although the type of this approach (e.g., whether the function \( G \) oscillates approaching zero – see Fig. 4) depends on the elementary dipole’s properties. Finally, if parameters of the medium do not change in time, the polarization response to an electric field pulse should be dependent not on its absolute timing, but only on the time difference \( \theta \equiv t - t' \) between the pulse and observation instants, i.e. Eq. (21) is reduced to

\[
P(t) = \int_{-\infty}^{\infty} E(t')G(t-t')dt' \equiv \int_{0}^{\infty} E(t-\theta)G(\theta)d\theta .
\]

For a sinusoidal waveform, \( E(t) = \text{Re} [E_\omega e^{-i\omega t}] \), this equation yields

\[
P(t) = \text{Re} \left[ \int_{0}^{\infty} E_\omega e^{-i\omega (t-\theta)} G(\theta)d\theta \right] \equiv \text{Re} \left[ \int_{0}^{\infty} \left( E_\omega \int_{0}^{\infty} G(\theta)e^{i\omega \theta} d\theta \right) e^{-i\omega t} \right] .
\]

The expression in the parentheses is of course nothing else than the complex amplitude \( P_\omega \) of the polarization. This means that though even if the static linear relation (3.43), \( P = \chi_0 \varepsilon_0 E \), is invalid for an arbitrary time-dependent process, we may still keep its Fourier analog,

\[
P_\omega = \chi_0(\omega)\varepsilon_0 E_\omega , \quad \text{with} \quad \chi_0(\omega) = \frac{1}{\varepsilon_0} \int_{0}^{\infty} G(\theta)e^{i\omega \theta} d\theta ,
\]

for each sinusoidal component of the process, using it as the definition of the frequency-dependent electric susceptibility \( \chi_0(\omega) \). Similarly, the frequency-dependent electric permittivity may be defined using the Fourier analog of Eq. (3.46):

\(^8\) The idea of these functions is very similar to that of the spatial Green’s functions (see Sec. 2.10), but with the new twist, due to the causality principle. A discussion of the temporal Green’s functions in application to classical mechanics (which substantially overlaps with our current discussion) may be found in CM Sec. 5.1.
Then, according to the definition (3.33), the permittivity is related to the temporal Green’s function by
the usual Fourier transform:

\[
\varepsilon(\omega) \equiv \varepsilon_0 + \frac{P_\omega}{E_\omega} = \varepsilon_0 + \int_0^\infty G(\theta) e^{i\omega \theta} d\theta.
\] (7.26b)

This relation shows that \( \varepsilon(\omega) \) may be complex,

\[
\varepsilon(\omega) = \varepsilon'(\omega) + i\varepsilon''(\omega), \quad \text{with} \quad \varepsilon'(\omega) = \varepsilon_0 + \int_0^\infty G(\theta) \cos \omega \theta \, d\theta, \quad \varepsilon''(\omega) = \int_0^\infty G(\theta) \sin \omega \theta \, d\theta,
\] (7.27)

and that its real part \( \varepsilon'(\omega) \) is always an even function of frequency, while the imaginary part \( \varepsilon''(\omega) \) is an odd function of \( \omega \). Note that though the particular causal relationship (21) between \( P(t) \) and \( E(t) \) is conditioned by the elementary dipole independence, the frequency-dependent complex electric permittivity \( \varepsilon(\omega) \) may be introduced, in a similar way, if any two linear combinations of these variables are related by a similar formula. Absolutely similar arguments show that magnetic properties of a linear, isotropic medium may be characterized with a frequency-dependent, complex permeability \( \mu(\omega) \).

Now rewriting Eqs. (1) for the complex amplitudes of the fields at a particular frequency, we may repeat all calculations of Sec. 1, and verify that all its results are valid for monochromatic waves even for a dispersive (but necessarily linear!) medium. In particular, Eqs. (7) and (13) now become

\[
\left[ \frac{\mu(\omega)}{\varepsilon(\omega)} \right]^{1/2}, \quad k'(\omega) = \frac{\omega}{\varepsilon(\omega)} \mu(\omega), \quad k''(\omega) = \varepsilon''(\omega), \quad \text{so that the wave impedance and the wave number may be both complex functions of frequency.}^9
\] (7.28)

This fact has important consequences for electromagnetic wave propagation. First, plugging the representation of the complex wave number as the sum of its real and imaginary parts, \( k(\omega) = k'(\omega) + ik''(\omega) \), into Eq. (11):

\[
f = \text{Re} \left\{ \int f_\omega e^{i[k'(\omega)z-\omega t]} \right\} = e^{-k''(\omega)z} \text{Re} \left\{ \int f_\omega e^{i[k'(\omega)z-\omega t]} \right\},
\] (7.29)

we see that \( k''(\omega) \) describes the rate of wave attenuation in the medium at frequency \( \omega \).^10 Second, if the waveform is not sinusoidal (and hence should be represented as a sum of several/many sinusoidal components), the frequency dependence of \( k'(\omega) \) provides for wave dispersion, i.e. the waveform deformation at the propagation, because the propagation velocity \( c \) of component waves is now different.^11

---

9 The first unambiguous observations of dispersion (for the case of light refraction) were described by Sir Isaac Newton in his Optics (1704) – even though this genius has never recognized the wave nature of light!

10 It may be tempting to attribute this effect to wave absorption, i.e. the dissipation of the wave’s energy, but we will see very soon that wave attenuation may be due to different effects as well.

11 The reader is probably familiar with the most noticeable effect of the dispersion: the difference between that group velocity \( v_g \equiv d\omega/dk' \), giving the speed of the envelope of a wave packet with a narrow frequency spectrum, and the phase velocity \( v_p \equiv \omega/k' \) of the component waves. The second-order dispersion effect, proportional to \( d^2 \omega/dk'^2 \), leads to the deformation (gradual broadening) of the envelope itself. Following tradition, these effects
As an example of such a dispersive medium, let us consider a simple but very representative *Lorentz oscillator model*. In dilute atomic or molecular systems (e.g., gases), electrons respond to the external electric field especially strongly when frequency \( \omega \) is close to certain frequencies \( \omega_j \) corresponding to the spectrum of quantum transitions of a single atom/molecule. An approximate, phenomenological description of this behavior may be obtained from a classical model of several externally-driven harmonic oscillators, generally with non-zero damping. For a single oscillator, driven by electric field’s force \( F(t) = qE(t) \), we can write the 2nd Newton law as
\[
m\dddot{x} + 2\delta_0\ddot{x} + \omega_0^2 x = qE(t),
\]
where \( \omega_0 \) is the own frequency of the oscillator, and \( \delta_0 \) its damping coefficient. For the electric field of a monochromatic wave, \( E(t) = \text{Re} [E_0\exp\{-i\omega t\}] \), we may look for a particular, forced-oscillation solution of this equation in a similar form \( x(t) = \text{Re} [x_0\exp\{-i\omega t\}] \). Plugging this solution into Eq. (30), we can readily find the complex amplitude of these oscillations:
\[
x_\omega = \frac{q}{m} \frac{E_0}{(\omega_0^2 - \omega^2) + 2i\omega\delta_0}.
\]
Using this result to calculate the complex amplitude of the dipole moment as \( p_\omega = qx_\omega \) and then the electric polarization \( P_\omega = np_\omega \) of a dilute medium with \( n \) independent oscillators for unit volume, for its frequency-dependent permittivity (26) we get
\[
\varepsilon(\omega) = \varepsilon_0 + n\frac{q^2}{m} \frac{1}{(\omega_0^2 - \omega^2) + 2i\omega\delta_0}.
\]
This result may be readily generalized to the case when the system has several types of oscillators with different own frequencies:
\[
\varepsilon(\omega) = \varepsilon_0 + n\frac{q^2}{m} \sum_j \frac{f_j}{(\omega_j^2 - \omega^2) + 2i\omega\delta_j},
\]
where \( f_j = n_j/n \) is the fraction of oscillators with eigenfrequency \( \omega_j \), so that the sum of all \( f_j \) equals 1. Figure 5 shows a typical behavior of the real and imaginary parts of the complex dielectric constant, described by Eq. (33), as functions of frequency. The oscillator resonances’ effect is clearly visible, and dominates the media response at \( \omega \approx \omega_j \), especially in the case of low damping, \( \delta_j \ll \omega_j \). Note that in the low-damping limit, the imaginary part of the dielectric constant \( \varepsilon'' \), and hence the wave attenuation \( k'' \), are negligibly small at all frequencies besides small vicinities of frequencies \( \omega_j \), where derivative

are discussed in more detail in the quantum-mechanics part of this series (QM Sec. 2.2), because they are the crucial factor of Schrödinger’s wave mechanics. (See also a brief discussion in CM Sec. 6.3.)

12 This example is focused on the frequency dependence of \( \varepsilon \) rather than \( \mu \), because electromagnetic waves interact with “usual” media via their electric field much more than via the magnetic field. Indeed, according to Eq. (7), the magnetic field of the wave is of the order of \( E/c \), so that the magnetic component of the Lorentz force (5.10), acting on a nonrelativistic particle, \( F_m \sim quB \sim (u/c)qE \), is much smaller than that of its electric component, \( F_e = qE \), and may be neglected. However, as will be discussed in Sec. 6, forgetting about the possible dispersion of \( \mu(\omega) \) may result in missing some remarkable opportunities for manipulating the waves.

13 If this point is not absolutely clear, please see CM Sec. 5.1 for a more detailed discussion.
\(d\varepsilon'(\omega)/d\omega\) is negative.\(^{14}\) Thus, for a system of for weakly-damped oscillators, Eq. (33) may be well approximated by a sum of singularities ("poles"):

\[
\varepsilon(\omega) \approx \varepsilon_0 + n \frac{q^2}{2m} \sum_j \frac{f_j}{\omega_j (\omega - \omega_j)}, \quad \text{for } \delta_j \ll |\omega - \omega_j| \ll |\omega_j - \omega|.
\]

(7.34)

This result is especially important because, according to quantum mechanics,\(^{15}\) Eq. (34) is also valid for a set of non-interacting, similar quantum systems (whose dynamics may be completely different from that of a harmonic oscillator!), provided that \(\omega_j\) are replaced with frequencies of possible quantum interstate transitions, and coefficients \(f_j\) are replaced with the so-called oscillator strengths of the transitions – which obey the same sum rule, \(\Sigma f_j = 1\).

At \(\omega \to 0\), the imaginary part of the permittivity (33), generalized to the case of different masses of the oscillators, also vanishes (for any \(\delta_j\)), while its real part approaches its electrostatic ("dc") value

\[
\varepsilon(0) = \varepsilon_0 + \frac{q^2}{2m} \sum_j \frac{n_j}{m_j \omega_j^2}.
\]

(7.35)

Note that according to Eq. (30), the denominator in Eq. (35) is just the effective spring constant \(\kappa_j = m_j \omega_j^2\) of the \(j\)th oscillator, so that the oscillator masses \(m_j\) as such are actually (and quite naturally) not involved in the static dielectric response.

In the opposite limit of very high frequencies, \(\omega \gg \omega_j, \delta_j\), the permittivity also becomes real, and may be represented as

\[
\varepsilon(\omega) = \varepsilon_0 \left(1 - \frac{\omega^2_0}{\omega^2}\right), \quad \text{where } \omega^2_0 \equiv \frac{q^2}{\varepsilon_0} \sum_j \frac{n_j}{m_j}.
\]

(7.36)

This result is very important, because it is also valid at all frequencies if all \(\omega_j\) and \(\delta_j\) vanish, i.e. for a gas of free charged particles, in particular for plasmas – ionized atomic gases, provided that the ion

\(^{14}\) In optics, such behavior is called the anomalous dispersion.

\(^{15}\) See, e.g., QM Chapters 5-6.
collision effects are negligible. (This is why the parameter \( \omega_p \) defined by Eq. (36) is called the *plasma frequency*. Typically, the plasma as a whole is neutral, i.e. the density \( n \) of positive atomic ions is equal to that of the free electrons. Since the ratio \( n_j/m_j \) for electrons is much higher than that for ions, the general formula (36) for the plasma frequency is usually well approximated by the following simple expression:

\[
\omega_p^2 = \frac{ne^2}{\varepsilon_0 m_e}.
\]  

(7.37)

This expression has a simple physical sense: the effective spring constant \( \kappa_{ef} = m_e \omega_p^2 = ne^2/\varepsilon_0 \) describes the Coulomb force that appears when the electron subsystem of plasma is shifted, as a whole, from its positive-ion subsystem, thus violating the electroneutrality. (Indeed, let us consider such a small shift, \( \Delta x \), perpendicular to the plane surface of a broad, plane slab filled with plasma. The uncompensated ion charges, with equal and opposite surface densities \( \sigma = \pm e n \Delta x \), that appear at the slab surfaces, create inside it, according to Eq. (2.3), a uniform electric field with \( E_x = e n \Delta x/\varepsilon_0 \). This field exerts force \(-e E = -(ne^2/\varepsilon_0)\Delta x = -\kappa_{ef} \Delta x \) on each electron, pulling it back to its equilibrium position.) Hence, there is no surprise that the function \( \varepsilon(\omega) \) given by Eq. (36) vanishes at \( \omega = \omega_p \): at this resonance frequency, the polarization electric field \( E \) may oscillate, i.e. have a non-zero amplitude \( E_\omega = D_\omega/\varepsilon(\omega) \), even in the absence of external forces induced by external (stand-alone) charges, i.e. in the absence of the field \( D \) these charges induce – see Eq. (3.32).

The behavior of electromagnetic waves in a medium that obeys Eq. (36), is very remarkable. If the wave frequency \( \omega \) is above \( \omega_p \), the dielectric constant \( \varepsilon(\omega) \), and hence the wave number (28) are positive and real, and waves propagate without attenuation, following the dispersion relation,

\[
k(\omega) = \omega [\varepsilon(\omega) \mu_0]^{1/2} = \frac{1}{c} \left( \omega^2 - \omega_p^2 \right)^{1/2},
\]

(7.38)

which is shown in Fig. 6.

At \( \omega \to \omega_p \) the wave number \( k \) tends to zero. Beyond that point (i.e. at \( \omega < \omega_p \)), we still can use Eq. (38), but it is instrumental to rewrite it in the mathematically equivalent form

\[
k(\omega) = \frac{i}{c} \left( \omega_p^2 - \omega^2 \right)^{1/2} = \frac{i}{\delta}, \quad \text{where} \quad \delta \equiv \frac{c}{\left( \omega_p^2 - \omega^2 \right)^{1/2}}.
\]  

(7.39)

According to Eq. (29), this means that the electromagnetic field exponentially decreases with distance:
\[ f = \text{Re} f_\omega e^{i(kz-\omega t)} = \exp\left(-\frac{z}{\delta}\right) \text{Re} f_\omega e^{-i\omega t}. \quad (7.40) \]

Does this mean that the wave is being absorbed in the plasma? Answering this question is a good pretext to calculate the time average of the Poynting vector \( \mathbf{S} = \mathbf{E} \times \mathbf{H} \) of a monochromatic electromagnetic wave in an arbitrary dispersive (but still linear!) medium. First, let us spell out the real fields’ time dependences:

\[ E(t) = \text{Re}\left[ E_\omega e^{-i\omega t} \right] = \frac{1}{2} \left[ E_\omega e^{-i\omega t} + \text{c.c.} \right], \quad H(t) = \text{Re}\left[ H_\omega e^{-i\omega t} \right] = \frac{1}{2} \left[ \frac{E_\omega}{Z(\omega)} e^{-i\omega t} + \text{c.c.} \right]. \quad (7.41) \]

Now, a straightforward calculation yields\(^{16}\)

\[ \bar{S} = \frac{E(t)H(t)}{4} = \frac{E_\omega E^*_\omega}{2} \text{Re} \frac{1}{Z(\omega)} = \frac{|E_\omega|^2}{2} \text{Re} \left[ \frac{\varepsilon(\omega)}{\mu(\omega)} \right]^{1/2}. \quad (7.42) \]

Let us apply this important general formula to our simple model of plasma at \( \omega < \omega_p \). In this case, the magnetic permeability equals \( \mu_0 \), i.e. \( \mu(\omega) = \mu_0 \) is positive and real, while \( \varepsilon(\omega) \) is real and negative, so that \( 1/Z(\omega) = [\varepsilon(\omega)/\mu(\omega)]^{1/2} \) is purely imaginary, and the average Poynting vector (42) vanishes. This means that the energy, on the average, does not flow along axis \( z \). However, this does not mean that the waves with \( \omega < \omega_p \) are absorbed in plasma. (Indeed, the Lorentz model with \( \delta_j = 0 \) does not describe any energy dissipation mechanism.) Instead, as we will see in the next section, the waves are rather reflected from plasma’s boundary.

Note also that in the limit \( \omega \ll \omega_p \), Eq. (39) yields

\[ \delta \to \frac{c}{\omega_p} = \left( \frac{c^2 \varepsilon_0 m_e}{n e^2} \right)^{1/2} = \left( \frac{m_e}{\mu_0 n e^2} \right)^{1/2}. \quad (7.43) \]

But this is just a particular case (for \( q = e \), \( m = m_e \), and \( \mu = \mu_0 \) of the expression (6.44), which was derived in Sec. 6.4 for the depth of the magnetic field’s penetration into a lossless (collision-free) conductor in the quasistatic approximation. This fact shows again that, as was already discussed in Sec. 6.7, this approximation (in which the displacement currents are neglected) gives an adequate description of the time-dependent phenomena at \( \omega \ll \omega_p \), i.e. at \( \delta \ll c/\omega = 1/k = \lambda/2\pi \).\(^{17}\)

---

\(^{16}\) For an arbitrary plane wave the total average power flow may be calculated as an integral of Eq. (42) over all frequencies. By the way, combining this integral and the Poynting theorem (6.111), it is straightforward to prove the following interesting expression for the average electromagnetic energy density of a narrow \( (\Delta \omega \ll \omega) \) wave packet propagating in an arbitrary dispersive (but linear and isotropic) medium:

\[ \bar{u} = \frac{1}{\Delta \omega} \int \left\{ \frac{d}{d\omega} \varepsilon(\omega) E_\omega E^*_\omega + \frac{d}{d\omega} \mu(\omega) H_\omega H^*_\omega \right\} d\omega. \]

\(^{17}\) One more convenience of the simple model of a collision-free plasma, which has led us to Eq. (36), is that it may be readily generalized to the case of an additional strong dc magnetic field \( B_0 \) (much higher than that of the wave) applied in the direction \( \mathbf{n} \) of wave propagation. It is straightforward (and hence left for the reader) to show that such plasma exhibits the Faraday effect of the polarization plane’s rotation, and hence gives an example of an anisotropic medium that violates the Lorentz reciprocity relation (6.121).
There are two most important examples of plasmas. For the Earth’s ionosphere, i.e. the upper part of its atmosphere, which is almost completely ionized by the ultra-violet and X-ray components of the Sun’s radiation, the maximum value of \( n \), reached at about 300 km over the Earth surface, is between \( 10^{10} \) and \( 10^{12} \) m\(^{-3}\) (depending on the time of the day and the Sun’s activity phase), so that that the maximum plasma frequency (37) is between 1 and 10 MHz. This is much higher than the particles’ typical reciprocal collision time \( \tau \), so that the first of Eqs. (36) gives a good description of plasma’s electric polarization. The effect of reflection of waves with \( \omega < \omega_p \) from the ionosphere enables the long-range (over-the-globe) radio communications and broadcasting at the so-called *short waves*, with cyclic frequencies of the order of 10 MHz: \(^{18}\) they may propagate in the flat channel formed by the Earth surface and the ionosphere, being reflected repeatedly by these parallel “walls”. Unfortunately, due to the random variations of Sun’s activity, and hence of \( \omega_p \), such natural communication channel is not too reliable, and in our age of trans-world optical fiber cables, its practical importance has diminished.

Another important example of plasmas is free electrons in metals and other conductors. For a typical metal, \( n \) is of the order of \( 10^{23} \) cm\(^{-3}\) \( \equiv 10^{29} \) m\(^{-3}\), so that Eq. (37) yields \( \omega_p \sim 10^{16} \) s\(^{-1}\). Note that this value of \( \omega_p \) is somewhat higher than the mid-optical frequencies (\( \omega \sim 3 \times 10^{15} \) s\(^{-1}\)). This explains why planar, clean metallic surfaces, such as aluminum and silver films used in mirrors, are so shiny: at these frequencies their complex permittivity \( \varepsilon(\omega) \) is almost exactly real and negative, leading to light reflection, with very little absorption.

The simple model (36), which neglects electron scattering, becomes inadequate at lower frequencies, \( \omega \tau \sim 1 \). A good phenomenological way of extending the model to the account of scattering is to take, in Eq. (33), the lowest frequency \( \omega_j \) to be equal zero (to describe the free electrons), while keeping the damping coefficient \( \delta_0 \) of this mode non-vanishing, to account for their energy loss due to scattering. Then Eq. (33) is reduced to

\[
\varepsilon_{ef}(\omega) = \varepsilon_{opt}(\omega) + \frac{n_0 q^2}{m} \frac{1}{\omega^2 - 2 i \omega \delta_0} \equiv \varepsilon_{opt}(\omega) + i \frac{n_0 q^2}{2 \delta_0 m \omega} \frac{1}{1 - i \omega / 2 \delta_0},
\]

(7.44)

where the response \( \varepsilon_{opt}(\omega) \) at high (in practice, optical) frequencies is still given by Eq. (33), but now with \( j > 0 \). The result (44) allows for a simple interpretation. To show that, let us incorporate into our calculations the Ohmic conduction of the medium, generalizing Eq. (4.7) as \( j_\omega = \sigma(\omega) E_\omega \) to account for the possible frequency dependence of the Ohmic conductivity. Plugging this relation into the Fourier image of the relevant macroscopic Maxwell equation, \( \nabla \times H_\omega = j_\omega - i \omega D_\omega \equiv j_\omega - i \omega \varepsilon(\omega) E_\omega \), we get

\[
\nabla \times H_\omega = [\sigma(\omega) - i \omega \varepsilon(\omega)]E_\omega.
\]

(7.45)

This relation shows that for a sinusoidal process, the addition of the Ohmic current density \( j_\omega \) to the displacement current density is equivalent to the addition of \( \sigma(\omega) \) to \(- i \omega \varepsilon(\omega)\), i.e. to the following change of the ac electric permittivity: \(^{19}\)

\[
\varepsilon(\omega) \rightarrow \varepsilon_{ef}(\omega) \equiv \varepsilon_{opt}(\omega) + i \frac{\sigma(\omega)}{\omega}.
\]

(7.46)

\(^{18}\) These frequencies are an order of magnitude lower than those used for TV and FM-radio broadcasting.

\(^{19}\) Alternatively, according to Eq. (45), it is possible (and in the field of infrared spectroscopy, conventional) to attribute the ac response of a medium at *all* frequencies to its effective complex conductivity: \( \sigma_{ef}(\omega) \equiv \sigma(\omega) - i \omega \varepsilon_{ef}(\omega) \).
Now the comparison of Eqs. (44) and (46) shows that they coincide if we take

\[
\sigma(\omega) = \frac{n_0q^2\tau}{m_0} \frac{1}{1-i\omega\tau} \equiv \sigma(0) \frac{1}{1-i\omega\tau},
\]

where the dc conductivity \(\sigma(0)\) is described by the Drude formula (4.13), and the phenomenologically introduced coefficient \(\delta_0\) is associated with \(1/2\tau\). Eq. (47), which is frequently called the generalized (or “ac”, or “rf”) Drude formula,\(^\text{20}\) gives a very reasonable (semi-quantitative) description of the ac conductivity of many metals almost all the way up to optical frequencies.

Now returning to our discussion of the generalized Lorentz model (33), we see that the frequency dependences of the real \((\varepsilon')\) and imaginary \((\varepsilon'')\) parts of the complex permittivity it yields are not quite independent. For example, let us have one more look at the resonance peaks in Fig. 5. Each time the real part drops with frequency, \(d\varepsilon'/d\omega < 0\), its imaginary part \(\varepsilon''\) has a positive peak. Ralph Kronig (in 1926) and Hendrik (“Hans”) Kramers (in 1927) independently showed that this is not an occasional coincidence pertinent only to this particular model. Moreover, the full knowledge of the function \(\varepsilon'(\omega)\) enables the calculation of the function \(\varepsilon''(\omega)\), and vice versa. The mathematical reason for this fact is that both these functions are always related to a single real function \(G(\theta)\) by Eqs. (28).

To derive the Kramers-Kronig relations, let us consider Eq. (26b) on the complex frequency plane, \(\omega \rightarrow \omega = \omega' + i\omega''\):

\[
f(\omega) = \varepsilon(\omega) - \varepsilon_0 = \int_0^\infty G(\theta)e^{i\omega'\theta}d\theta = \int_0^\infty G(\theta)e^{i\omega'\theta} e^{-\omega''\theta}d\theta.
\]

For all stable physical systems, \(G(\theta)\) has to be finite for all important values of the real integration variable \((\theta > 0)\), and tend to zero at \(\theta \rightarrow 0\) and \(\theta \rightarrow \infty\). (Indeed, according to Eq. (23), a non-vanishing \(G(0)\) would mean an instantaneous response of the medium to the external force, while \(G(\infty) \neq 0\) would mean that is has an infinitely long memory.) Because of that, and thanks to factor \(e^{-\omega''\theta}\), the expression under the integral in Eq. (48) tends to zero at \(|\omega| \rightarrow \infty\) in all upper half-plane \((\omega'' \geq 0)\). As a result, we may claim that the complex function \(f(\omega)\), given by this relation, is analytical in that half-plane. This fact allows us to apply to it the general Cauchy integral formula\(^\text{21}\)

\[
f(\omega) = \frac{1}{2\pi i} \oint_C f(\Omega) \frac{d\Omega}{\Omega - \omega},
\]

where \(\Omega \equiv \Omega' + i\Omega''\) is also a complex variable. Let us take the integration contour \(C\) of the form shown in Fig. 7, with the radius \(R\) of the larger semicircle tending to infinity, and the radius \(r\) of the smaller semicircle (around the singular point \(\Omega = \omega\)) tending to zero. Due to the exponential decay of \(|f(\Omega)|\) at \(|\Omega| \rightarrow \infty\), the contribution to the right-hand side of Eq. (49) from the larger semicircle vanishes,\(^\text{22}\) while the contribution from the small semicircle, where \(\Omega = \omega + r\exp\{i\varphi\}\), with \(-\pi \leq \varphi \leq 0\), is

---

\(^{20}\) It may be also derived from the Boltzmann kinetic equation in the so-called relaxation-time approximation (RTA) – see, e.g., SM Sec. 6.2.

\(^{21}\) See, e.g., MA Eq. (15.2).

\(^{22}\) Strictly speaking, this also requires \(|f(\Omega)|\) to decrease faster than \(\Omega^{-1}\) at the real axis (at \(\Omega'' = 0\)), but due to the inertia of charged particles, this requirement is fulfilled for all realistic models of dispersion – see, e.g., Eq. (36).
\[ \lim_{r \to 0} \frac{1}{2\pi i} \int_{\Omega = \omega + r} \exp \{ i \varphi \} \frac{d\Omega}{\Omega - \omega} = \frac{f(\omega)}{2\pi} \int_{-\pi}^{0} \frac{\exp \{ i \varphi \} d\varphi}{\pi r \exp \{ i \varphi \}} \equiv \frac{f(\omega)}{2} \left( -\int_{-\pi}^{0} d\varphi \right). \quad (7.50) \]

As a result, for our contour \( C \), Eq. (49) yields

\[ f(\omega) = \lim_{r \to 0} \frac{1}{2\pi i} \int_{-\infty}^{\omega-r} + \int_{\omega+r}^{+\infty} \frac{f(\Omega) d\Omega}{\Omega - \omega} \frac{1}{2} f(\omega). \quad (7.51) \]

where \( \Omega \equiv \Omega' \) on the real axis (where \( \Omega'' = 0 \)). Such an integral, excluding a symmetric infinitesimal vicinity of a pole singularity, is called the principal value of the (formally, diverging) integral from \(-\infty\) to \(+\infty\), and is denoted by letter P before it. Using this notation, subtracting \( f(\omega)/2 \) from both parts of Eq. (51), and multiplying them by 2, we get

\[ f(\omega) = \frac{1}{\pi i} P \int_{-\infty}^{+\infty} f(\Omega) \frac{d\Omega}{\Omega - \omega}. \quad (7.52) \]

Now plugging into this complex equality the polarization-related difference \( f(\omega) \equiv \varepsilon(\omega) - \varepsilon_0 \) in the form \( [\varepsilon'(\omega) - \varepsilon_0] + i[\varepsilon''(\omega)] \), and requiring both real and imaginary components of two sides of Eq. (52) to be equal separately, we get the famous Kramers-Kronig dispersion relations

\[ \varepsilon'(\omega) = \varepsilon_0 + \frac{1}{\pi} P \int_{-\infty}^{+\infty} \frac{d\Omega}{\Omega - \omega}, \quad \varepsilon''(\omega) = -\frac{1}{\pi} P \int_{-\infty}^{+\infty} \left[ \varepsilon'(\Omega) - \varepsilon_0 \right] \frac{d\Omega}{\Omega - \omega}. \quad (7.53) \]

We may use the already mentioned fact that \( \varepsilon'(\omega) \) is always an even function, while \( \varepsilon''(\omega) \) an odd function of frequency, to rewrite these relations in the following equivalent form,

\[ \varepsilon'(\omega) = \varepsilon_0 + \frac{2}{\pi} P \int_{0}^{+\infty} \frac{\Omega d\Omega}{\Omega^2 - \omega^2}, \quad \varepsilon''(\omega) = -\frac{2\omega}{\pi} P \int_{0}^{+\infty} \left[ \varepsilon'(\Omega) - \varepsilon_0 \right] \frac{d\Omega}{\Omega^2 - \omega^2}, \quad (7.54) \]

which is more convenient for most applications, because it involves only physical (positive) frequencies.

Though the Kramers-Kronig relations are “global” in frequency, in certain cases they allow an approximate calculation of dispersion from experimental data for absorption, collected even in a limited

---

23 I am typesetting this symbol in a Roman (upright) font, to avoid any possibility of its confusion with the medium’s polarization.
(“local”) frequency range. Most importantly, if a medium has a sharp absorption peak at some frequency \( \omega_j \), we may describe it as

\[
\varepsilon''(\omega) \approx c \delta(\omega - \omega_j) + \text{a more smooth function of } \omega , \tag{7.55}
\]

and the first of Eqs. (54) immediately gives

\[
\varepsilon'(\omega) \approx \varepsilon_0 + \frac{2c}{\pi} \frac{\omega_j}{\omega_j^2 - \omega^2} + \text{another smooth function of } \omega , \tag{7.56}
\]

thus predicting the anomalous dispersion near such a point. This calculation shows that such behavior observed in the Lorentz oscillator model (see Fig. 5) is by no means occasional or model-specific.

Let me emphasize again that the Kramers-Kronig relations (53)-(54) are much more general than the Lorentz model (33), depending only on the causal, linear relation (21) between the polarization \( P(t) \) with the electric field \( E(t') \). Hence, these relations are also valid for the complex functions relating Fourier images of any cause/effect-related pair of variables. In particular, at a measurement of any linear response \( r(t) \) of any experimental sample to any external applied field \( f(t') \), whatever the nature of this response and physics behind it, we may be confident that there is a causal relation between the variables \( r \) and \( f \), so that the corresponding complex function \( \chi(\omega) \equiv r_\omega / f_\omega \) does obey the Kramers-Kronig relations. However, it is still important to remember that a linear relation between the Fourier amplitudes of two variables does not necessarily imply a causal relationship between them.

7.3. Reflection

The most important new effect arising in nonuniform media is wave reflection. Let us start its discussion from the simplest case of a plane electromagnetic wave that is normally incident on a sharp interface between two uniform, linear, isotropic media.

As the simplest example, let us assume that one of the two media (say, located at \( z > 0 \), see Fig. 8) cannot sustain any electric field at all:

\[
E\bigg|_{z>0} = 0 . \tag{7.57}
\]

This condition is evidently incompatible with the single traveling wave (5). However, this solution may be readily corrected using the fact that the dispersion-free 1D wave equation,

\[
\left( \frac{\partial^2}{\partial z^2} - \frac{1}{v^2} \frac{\partial^2}{\partial t^2} \right) E = 0 , \tag{7.58}
\]

24 Actually, in mathematics, the relations even somewhat more general than Eqs. (53), valid for an arbitrary analytic function of complex argument, are known at least from 1868 (the Sokhotski-Plemelj theorem).

25 For example, the function \( \phi(\omega) \equiv E_\omega / P_\omega \), in the Lorentz oscillator model, does not obey the Kramers-Kronig relations. This is evident not only physically, from the fact that \( E(t) \) is not a causal function of \( P(t) \), but even mathematically. Indeed, the Green’s function describing a causal relationship has to tend to zero at small time delays \( \theta \equiv t - t' \), so that its Fourier image has to tend to zero at \( \omega \to \pm \infty \). This is certainly true for the function \( f(\omega) \) given by Eq. (32), but not for the reciprocal function \( \phi(\omega) \equiv 1 / f(\omega) \propto (\omega^2 - \omega_0^2) - 2i\omega_0 \), which diverges at large frequencies.

26 Such equality is given, in particular, by the macroscopic model of a good conductor – see Eq. (2.1).
supports waves propagating, with the same speed, in opposite directions. As a result, the following linear superposition of two such waves,

$$E|_{z<0} = f(z - vt) - f(-z - vt), \quad (7.59)$$

satisfies both the equation and the boundary condition (57), for an arbitrary function $f$. The second term in Eq. (59) may be interpreted as a result of total reflection of the incident wave (described by its first term) – in this particular case, with the change of the electric field’s sign. This means, in particular, that within the macroscopic model, a conductor acts as a perfect mirror. By the way, since the vector $n$ of the reflected wave is opposite to that incident one (see the arrows in Fig. 8), Eq. (6) shows that the magnetic field of the wave does not change its sign at the reflection:

$$H|_{z<0} = \frac{1}{Z} [f(z - vt) + f(-z - vt)]. \quad (7.60)$$

The blue lines in Fig. 8 show the resulting pattern (59) for the simplest, monochromatic wave:

$$E|_{z<0} = \text{Re} \left[ E_0 e^{i(kz - \omega t)} - E_0 e^{i(-kz - \omega t)} \right]. \quad (7.61a)$$

Depending on convenience in a particular context, this pattern may be legitimately represented and interpreted either as the linear superposition (61a) of two traveling waves, or as a single standing wave:

$$E|_{z<0} = -2 \text{Im} \left( E_0 e^{-i\omega t} \right) \sin kz \equiv 2 \text{Re} \left( i E_0 e^{-i\omega t} \right) \sin kz \equiv 2 \text{Re} \left[ E_0 e^{-i(\omega t - \pi/2)} \right] \sin kz, \quad (7.61b)$$

in which the electric and magnetic field oscillate with the phase shifts by $\pi/2$ both in time and space:

$$H|_{z<0} = \text{Re} \left[ \frac{E_0}{Z} e^{ikz-\omega t} + \frac{E_0}{Z} e^{-ikz-\omega t} \right] \equiv 2 \text{Re} \left( \frac{E_0}{Z} e^{-i\omega t} \right) \cos kz. \quad (7.62)$$

As a result of this shift, the time average of the Poynting vector’s magnitude,

$$S(z,t) = EH = \frac{1}{Z} \text{Re} \left[ E_0^2 e^{-2i\omega t} \right] \sin 2kz, \quad (7.63)$$

equals zero, showing that at the total reflection there is no average power flow. (This is natural, because the perfect mirror can neither transmit the wave nor absorb it.) However, Eq. (63) shows that the
Standing wave provides local oscillations of energy, transferring it periodically between the concentrations of the electric and magnetic fields, separated by the distance \( \Delta z = \pi/2k = \lambda/4 \).

In the case of the sinusoidal waves, the reflection effects may be readily explored even for the more general case of dispersive and/or lossy (but still linear) media in which \( \varepsilon(\omega) \) and \( \mu(\omega) \), and hence the wave vector \( k(\omega) \) and the wave impedance \( Z(\omega) \), defined by Eqs. (28), are certain complex functions of frequency. The “only” new factors we have to account for is that in this case, the reflection may not be total, and that inside the second media we have to use the traveling-wave solution as well. Both these factors may be taken care of by looking for the solution of our boundary problem in the form

\[
E|_{z=0} = \text{Re} \left[ E_\omega \left( e^{ikz} + R e^{-ikz} \right) e^{-i\omega t} \right], \quad E|_{z>0} = \text{Re} \left[ E_\omega T e^{ikz} e^{-i\omega t} \right].
\]

(7.64)

and hence, according to Eq. (6),

\[
H|_{z=0} = \text{Re} \left[ \frac{E_\omega}{Z(\omega)} \left( e^{ikz} - Re^{-ikz} \right) e^{-i\omega t} \right], \quad H|_{z>0} = \text{Re} \left[ \frac{E_\omega}{Z_+(\omega)} T e^{ikz} e^{-i\omega t} \right].
\]

(7.65)

(The indices + and – correspond to, respectively, the media at \( z > 0 \) and \( z < 0 \).) Please note the following important features of these relations:

(i) Due to the problem linearity, we could (and did :-) take the complex amplitudes of the reflected and transmitted wave proportional to that \( (E_\omega) \) of the incident wave, scaling them with dimensionless, generally complex coefficients \( R \) and \( T \). As the comparison of Eqs. (64)-(65) with Eqs. (61)-(62) shows, the total reflection from an ideal mirror, which was discussed above, corresponds to the particular case \( R = -1 \) and \( T = 0 \).

(ii) Since the incident wave we are considering, arrives from one side only (from \( z = -\infty \)), there is no need to include a term proportional to \( \exp\{-ikz\} \) into Eqs. (64)-(65) – in our current problem. However, we would need such a term if the medium at \( z > 0 \) had been non-uniform (e.g., had at least one more interface or any other inhomogeneity), because the wave reflected from that additional inhomogeneity would be incident on our interface (located at \( z = 0 \)) from the right.

(iii) The solution (64)-(65) is sufficient even for the description of the cases when waves cannot propagate at \( z \geq 0 \), for example a conductor or a plasma with \( \omega_p > \omega \). Indeed, the exponential drop of the field amplitude at \( z > 0 \) in such cases is automatically described by the imaginary part of the wave number \( k_+ \) – see Eq. (29).

In order to calculate the coefficients \( R \) and \( T \), we need to use boundary conditions at \( z = 0 \). Since the reflection does not change the transverse character of the partial waves, at the normal incidence both vectors \( E \) and \( H \) remain tangential to the interface plane (in our notation, \( z = 0 \)). Reviewing the arguments that have led us, in statics, to the boundary conditions (3.37) and (5.117) for these components, we see that they remain valid for the time-dependent situation as well,\(^{27}\) so that for our current case of normal incidence we may write:

\(^{27}\) For example, the first of conditions (66) may be obtained by integrating the full (time-dependent) Maxwell equation \( \nabla \times E + \partial B/\partial t = 0 \) over a narrow and long rectangular contour with dimensions \( l \) and \( d \) \( (d \ll l) \) stretched along the interface. In the Stokes theorem, the first term gives \( \Delta E \cdot l \), while the contribution of the second term is proportional to product \( dl \) and vanishes as \( d/l \rightarrow 0 \). The proof of the second boundary condition is similar – as was already discussed in Sec. 6.2.
\[ E|_{z=0} = E|_{z=t}, \quad H|_{z=0} = H|_{z=t}. \quad (7.66) \]

Plugging Eqs. (64)-(65) into these conditions, we readily get two equations for the coefficients \( R \) and \( T \):
\[ 1 + R = T, \quad \frac{1}{Z_-} (1 - R) = \frac{1}{Z_+} T. \quad (7.67) \]

Solving this simple system of linear equations, we get\(^{28}\)
\[ R = \frac{Z_+ - Z_-}{Z_+ + Z_-}, \quad T = \frac{2Z_+}{Z_+ + Z_-}. \quad (7.68) \]

These formulas are very important, and much more general than one might think, because they are applicable for virtually any 1D waves – electromagnetic or not, if only the impedance \( Z \) is defined properly.\(^{29}\) Since in the general case the wave impedances \( Z_z \), defined by Eq. (28) with the corresponding indices, are complex functions of frequency, Eqs. (68) show that \( R \) and \( T \) may have imaginary parts as well. This fact has important consequences at \( z < 0 \), where the reflected wave, proportional to \( R \), mixes (“interferes”) with the incident wave. Indeed, with \( R = |R| e^{i\phi} \) (where \( \phi \equiv \arg R \) is a real phase shift), the expression in the parentheses in the first of Eqs. (64) becomes
\[ e^{ikz} + RE^{-ikz} = (1 - |R| + |R|)e^{ikz} + |R|e^{i\phi} e^{-ikz} \]
\[ = (1 - |R|)e^{ikz} + 2|R|e^{i\phi/2} \sin[k_-(z - \delta_-)], \quad \text{where} \ \delta_- \equiv \frac{\phi - \pi}{2k_-}. \quad (7.69) \]

This means that the field may be represented as a sum of a traveling wave and a standing wave, with an amplitude proportional to \( |R| \), shifted by distance \( \delta_- \) toward the interface, relatively to the ideal-mirror pattern (61b) – see Fig. 8. This effect is frequently used for the experimental measurements of an unknown impedance \( Z_z \) of some medium, provided than \( Z_- \) is known (e.g., for the free space, \( Z_0 \)). For that, a small antenna (the probe), not disturbing the fields’ distribution too much, is placed into the wave field, and the amplitude of the ac voltage induced in it by the wave in the probe is measured by a detector (e.g., a semiconductor diode with a nearly-quadratic \( I-V \) curve), as a function of \( z \) (Fig. 9). From the results of such a measurement, it is straightforward to find both \( |R| \) and \( \delta_- \), and hence restore the complex \( R \), and then use Eq. (67) to calculate both the modulus and the argument of \( Z_+ \). (Before the advent of computers, a specially lined paper, called the Smith chart, was commercially available for performing this recalculation graphically; it is occasionally used even nowadays for result presentation.)

\[ V \propto \overline{E^2(z,t)} \]

![Fig. 7.9. Measurement of the complex impedance of a medium (schematically).](image)

\(^{28}\) Please note that only the media impedances (rather than wave velocities) are important for the reflection in this case! Unfortunately, this fact is not clearly emphasized in some textbooks that discuss only the case \( \mu_0 = \mu_0 \), when \( Z = (\mu_0/\varepsilon)^{1/2} \) and \( v = 1/(\mu_0\varepsilon)^{1/2} \) are proportional to each other.

\(^{29}\) See, e.g., the discussion of elastic waves of mechanical deformation in CM Secs. 6.3, 6.4, 7.7, and 7.8.
Now let us discuss what do these results give for waves incident from the free space \((Z_c(\omega) = Z_0 = \text{const}, k = k_0 = \omega/c)\) onto the surfaces of two particular, important media.

(i) For a collision-free plasma (with negligible magnetization) we may use Eq. (36) with \(\mu(\omega) = \mu_0\), to represent the impedance in either of two equivalent forms:

\[
Z_+ = Z_0 \frac{\omega}{(\omega^2 - \omega_p^2)^{1/2}} = -iZ_0 \frac{\omega}{(\omega_p^2 - \omega^2)^{1/2}}.
\]  

(7.70)

The former of these forms is more convenient in the case \(\omega > \omega_p\), when the wave vector \(k_+\) and the wave impedance \(Z_+\) of plasma are real, so that a part of the incident wave does propagate into the plasma. Plugging this expression into the latter of Eqs. (68), we see that \(T\) is real:

\[
T = \frac{2\omega}{\omega + (\omega^2 - \omega_p^2)^{1/2}}. 
\]  

(7.71)

Note that according to this formula, and somewhat counter-intuitively, \(T > 1\) for any frequency (above \(\omega_p\)). How can the transmitted wave be more intensive than the incident one that has induced it? For a better understanding of this result, let us compare the powers (rather than the electric field amplitudes) of these two waves, i.e. their average Poynting vectors (42):

\[
\frac{\mathcal{S}}{2Z_0} = \frac{|E_\omega|^2}{2Z_0}, \quad \frac{\mathcal{S}_+}{2Z_+} = \frac{|TE_\omega|^2}{2Z_+} = \frac{|E_\omega|^2}{2Z_+} \frac{4\omega(\omega^2 - \omega_p^2)^{1/2}}{\omega + (\omega^2 - \omega_p^2)^{1/2}}.
\]  

(7.72)

It is easy to check that the ratio of these two values\(^{30}\) is always below 1 (and tends to zero at \(\omega \to \omega_p\)), so that only a fraction of the incident wave power may be transmitted. Hence the result \(T > 1\) may be interpreted as follows: the interface between two media also works as an impedance transformer: though it can never transmit more power than the incident wave provides, i.e. can only decrease the product \(S = EH\), but since the ratio \(Z = E/H\) changes at the interface, the amplitude of one of the fields may increase at the transmission.

Now let us proceed to case \(\omega < \omega_p\), when the waves cannot propagate in the plasma. In this case, the last of the expressions (70) is more convenient, because it immediately shows that \(Z_+\) is purely imaginary, while \(Z_0\) is purely real. This means that \((Z_+ - Z_0) = (Z_+ + Z_0)^*\), i.e. according to the first of Eqs. (68), \(|R| = 1\), so that the reflection is total, i.e. no incident power (on the average) is transferred into the plasma – as was already discussed in Sec. 2. However, the complex \(R\) has a finite argument,

\[
\varphi \equiv \arg R = 2 \arg(Z_+ - Z_0) = -2 \tan^{-1} \frac{\omega}{(\omega_p^2 - \omega^2)^{1/2}},
\]  

(7.73)

and hence provides a finite spatial shift (69) of the standing wave toward the plasma surface:

\[
\delta_- = \frac{\varphi - \pi}{2k_0} = \frac{c}{\omega} \tan^{-1} \frac{\omega}{(\omega_p^2 - \omega^2)^{1/2}}.
\]  

(7.74)

\(^{30}\) This ratio is sometimes also called the transmission coefficient, but in order to avoid its confusion with the \(T\) defined by Eq. (64), it is better to call it the power transmission coefficient.
On the other hand, we already know from Eq. (40) that the solution at \( z > 0 \) is exponential, with the decay length \( \delta \) that is described by Eq. (39). Calculating, from the coefficient \( T \), the exact coefficient before this exponent, it is straightforward to verify that the electric and magnetic fields are indeed continuous at the interface, completing the pattern shown with red lines in Fig. 8. This penetration may be experimentally observed, for example, by thinning the sample of the reflecting material to have a finite thickness \( d \). Even without solving this problem exactly, it is evident that if \( d \) becomes comparable to \( \delta \), a part of the exponential “tail” of the field reaches the second interface, and induces a propagating wave. This is an electromagnetic analog of the quantum-mechanical tunneling through a potential barrier.\(^{31}\)

Note that at low frequencies, both \( \delta \) and \( \delta \) tend to the same frequency-independent value,

\[
\delta, \delta_0 \rightarrow \frac{c}{\omega_p} = \left( \frac{c^2 \epsilon_0 m_e n e^2}{\mu_0 n e^2} \right)^{1/2} = \left( \frac{m_e}{\mu_0 n e^2} \right)^{1/2}, \quad \text{at } \frac{\omega}{\omega_p} \rightarrow 0, \quad (7.75)
\]

which is just the field penetration depth (6.44) calculated for a perfect conductor model (assuming \( m = m_e \) and \( \mu = \mu_0 \)) in the quasistatic limit. This is natural, because the condition \( \omega << \omega_p \) may be recast as \( \lambda_0 = 2\pi/\omega >> 2\pi/\omega_0 = 2\pi\delta \), justifying the quasistatic approximation.

(ii) Now let us consider electromagnetic wave reflection from an Ohmic, non-magnetic conductor. In the simplest low-frequency limit, when \( \omega \tau \) is much less than 1, the conductor may be described by a frequency-independent conductivity \( \sigma \).\(^{32}\) According to Eq. (46), in this case we can take

\[
Z_+ = \left( \frac{\mu_0}{\epsilon_{\text{opt}}(\omega) + i \sigma / \omega} \right)^{1/2}. \quad (7.76)
\]

With this substitution, Eqs. (68) immediately give us all the results of interest. In particular, in the most important quasistatic limit (when \( \delta_0 = (2/\mu_0 \sigma_0)^{1/2} \ll \lambda_0 \equiv 2\pi/\omega_0 \), i.e. \( \sigma \omega >> \epsilon_0 \sim \epsilon_{\text{opt}} \)), the conductor’s impedance is low:

\[
Z_+ \approx \left( \frac{\mu_0 \omega}{i \sigma} \right)^{1/2} \equiv \pi \left( \frac{2}{i} \right)^{1/2} \frac{\delta}{\lambda_0}, \quad \text{i.e. } \left| \frac{Z_+}{Z_0} \right| << 1. \quad (7.77)
\]

The impedance is complex, and hence some fraction \( f \) of the incident wave is absorbed by the conductor. This fraction may be found as the ratio of the dissipated power (either calculated, as was done above, from Eqs. (68), or just taken from Eq. (6.36) with the magnetic field amplitude \( |H_0| = 2|E_0|/Z_0 \) – see Eq. (62)) to the incident wave’s power given by the first of Eqs. (72). The result is

\[
f = \frac{2 \omega \delta_s}{c} \equiv 4\pi \frac{\delta_s}{\lambda_0} \ll 1. \quad (7.78)
\]

This important result is widely used for crude estimates of the energy dissipation in metallic-wall waveguides and resonators, and immediately shows that to keep the energy losses low, the characteristic size of such systems (which gives a scale of the free-space wavelengths \( \lambda_0 \) at which they are used)

\(^{31}\) See, e.g., QM Sec. 2.3.

\(^{32}\) In a typical metal, \( \tau \sim 10^{13} \) s, so that this approximation works well all the way up to \( \omega \sim 10^{13} \) s\(^{-1} \), i.e. up to the far-infrared frequencies.
should be much larger than $\delta$. A more detailed theory of these structures, and the effects of energy loss in them, will be discussed later in this chapter.

### 7.4. Refraction

Now let us consider the effects arising at a plane interface between two uniform media if the wave’s incidence angle $\theta$ (Fig. 10) is arbitrary, rather than equal to zero as in our previous analysis, for the simplest case of fully transparent media, with real $\varepsilon(\omega)$ and $\mu(\omega)$. (For the sake of notation simplicity, the argument of these functions will be dropped, i.e. just implied in most formulas below.)

![Fig. 7.10. Plane wave’s reflection, transmission, and refraction at a plane interface. The plane of the drawing is selected to contain all three wave vectors: $k_+$, $k_-$, and $k'$.](image)

In contrast with the case of normal incidence, here the wave vectors $k_-$, $k_+$, and $k'$ of the three components (incident, reflected, and transmitted) waves may have different directions. (Such change of the transmitted wave’s direction is called refraction.) Hence now we have to start our analysis with writing a general expression for a single plane, monochromatic wave for the case when its wave vector $\mathbf{k}$ has all 3 Cartesian components, rather than one. An evident generalization of Eq. (11) for this case is

$$f(\mathbf{r},t) = \text{Re} \left[ \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} f_0 e^{i(k_xx + k_yy + k_zz - \omega t)} \right] = \text{Re} \left[ f_0 e^{i(k_0r - \omega t)} \right]. \quad (7.79)$$

This relation enables a ready analysis of “kinematic” relations that are independent of the media impedances. Indeed, it is sufficient to notice that to satisfy any linear, homogeneous boundary conditions at the interface ($z = 0$), all waves must have the same temporal and spatial dependence on this plane. Hence if we select the $x$-$z$ plane so that the vector $\mathbf{k}$ lies in it, then $(k_y) = 0$, and $k_-$ and $k'$ cannot have any $y$-component either, i.e. all three wave vectors lie in the same plane – that is selected as the plane of drawing in Fig. 10. Moreover, due to the same reason, their $x$-components should be equal:

$$k_- \sin \theta = k'_- \sin \theta' = k_+ \sin r. \quad (7.80)$$

From here we immediately get the well-known laws: of reflection

$$\theta' = \theta, \quad (7.81)$$

and refraction:33

---

33 The latter relation is traditionally called the **Snell law**, after a 17th century’s astronomer Willebrord Snellius, but it has been traced all the way back to a circa 984 work by Abu Saad Al-Ala ibn Sahl. (Claudius Ptolemy who performed pioneering experiments on light refraction in the 2nd century AD, was just one step from this result.)
In this form, the laws are valid for plane waves of any nature. In optics, the Snell law (82) is frequently represented in the form

\[
\frac{\sin r}{\sin \theta} = \frac{n_+}{n_-},
\]

(7.83)

where \(n_\pm\) is the index of refraction, also called the “refractive index” of the corresponding medium, defined as its wave number normalized to that of the free space (at the particular wave’s frequency):

\[
n_\pm \equiv \frac{k_\pm}{k_0} \equiv \left(\frac{\varepsilon_\pm \mu_\pm}{\varepsilon_0 \mu_0}\right)^{1/2}.
\]

(7.84)

Perhaps the most famous corollary of the Snell law is that if a wave propagates from a medium with a higher index of refraction to that with a lower one (i.e. if \(n_+ > n_-\) in Fig. 10), for example from water to air, there is always a certain critical value \(\theta_c\) of the incidence angle, at which the refraction angle \(r\) (see Fig. 10 again) reaches \(\pi/2\). At a larger \(\theta\), i.e. within the range \(\theta_c < \theta < \pi/2\), the boundary conditions (80) cannot be satisfied by a refracted wave with a real wave vector, so that the wave experiences the so-called total internal reflection. This effect is very important for practice, because it means that dielectric surfaces may be used as optical mirrors, in particular in optical fibers – to be discussed in more detail in Sec. 7 below. This is very fortunate for the telecommunication technology, because light’s reflection from metals is rather imperfect. Indeed, according to Eq. (78), in the optical range (\(\lambda_0 \sim 0.5 \mu m\), i.e. \(\omega \sim 10^{15} \text{s}^{-1}\)), even the best conductors (with \(\sigma \sim 6 \times 10^8 \text{S/m}\) and hence the normal skin depth \(\delta_s \sim 1.5 \text{nm}\)) provide power loss of at least a few percent at each reflection.

Note, however, that even within the range \(\theta_c < \theta < \pi/2\), the field at \(z > 0\) is not identically equal to zero: it penetrates into the less dense media by a distance of the order of \(\lambda_0\), exponentially decaying inside it, just as it does at the normal incidence – see Fig. 8. However, at \(\theta \neq 0\) the penetrating field still propagates, with the wave number (80), along the interface. Such a field, exponentially dropping in one direction but still propagating as a wave in another direction, is commonly called the evanescent wave.

One more remark: just as at the normal incidence, the field’s penetration into another medium causes a phase shift of the reflected wave – see, e.g., Eq. (69) and its discussion. A new feature of this phase shift, arising at \(\theta \neq 0\), is that it also has a component parallel to the interface – the so-called Goos-Hänchen effect. In the geometric optics, this effect leads to an image shift (relative to that its position in a perfect mirror) with components both normal and parallel to the interface.

Now let us carry out an analysis of “dynamic” relations that determine amplitudes of the refracted and reflected waves. For this, we need to write explicitly the boundary conditions at the interface (i.e. the plane \(z = 0\)). Since now the electric and/or magnetic fields may have components normal to the plane, in addition to the continuity of their tangential components, which were repeatedly discussed above,
we also need relations for the normal components. As it follows from the homogeneous macroscopic Maxwell equations (6.99b), they are also the same as in statics, i.e. \( D_n = \text{const} \), and \( B_n = \text{const} \), for our reference frame choice (Fig. 10) giving

\[
\varepsilon_{-} E_z \big|_{z=0} = \varepsilon_{+} E_z \big|_{z=0}, \quad \mu_{-} H_z \big|_{z=0} = \mu_{+} H_z \big|_{z=0}.
\]  

(7.87)

The expressions of these components via the amplitudes \( E_{\omega}, R E_{\omega}, \) and \( T E_{\omega} \) of the incident, reflected and transmitted waves depend on the incident wave’s polarization. For example, for a linearly-polarized wave with the electric field vector \textit{perpendicular} to the plane of incidence, i.e. \textit{parallel} to the interface plane, the reflected and refracted waves are similarly polarized – see Fig. 11a.

As a result, all \( E_z \) are equal to zero (so that the first of Eqs. (87) is inconsequential), while the tangential components of the electric field are just equal to their full amplitudes, just as at the normal incidence, so we still can use Eqs. (64) expressing these components via the coefficients \( R \) and \( T \). However, at \( \theta \neq 0 \) the magnetic fields have not only tangential components

\[
H_x \big|_{z=0} = \text{Re} \left[ \frac{E_{\omega}}{Z_{-}} (1 - R) \cos \theta e^{-i\omega t} \right], \quad H_x \big|_{z=0} = \text{Re} \left[ \frac{E_{\omega}}{Z_{+}} T \cos \theta e^{-i\omega t} \right],
\]  

(7.88)

but also normal components (see Fig. 11a):

\[
H_z \big|_{z=0} = \text{Re} \left[ \frac{E_{\omega}}{Z_{-}} (1 + R) \sin \theta e^{-i\omega t} \right], \quad H_z \big|_{z=0} = \text{Re} \left[ \frac{E_{\omega}}{Z_{+}} T \sin \theta e^{-i\omega t} \right].
\]  

(7.89)

Plugging these expressions into the boundary conditions expressed by Eqs. (86) (in this case, for the \( y \)-components only) and the second of Eqs. (87), we get \textit{three} equations for \textit{two} unknown coefficients \( R \) and \( T \). However, two of these equations duplicate each other because of the Snell law, and we get just two independent equations,

\[
1 + R = T, \quad \frac{1}{Z_{-}} (1 - R) \cos \theta = \frac{1}{Z_{+}} T \cos \theta,
\]  

(7.90)
which are a very natural generalization of Eqs. (67), with the replacements \( Z \rightarrow Z \cos r \), \( Z_+ \rightarrow Z_+ \cos \theta \). As a result, we can immediately use Eq. (68) to write the solution of the system (90):

\[
R = \frac{Z_+ \cos \theta - Z_- \cos r}{Z_+ \cos \theta + Z_- \cos r}, \quad T = \frac{2Z_+ \cos \theta}{Z_+ \cos \theta + Z_- \cos r}. \quad (7.91a)
\]

If we want to express these coefficients via the angle of incidence alone, we should use the Snell law (82) to eliminate the angle \( r \), getting the commonly used, more bulky expressions:

\[
R = \frac{Z_+ \cos \theta - Z_+ \left[1 - (k_-/k_+)^2 \sin^2 \theta \right]^{1/2}}{Z_+ \cos \theta + Z_+ \left[1 - (k_-/k_+)^2 \sin^2 \theta \right]^{1/2}}, \quad T = \frac{2Z_+ \cos \theta}{Z_+ \cos \theta + Z_+ \left[1 - (k_-/k_+)^2 \sin^2 \theta \right]^{1/2}}. \quad (7.91b)
\]

However, my strong preference is to use the kinematic relation (82) and the dynamic relations (91a) separately, because Eq. (91b) obscures the very important physical fact that and the ratio of \( k_+ \), i.e. of the wave velocities of the two media, is only involved in the Snell law, while the dynamic relations essentially include only the ratio of wave impedances – just as in the case of normal incidence.

In the opposite case of the linear polarization of the electric field within the plane of incidence (Fig. 11b), it is the magnetic field that does not have a normal component, so it is now the second of Eqs. (87) that does not participate in the solution. However, now the electric fields in two media have not only tangential components,

\[
E_x \big|_{z=0} = \text{Re} \left[ E_\omega (1 + R) \cos \theta e^{-i\omega t} \right], \quad E_x \big|_{z=0} = \text{Re} \left[ E_\omega T \cos r e^{-i\omega t} \right] \quad (7.92)
\]

but also normal components (Fig. 11b):

\[
E_z \big|_{z=0} = E_\omega (-1 + R) \sin \theta, \quad E_z \big|_{z=0} = -E_\omega T \sin r. \quad (7.93)
\]

As a result, instead of Eqs. (90), the reflection and transmission coefficients are related as

\[
(1 + R) \cos \theta = T \cos r, \quad \frac{1}{Z_-} (1 - R) = \frac{1}{Z_+} T. \quad (7.94)
\]

Again, the solution of this system may be immediately written using the analogy with Eq. (67):

\[
R = \frac{Z_+ \cos r - Z_- \cos \theta}{Z_+ \cos r + Z_- \cos \theta}, \quad T = \frac{2Z_+ \cos \theta}{Z_+ \cos r + Z_- \cos \theta}, \quad (7.95a)
\]

or, alternatively, using the Snell law, in a more bulky form:

\[
R = \frac{Z_+ \left[1 - (k_-/k_+)^2 \sin^2 \theta \right]^{1/2} - Z_- \cos \theta}{Z_+ \left[1 - (k_-/k_+)^2 \sin^2 \theta \right]^{1/2} + Z_- \cos \theta}, \quad T = \frac{2Z_+ \cos \theta}{Z_+ \left[1 - (k_-/k_+)^2 \sin^2 \theta \right]^{1/2} + Z_- \cos \theta}. \quad (7.95b)
\]

For the particular case \( \mu_+ = \mu_+ = \mu_0 \), when \( Z_+/Z_- = (\varepsilon_+ / \varepsilon_-)^{1/2} = k_+ / k_- = n_- / n_+ \) (which is approximately correct for traditional optical media), Eqs. (91b) and (95b) are called the Fresnel formulas.\(^{35} \) Most

\(^{34} \) Note that we may calculate the reflection and transmission coefficients \( R' \) and \( T' \) for the wave traveling in the opposite direction just by making the following parameter swaps: \( Z_+ \leftrightarrow Z_- \) and \( \theta \leftrightarrow r \), and that the resulting coefficients satisfy the following Stokes relations: \( R' = -R \), and \( T'^2 + TT' = 1 \), for any \( Z_\pm \).
textbooks are quick to point out that there is a major difference between them: while for the electric field polarization within the plane of incidence (Fig. 11b), the reflected wave’s amplitude (proportional to the coefficient $R$) turns to zero\footnote{Named after Augustin-Jean Fresnel (1788-1827), one of the pioneers of the wave optics, who is credited, among many other contributions (see, in particular, discussions in Ch. 8), for the concept of light as a purely transverse wave.} at a special value of $\theta$ (called the Brewster angle)\footnote{This effect is used in practice to obtain linearly polarized light, with the electric field vector perpendicular to the plane of incidence, from the natural light with its random polarization. An even more practical application of the effect is a partial reduction of undesirable glare from wet surfaces (for the water/air interface, $n_+/n_- \approx 1.33$, giving $\theta_B \approx 50^\circ$) by making car light covers and sunglasses of vertically-polarizing materials.}:

$$\theta_B = \tan^{-1} \frac{n_+}{n_-}, \quad (7.96)$$

while there is no such angle in the opposite case (shown in Fig. 11a). However, note that this statement, as well as Eq. (96), is true only for the case $\mu_+ = \mu_-$. In the general case of different $\varepsilon$ and $\mu$, Eqs. (91) and (95) show that the reflected wave vanishes at $\theta = \theta_B$ with

$$\tan^2 \theta_B = \frac{\varepsilon_+ \mu_+ - \varepsilon_- \mu_-}{\varepsilon_+ \mu_+ - \varepsilon_- \mu_-} \times \begin{cases} \left( \frac{\mu_+}{\mu_-} \right), & \text{for } E \perp n_z \text{ (Fig.11a)}, \\ \left( \frac{-\varepsilon_+}{\varepsilon_-} \right), & \text{for } H \perp n_z \text{ (Fig.11b)}. \end{cases} \quad (7.97)$$

Note the natural $\varepsilon \leftrightarrow \mu$ symmetry of these relations, resulting from the $E \leftrightarrow H$ symmetry for these two polarization cases (Fig. 11). These formulas also show that for any set of parameters of the two media (with $\varepsilon_+, \mu_+ > 0$), $\tan^2 \theta_B$ is positive (and hence a real Brewster angle $\theta_B$ exists) only for one of these two polarizations. In particular, if the interface is due to the change of $\mu$ alone (i.e. if $\varepsilon_+ = \varepsilon_-$), the first of Eqs. (97) is reduced to the simple form (96) again, while for the polarization shown in Fig. 11b there is no Brewster angle, i.e. the reflected wave has a non-vanishing amplitude for any $\theta$.

Such an account of both media parameters, $\varepsilon$ and $\mu$, on an equal footing is especially necessary to describe the so-called negative refraction effects\footnote{A very simple interpretation of Eq. (96) is based on the fact that, together with the Snell law (82), it gives $r + \theta = \pi/2$. As a result, the vector $\mathbf{E}_r$ is parallel to the vector $\mathbf{k}$, and hence oscillating electric dipoles of the medium at $z > 0$ do not have the component which could induce the transverse electric field $\mathbf{E}_t$ of the potential reflected wave.}. As was shown in Sec. 2, in a medium with electric-field-driven resonances, the function $\varepsilon(\omega)$ may be almost real and negative, at least within limited frequency intervals – see, in particular, Eq. (34) and Fig. 5. As has already been discussed, if, at these frequencies, the function $\mu(\omega)$ is real and positive, then $k^2(\omega) = \omega^2 \varepsilon(\omega) \mu(\omega) < 0$, and $k$ may be represented as $i/\delta$ with real $\delta$, meaning the exponential field decay into the medium. However, let us consider the case when both $\varepsilon(\omega) < 0$ and $\mu(\omega) < 0$ at a certain frequency. (This is possible in a medium with both $E$-driven and $H$-driven resonances, at a proper choice of their resonant frequencies.) Since in this case $k^2(\omega) = \omega^2 \varepsilon(\omega) \mu(\omega) > 0$, the wave vector is real, so that Eq. (79) describes a traveling wave, and one could think that there is nothing new in this case. Not quite so!

\footnotesize{35 Named after Augustin-Jean Fresnel (1788-1827), one of the pioneers of the wave optics, who is credited, among many other contributions (see, in particular, discussions in Ch. 8), for the concept of light as a purely transverse wave.} 
\footnotesize{36 This effect is used in practice to obtain linearly polarized light, with the electric field vector perpendicular to the plane of incidence, from the natural light with its random polarization. An even more practical application of the effect is a partial reduction of undesirable glare from wet surfaces (for the water/air interface, $n_+/n_- \approx 1.33$, giving $\theta_B \approx 50^\circ$) by making car light covers and sunglasses of vertically-polarizing materials.} 
\footnotesize{37 A very simple interpretation of Eq. (96) is based on the fact that, together with the Snell law (82), it gives $r + \theta = \pi/2$. As a result, the vector $\mathbf{E}_r$ is parallel to the vector $\mathbf{k}$, and hence oscillating electric dipoles of the medium at $z > 0$ do not have the component which could induce the transverse electric field $\mathbf{E}_t$ of the potential reflected wave.} 
\footnotesize{38 Despite some important background theoretical work by A. Schuster (1904), L. Mandelstam (1945), D. Sivikhin (1957), and especially V. Veselago (1966-67), the negative refractivity effects became a subject of intensive scientific research and engineering development only in the 2000s.}
First of all, for a sinusoidal, plane wave (79), the operator $\nabla$ is equivalent to the multiplication by $ik$. As the Maxwell equations (2a) show, this means that at a fixed direction of vectors $\mathbf{E}$ and $\mathbf{k}$, the simultaneous reversal of signs of $\varepsilon$ and $\mu$ means the reversal of the direction of the vector $\mathbf{H}$. Namely, if both $\varepsilon$ and $\mu$ are positive, these equations are satisfied with mutually orthogonal vectors {$\mathbf{E}$, $\mathbf{H}$, $\mathbf{k}$} forming the usual, *right-hand* system (see Fig. 1 and Fig. 12a), the name stemming from the popular “right-hand rule” used to determine the vector product’s direction. However, if both $\varepsilon$ and $\mu$ are negative, the vectors form a *left-hand* system – see Fig. 12b. (Due to this fact, the media with $\varepsilon < 0$ and $\mu < 0$ are frequently called the *left-handed materials*, LHM for short.) According to the basic relation (6.114), which does not involve media parameters, this means that for a plane wave in a left-hand material, the Poynting vector $\mathbf{S} = \mathbf{E} \times \mathbf{H}$, i.e. the energy flow, is directed *opposite* to the wave vector $\mathbf{k}$.

This fact may look strange, but is in no contradiction with any fundamental principle. Let me remind you that, according to the definition of the vector $\mathbf{k}$, its direction shows the direction of the *phase* velocity $v_{ph} = \omega/k$ of a sinusoidal (and hence infinitely long) wave, which cannot be used, for example, for signaling. Such signaling (by sending wave packets – see Fig. 13) is possible only with the *group* velocity $v_{gr} = d\omega/dk$. This velocity in left-hand materials is always positive (directed along the vector $\mathbf{S}$).

Perhaps the most fascinating effect possible with left-hand materials is the wave refraction at their interfaces with the usual, right-handed materials – first predicted by V. Veselago in 1960. Consider the example shown in Fig. 14a. In the incident wave, coming from the usual material, the directions of vectors $\mathbf{k}$ and $\mathbf{S}$ coincide, and so they are in the reflected wave with vectors $\mathbf{k}'$ and $\mathbf{S}'$. This means that the electric and magnetic fields in the interface plane ($z = 0$) are, at our choice of coordinates, proportional to $\exp\{ik_x x\}$, with a positive component $k_x = k \cos \theta$. To satisfy any linear boundary conditions, the refracted wave, going into the left-handed material, should match that dependence, i.e. must have a positive $x$-component of its wave vector $k_x$. But in this medium, this vector has to be antiparallel to the vector $\mathbf{S}$, which in turn should be directed out of the interface, because it represents...
the power flow from the interface into the material’s bulk. These conditions cannot be reconciled by the refracted wave propagating along the usual Snell-law direction (shown with the dashed line in Fig. 13a), but are all satisfied at refraction in the direction given by Snell’s angle with the opposite sign. (Hence the term “negative refraction”).

In order to understand how unusual the results of the negative refraction may be, let us consider a parallel slab of thickness $d$, made of a hypothetical left-handed material with exactly selected values $\varepsilon = -\varepsilon_0$ and $\mu = -\mu_0$ – see Fig. 14b. For such a material, placed in free space, the refraction angle $r = -\theta$, so that the rays from a point source, located in free space, at a distance $a < d$ from the slab, propagate as shown on that panel, i.e. all meet again at the distance $a$ inside the plate, and then continue to propagate to the second surface of the slab. Repeating our discussion for this surface, we see that a point’s image is also formed beyond the slab, at distance $2a + 2b = 2a + 2(d - a) = 2d$ from the object.

Superficially, this system looks like the usual lens, but the well-known lens formula, which relates $a$ and $b$ with the focal length $f$, is not satisfied. (In particular, a parallel beam is not focused into a point at any finite distance.) As an additional difference from the usual lens, the system shown in Fig. 14b does not reflect any part of the incident light. Indeed, it is straightforward to check that for all above formulas for $R$ and $T$ to be valid, the sign of the wave impedance $Z$ in left-handed materials has to be kept positive. Thus, for our particular choice of parameters ($\varepsilon = -\varepsilon_0$, $\mu = -\mu_0$), Eqs. (91a) and (95a) are valid with $Z_+ = Z_0$ and $\cos r = \cos \theta = 1$, giving $R = 0$ for any linear polarization, and hence for any other wave polarization – circular, elliptic, natural, etc.

The perfect lens suggestion has triggered a wave of efforts to implement left-hand materials experimentally. (Attempts to find such materials in nature have failed so far.) Most progress in this direction has been achieved using the so-called metamaterials, which are essentially quasi-periodic arrays of specially designed electromagnetic resonators, ideally with high density $n >> \lambda^3$. For example, Fig. 15 shows the metamaterial that was used for the first demonstration of negative refractivity in the microwave region – for $\sim$10-GHz frequencies. It combines straight strips of a metallic film, working as

---

39 In some publications inspired by this fact, the left-hand materials are prescribed a negative index of refraction $n$. However, this prescription should be treated with care. For example, it complies with the first form of Eq. (84), but not its second form, and the sign of $n$, in contrast to that of the wave vector $k$, is the matter of convention.

lumped resonators with a large electric dipole moment (hence strongly coupled to wave’s electric field $E$), and several almost-closed film loops (so-called *split rings*), working as lumped resonators with large magnetic dipole moments, coupled to the field $H$. The negative refractivity is achieved by designing the resonance frequencies close to each other. More recently, metamaterials with negative refractivity were demonstrated in the optical range,\(^{41}\) although to the best of my knowledge, their relatively large absorption still prevents practical applications.

This progress has stimulated the development of other potential uses of metamaterials (not necessarily the left-handed ones), in particular, designs of nonuniform systems with engineered distributions $\varepsilon(r, \omega)$ and $\mu(r, \omega)$, which may provide electromagnetic wave propagation along the desired paths, e.g., around a certain region of space, making it virtually invisible for an external observer – so far, within a limited frequency range.\(^{42}\)

As was mentioned in Sec. 5.5, another way to reach negative values of $\mu(\omega)$ is to place a ferromagnetic material into such an external dc magnetic field that the frequency $\omega_0$ of the ferromagnetic resonance is somewhat lower than $\omega$. If thin layers of such a material (e.g., nickel) are interleaved with layers of a non-magnetic very good conductor (such as copper), the resulting metamaterial has an average value of $\mu(\omega)$ – say, positive, but substantially below $\mu_0$. According to Eq. (6.33), the skin-depth $\delta_\chi$ of such a material may be larger than that of the good conductor alone, enforcing a more uniform distribution of the ac current flowing along the layers, and hence making the energy losses lower than in the good conductor alone. This effect may be useful, in particular, for electronic circuit interconnects.\(^{43}\)

### 7.5. Transmission lines: TEM waves

So far, we have analyzed plane electromagnetic waves, implying that their cross-section is infinite – evidently, the unrealistic assumption. The cross-section may be limited, still sustaining wave propagation along *wave transmission lines*:\(^{44}\) long, uniform structures made of either good conductors or dielectrics. Let us first discuss the first option, using the following simplifying assumptions:

---

43 See, for example, N. Sato et al., *J. Appl. Phys.* **111**, 07A501 (2012), and references therein.
44 Another popular term is the *waveguide*, but it is typically reserved for the transmission lines with singly-connected cross-sections, to be analyzed in the next section. The first structure for guiding waves was proposed by J. J. Thomson in 1893, and experimentally tested by O. Lodge in 1894.
(i) the structure is a cylinder (not necessarily with a round cross-section, see Fig. 16) filled with a usual (right-handed), uniform dielectric material with negligible energy losses ($\varepsilon'' = \mu'' = 0$), and

(ii) the wave attenuation due to the skin effect is also negligibly low. (As Eq. (78) indicates, for that the characteristic size $a$ of the line’s cross-section has to be much larger than the skin-depth $\delta_s$ of its wall material. The energy dissipation effects will be analyzed in Sec. 9 below.)

With such exclusion of energy losses, we may look for a particular solution of the macroscopic Maxwell equations in the form of a monochromatic wave traveling along the line:

$$E(r,t) = \Re\left[ E_\omega(x,y)e^{i(k_z z - \omega t)} \right], \quad H(r,t) = \Re\left[ H_\omega(x,y)e^{i(k_z z - \omega t)} \right],$$

(7.98)

with real $k_z$, where the $z$-axis is directed along the transmission line – see Fig. 16. Note that this form allows an account for a substantial coordinate dependence of the electric and magnetic field within the plane $[x, y]$ of the transmission line’s cross-section, as well as for longitudinal components of the fields, so that the solution (98) is substantially more complex than the plane waves we have discussed above.

We will see in a minute that as a result of this dependence, the parameter $k_z$ may be very much different from its plane-wave value (13), $k \equiv \omega(\varepsilon\mu)^{1/2}$, in the same material, at the same frequency.

In order to describe these effects qualitatively, let us decompose the complex amplitudes of the wave’s fields into their longitudinal and transverse components (Fig. 16):\(^{45}\)

$$E_\omega = E_z n_z + E_z, \quad H_\omega = H_z n_z + H_z.$$  

(7.99)

Plugging Eqs. (98)-(99) into the source-free Maxwell equations (2), and requiring the longitudinal and transverse components to be balanced separately, we get

$$ik_z n_z \times E_z - i\omega \mu H_z = -\nabla_t \times (E_z n_z), \quad ik_z n_z \times H_z + i\omega \varepsilon E_z = -\nabla_t \times (H_z n_z),$$
$$\nabla_t \times E_z = i\omega \mu H_z n_z, \quad \nabla_t \times H_z = -i\omega E_z n_z,$$

(7.100)

$$\nabla_t \cdot E_z = -ik_z E_z, \quad \nabla_t \cdot H_z = -ik_z H_z.$$  

where $\nabla_t$ is the 2D del operator acting in the transverse plane $[x, y]$ only, i.e. the usual $\nabla$, but with $\partial/\partial z = 0$. The system of Eqs. (100) looks even bulkier than the original equations (2), but it is much simpler

\(^{45}\) Note that for the notation simplicity, I am dropping index $\omega$ in the complex amplitudes of the field components, and also have dropped the argument $\omega$ in $k_z$ and $Z$, even though these parameters of the wave may depend on its frequency rather substantially – see below.
for analysis. Indeed, eliminating the transverse components from these equations (or, even simpler, just plugging Eq. (99) into Eqs. (3) and keeping only their \( z \)-components), we get a pair of self-consistent equations for the longitudinal components of the fields, \(^{46}\)

\[
\begin{align*}
\left( \nabla_i^2 + k_i^2 \right) E_z &= 0, \\
\left( \nabla_i^2 + k_i^2 \right) H_z &= 0,
\end{align*}
\]

(7.101)

where \( k \) is still defined by Eq. (13), \( k = (\varepsilon \mu)^{1/2} \omega \), while

\[
k_i^2 \equiv k^2 - k_z^2 = \omega^2 \varepsilon \mu - k_z^2.
\]

(7.102)

After the distributions \( E_z(x,y) \) and \( H_z(x,y) \) have been found from these equations, they provide right-hand sides for the rather simple, closed system of equations (100) for the transverse components of field vectors. Moreover, as we will see below, each of the following three types of solutions:

(i) with \( E_z = 0 \) and \( H_z = 0 \) (called the transverse electromagnetic, or TEM waves),

(ii) with \( E_z = 0 \), but \( H_z \neq 0 \) (called either the TE waves or, more frequently, \( H \)-modes), and

(iii) with \( E_z \neq 0 \), but \( H_z = 0 \) (the so-called TM waves or \( E \)-modes),

has its own dispersion law and hence its own wave propagation velocity; as a result, these modes (i.e. the field distribution patterns) may be considered separately.

In this section, we will focus on the simplest, TEM waves (i), with no longitudinal components of either field. For them, the top two equations of the system (100) immediately give Eqs. (6) and (13), and \( k_z = k \). In plain English, this means that \( E = E_t \) and \( H = H_t \) are proportional to each other and are mutually perpendicular (just as in the plane wave) at each point of the cross-section, and that the TEM wave’s impedance \( Z \equiv E/H \) and dispersion law \( \omega(k) \), and hence the propagation speed, are the same as in a plane wave in the same material. In particular, if \( \varepsilon \) and \( \mu \) are frequency-independent within a certain frequency range, the dispersion law within this range is linear, \( \omega = k/(\varepsilon \mu)^{1/2} \), and the wave’s speed does not depend on its frequency. For practical applications to telecommunications, this is a very important advantage of the TEM waves over their TM and TE counterparts – to be discussed below.

Unfortunately, such waves cannot propagate in every transmission line. To show this, let us have a look at the two last lines of Eqs. (100). For the TEM waves \( (E_z = 0, H_z = 0, k_z = k) \), they are reduced to merely

\[
\begin{align*}
\nabla_i \times E_i &= 0, \\
\nabla_i \times H_i &= 0, \\
\nabla_i \cdot E_i &= 0, \\
\nabla_i \cdot H_i &= 0.
\end{align*}
\]

(7.103)

Within the coarse-grain description of the conducting walls of the line (i.e., neglecting the skin depth in comparison with the cross-section dimensions), we have to require that inside them, \( E = H = 0 \). Close to a wall but outside it, the normal component \( E_n \) of the electric field may be different from zero, because surface charges may sustain its jump – see Sec. 2.1, in particular Eq. (2.3). Similarly, the tangential component \( H_t \) of the magnetic field may have a finite jump at the surface due to skin currents – see Sec. 6.3, in particular Eq. (6.38). However, the tangential component of the electric field and the normal

\(^{46}\) The wave equation represented in the form (101), even with the 3D Laplace operator, is called the Helmholtz equation, named after Hermann von Helmholtz (1821-1894) – the mentor of H. Hertz and M. Planck, among many others.
component of the magnetic field cannot experience such jumps, and in order to have them equal to zero inside the walls they have to equal zero just outside the walls as well:

$$E_t = 0, \quad H_n = 0. \tag{7.104}$$

But the left columns of Eqs. (103) and (104) coincide with the formulation of the 2D boundary problem of electrostatics for the electric field induced by electric charges of the conducting walls, with the only difference that in our current case the value of $\varepsilon$ actually means $\varepsilon(\omega)$. Similarly, the right columns of those relations coincide with the formulation of the 2D boundary problem of magnetostatics for the magnetic field induced by currents in the walls, with $\mu \rightarrow \mu(\omega)$. The only difference is that in our current, coarse-grain approximation the magnetic fields cannot penetrate inside the conductors.

Now we immediately see that in waveguides with a singly-connected wall, for example, a hollow conducting tube (see, e.g., Fig. 16), the TEM waves are impossible, because there is no way to create a non-vanishing electrostatic field inside a conductor with such cross-section. However, such fields (and hence the TEM waves) are possible in structures with cross-sections consisting of two or more disconnected (galvanically-insulated) parts – see, e.g., Fig. 17.

In order to derive “global” relations for such a transmission line, let us consider the contour $C$ drawn very close to the surface of one of its conductors – see, e.g., the red dashed line in Fig. 17. We can consider it, on one hand, as the cross-section of a cylindrical Gaussian volume of a certain elementary length $dz \ll \lambda \equiv 2\pi/k$. Using the generalized Gauss law (3.34), we get

$$\oint_C (E_t)_n \, dr = \frac{\lambda_{\omega}}{\varepsilon}, \tag{7.105}$$

where $\lambda_{\omega}$ (not to be confused with the wavelength $\lambda$!) is the complex amplitude of the linear density of the electric charge of the conductor. On the other hand, the same contour $C$ may be used in the generalized Ampère law (5.116) to write

$$\oint_C (H_t)_i \, dr = I_{\omega}, \tag{7.106}$$

where $I_{\omega}$ is the total current flowing along the conductor (or rather its complex amplitude). But, as was mentioned above, in the TEM wave the ratio $E_t/H_t$ of the field components participating in these two integrals is constant and equal to $Z = (\mu/\varepsilon)^{1/2}$, so that Eqs. (105)-(106) give the following simple relation between the “global” variables of the conductor:

$$I_{\omega} = \frac{\lambda_{\omega}}{Z} \equiv \frac{\lambda_{\omega}}{(g\mu)^{1/2}} \equiv \frac{\omega}{k} \lambda_{\omega}, \tag{7.107}$$
This important relation may be also obtained in a different way; let me describe it as well, because (as we will see below) it has independent heuristic value. Let us consider a small segment \( dz \ll \lambda = 2\pi k \) of the line’s conductor, and apply the electric charge conservation law (4.1) to the instant values of the linear charge density and current. The cancellation of \( dz \) in both parts yields

\[
\frac{\partial \lambda(z,t)}{\partial t} = -\frac{\partial I(z,t)}{\partial z}.
\] (7.108)

If we accept the sinusoidal waveform, \( \exp\{i(kz - \omega t)\} \), for both these variables, we immediately recover Eq. (107) for their complex amplitudes, showing that this relation expresses just the charge continuity law.

The global equation (108) may be made more specific in the case when the frequency dependence of \( \varepsilon \) and \( \mu \) is negligible, and the transmission line consists of just two isolated conductors – see, e.g., Fig. 17. In this case, to have the wave localized in the space near the two conductors, we need a sufficiently fast decrease of its electric field at large distances. For that, their linear charge densities for each value of \( z \) should be equal and opposite, and we can simply relate them to the potential difference \( V \) between the conductors:

\[
\frac{\lambda(z,t)}{V(z,t)} = C_0,
\] (7.109)

where \( C_0 \) is the mutual capacitance of the conductors (per unit length) – which was repeatedly discussed in Chapter 2. Then Eq. (108) takes the form

\[
C_0 \frac{\partial V(z,t)}{\partial t} = -\frac{\partial I(z,t)}{\partial z}.
\] (7.110)

Next, let us consider the contour shown with the red dashed line in Fig. 18 (which shows a cross-section of the transmission line by a plane containing the wave propagation axis \( z \)), and apply to it the Faraday induction law (6.3).

Fig. 7.18. Electric current, magnetic flux, and voltage in a two-conductor transmission line.

Since, in the macroscopic approximation, the electric field inside the conductors (in Fig. 18, on the horizontal segments of the contour) vanishes, the total e.m.f. equals the difference of the voltages \( V \) at the ends of the segment \( dz \), while the only source of the magnetic flux through the area limited by the contour are the (equal and opposite) currents \( \pm I \) in the conductors, we can use Eq. (5.70) to express it. As a result, canceling \( dz \) in both parts of the equation, we get

\[
L_0 \frac{\partial I(z,t)}{\partial t} = -\frac{\partial V(z,t)}{\partial z},
\] (7.111)
where $L_0$ is the mutual inductance of the conductors per unit length. The only difference between this $L_0$ and the dc mutual inductances discussed in Chapter 5 is that at the high frequencies we are analyzing now, $L_0$ should be calculated neglecting the magnetic field penetration into the conductors. (In the dc case, we had the same situation for superconductor electrodes, within their coarse-grain, ideal-diamagnetic description.)

The system of Eqs. (110) and (111) is frequently called the telegrapher’s equations. Combined, they give for any “global” variable $f$ (either $V$, or $I$, or $\lambda$) the usual 1D wave equation,

$$\frac{\partial^2 f}{\partial z^2} - L_0 C_0 \frac{\partial^2 f}{\partial t^2} = 0,$$

which describes the dispersion-free TEM wave’s propagation. Again, this equation is only valid within the frequency range where the frequency dependence of both $\varepsilon$ and $\mu$ is negligible. If it is not so, the global approach may still be used for sinusoidal waves $f = \text{Re}[f_\omega \exp\{i(kz - \omega t)\}]$. Repeating the above arguments, instead of Eqs. (110)-(111) we get a more general system of two algebraic equations

$$\omega C_0 V_\omega = k I_\omega, \quad \omega L_0 I_\omega = k V_\omega,$$

in which $L_0 \propto \mu$ and $C_0 \propto \varepsilon$ may now depend on frequency. These equations are consistent only if

$$L_0 C_0 = \frac{k^2}{\omega^2} \equiv \frac{1}{v^2} \equiv \varepsilon \mu .$$

Besides the fact we have already known (that the TEM wave’s speed is the same as that of the plane wave), Eq. (114) gives us the result that I confess was not emphasized enough in Chapter 5: the product $L_0 C_0$ does not depend on the shape or size of line’s cross-section (provided that the magnetic field penetration into the conductors is negligible). Hence, if we have calculated the mutual capacitance $C_0$ of a system of two cylindrical conductors, the result immediately gives us their mutual inductance: $L_0 = \varepsilon \mu C_0$. This relation stems from the fact that both the electric and magnetic fields may be expressed via the solution of the same 2D Laplace equation for the system’s cross-section.

With Eq. (114) satisfied, any of Eqs. (113) gives the same result for the following ratio:

$$Z_W \equiv \frac{V_\omega}{I_\omega} = \left( \frac{L_0}{C_0} \right)^{1/2} ,$$

which is called the transmission line’s impedance. This parameter has the same dimensionality (in SI units, ohms) as the wave impedance (7),

$$Z \equiv \frac{E_\omega}{H_\omega} = \left( \frac{\mu}{\varepsilon} \right)^{1/2} ,$$

but these parameters should not be confused, because $Z_W$ depends on cross-section’s geometry, while $Z$ does not. In particular, $Z_W$ is the only important parameter of a transmission line for matching with a lumped load circuit (Fig. 19) in the important case when both the cable cross-section’s size and the load’s linear dimensions are much smaller than the wavelength.\footnote{The ability of TEM lines to have such a small cross-section is their another important practical advantage.}
Indeed, in this case, we may consider the load in the quasistatic limit and write

\[ V_\omega(z_0) = Z_L(\omega)I_\omega(z_0), \]  

(7.117)

where \( Z_L(\omega) \) is the (generally complex) impedance of the load. Taking \( V(z,t) \) and \( I(z,t) \) in the form similar to Eqs. (61) and (62), and writing the two Kirchhoff's laws for the point \( z = z_0 \), we get for the reflection coefficient a result similar to Eq. (68):

\[ R = \frac{Z_L(\omega) - Z_W}{Z_L(\omega) + Z_W}. \]  

(7.118)

This formula shows that for the perfect matching (i.e. the total wave absorption in the load), the load’s impedance \( Z_L(\omega) \) should be real and equal to \( Z_W \) – but not necessarily to \( Z \).

As an example, let us consider one of the simplest (and the most important) transmission lines: the coaxial cable (Fig. 20).\(^{48}\)

For this geometry, we already know the expressions for both \( C_0 \) and \( L_0 \),\(^{49}\) though they have to be modified for the dielectric and magnetic constants, and the magnetic field’s non-penetration into the conductors. As a result of such modification, we get the formulas,

\[
C_0 = \frac{2\pi \varepsilon}{\ln(b/a)}, \quad L_0 = \frac{\mu}{2\pi} \ln(b/a),
\]  

(7.119)

illustrating that the universal relation (114), independent of the geometric parameters \( a \) and \( b \), is indeed valid. On the contrary, for the cable’s impedance (115), Eqs. (119) yield a geometry-dependent value

\[
Z_w = \left( \frac{\mu}{\varepsilon} \right)^{1/2} \frac{\ln(b/a)}{2\pi} = Z \frac{\ln(b/a)}{2\pi} \neq Z.
\]  

(7.120)

\(^{48}\) It was invented by the same O. Heaviside in 1880.

\(^{49}\) See, respectively, Eqs. (2.49) and (5.79).
For the standard TV antenna cables (such as RG-6/U, with $b/a \sim 3$, $\epsilon/\epsilon_0 \approx 2.2$), $Z_W = 75$ ohms, while for most computer component connections, coaxial cables with $Z_W = 50$ ohms (such as RG-58/U) are prescribed by electronic engineering standards. Such cables are broadly used for the transmission of electromagnetic waves with frequencies up to 1 GHz over distances of a few km, and up to ~20 GHz on the tabletop scale (a few meters), limited by wave attenuation – see Sec. 9 below.

Moreover, the following two facts enable a wide application, in electrical engineering and physical experiment, the coaxial-cable-like systems. First, as Eq. (5.78) shows, in a cable with $a << b$, most wave energy is localized near the internal conductor. Second, the theory to be discussed in the next section shows that waves of other ($H$- and $E$-) modes in the cable are impossible until the wavelength $\lambda$ becomes smaller than $\sim \pi (a + b)$. As a result, the TEM mode propagation in a cable with $a << b < \lambda/\pi$ is not much affected even if the internal conductor is not straight, but is bent – for example, into a helix – see, e.g., Fig. 21.

In such a system, called the traveling-wave tube, the quasi-TEM wave propagates, with velocity $v = 1/(\epsilon\mu)^{1/2} \sim c$, along the helix’ length, so that the velocity’s component along the cable’s axis may be made close to the velocity $u << c$ of the electron beam moving ballistically along the tube’s axis, enabling their effective interaction, and as a result, a length-accumulating amplification of the wave.\(^{50}\)

Another important example of a TEM transmission line is a set of two parallel wires. In the form of twisted pairs,\(^{51}\) they allow communications, in particular long-range telephone and DSL Internet connections, at frequencies up to a few hundred kHz, as well as relatively short, multi-line Ethernet and TV cables at frequencies up to ~1 GHz, limited mostly by the mutual interference (“crosstalk”) between the individual lines of the same cable, and the unintentional radiation of the wave into the environment.

### 7.6. Waveguides: $H$ and $E$ waves

Let us now return to Eqs. (100) and explore the $H$- and $E$-waves – with, respectively, either $H_z$ or $E_z$ different from zero. At the first sight, they may seem more complex. However, Eqs. (101), which determine the distribution of these longitudinal components over the cross-section, are just the 2D Helmholtz equations for scalar functions. For simple cross-section geometries, they may be readily

---

\(^{50}\) Very unfortunately, in this course I will not have time/space to discuss even the (rather elegant) basic theory of such devices. The reader interested in this field may be referred, for example, to the detailed monograph by J. Whitaker, *Power Vacuum Tubes Handbook*, 3rd ed., CRC Press, 2017.

\(^{51}\) Such twisting, around the line’s axis, reduces the crosstalk between adjacent lines, and the parasitic radiation at their bends.
solved using the methods discussed for the Laplace equation in Chapter 2, in particular the variable separation. After the solution of such an equation has been found, the transverse components of the fields may be calculated by differentiation, using the simple formulas,

\[ E_z = \frac{i}{k_z^2} \left[ k_z \nabla_i E_z - k Z (n_z \times \nabla_i H_z) \right], \quad H_i = \frac{i}{k_z^2} \left[ k_z \nabla_i H_z + k Z (n_z \times \nabla_i E_z) \right], \]  

(7.121)

which follow from the two equations in the first line of Eqs. (100).\(^{52}\)

In comparison with the boundary problems of electro- and magnetostatics, the only conceptually new feature of Eqs. (101) is that they form the so-called eigenproblems, with typically many solutions (eigenfunctions), each describing a specific wave mode, and corresponding to a specific eigenvalue of the parameter \(k_z\). The good news here is that these values of \(k_z\) are determined by this 2D boundary problem and hence do not depend on \(k_z\). As a result, the dispersion law \(\omega(k_z)\) of any mode, which follows from the last form of Eq. (102),

\[ \omega = \left( \frac{k_z^2 + k_i^2}{\varepsilon \mu} \right)^{1/2} \equiv \left( v^2 k_z^2 + \omega_c^2 \right)^{1/2}, \]  

(7.122)

is functionally similar for all modes. It is also similar to that of plane waves in plasma (see Eq. (38), Fig. 6, and their discussion in Sec. 2), with the only differences are that the speed in light \(c\) is now replaced with \(v = 1/(\varepsilon \mu)^{1/2}\), i.e. the speed of plane (or any TEM) waves in the medium filling the waveguide, and \(\omega_p\) is replaced with the so-called cutoff frequency

\[ \omega_c \equiv v k_0, \]  

(7.123)

specific for each mode. (As Eq. (101) implies, and as we will see from several examples below, \(k_i\) has the order of \(1/a\), where \(a\) is the characteristic dimension of waveguide’s cross-section, so that the critical value of the free-space wavelength \(\lambda = 2\pi c/\omega\) is of the order of \(a\).) Below the cutoff frequency of each particular mode, such wave cannot propagate in the waveguide.\(^{53}\) As a result, the modes with the lowest values of \(\omega_c\) present special practical interest, because the choice of the signal frequency \(\omega\) between the two lowest values of the cutoff frequency (123) guarantees that the waves propagate in the form of only one mode, with the lowest \(k_i\). Such a choice enables engineers to simplify the excitation of the desired mode by wave generators, and to avoid the parasitic transfer of electromagnetic wave energy to undesirable modes by (virtually unavoidable) small inhomogeneities of the system.

The boundary conditions for the Helmholtz equations (101) depend on the propagating wave type. For the \(E\)-modes, with \(H_z = 0\) but \(E_z \neq 0\), the condition \(E_i = 0\) immediately gives

\(^{52}\)For the derivation of Eqs. (121), one of two linear equations (100) should be first vector-multiplied by \(n_z\). Note that this approach could not be used to analyze the TEM waves, because for them \(k_i = 0, E_z = 0, H_z = 0\, \), and Eqs. (121) yield uncertainty.

\(^{53}\)An interesting recent twist in the ideas of electromagnetic metamaterials (mentioned in Sec. 5 above) is the so-called \(\varepsilon\)-near-zero materials, designed to have the effective product \(\varepsilon \mu\) much lower than \(\varepsilon_0 \mu_0\) within certain frequency ranges. Since at these frequencies the speed \(v\) (4) becomes much lower than \(c\), the cutoff frequency (123) virtually vanishes. As a result, the waves may “tunnel” through very narrow sections of metallic waveguides filled with such materials – see, e.g., M. Silveirinha and N. Engheta, Phys. Rev. Lett. 97, 157403 (2006).
where $C$ is the contour limiting the conducting wall’s cross-section. For the $H$-modes, with $E_z = 0$ but $H_z \neq 0$, the boundary condition is slightly less obvious and may be obtained using, for example, the second equation of the system (100), vector-multiplied by $n_z$. Indeed, for the component perpendicular to the conductor surface, the result of such multiplication is

$$ik_z(H_t)_n - \frac{k}{Z}(n_z \times E_t)_n = \frac{\partial H_z}{\partial n}.$$  \hfill (7.125)

But the first term on the left-hand side of this relation must be zero on the wall surface, because of the second of Eqs. (104), while according to the first of Eqs. (104), the vector $E_t$ in the second term cannot have a component tangential to the wall. As a result, the vector product in that term cannot have a normal component, so that the term should equal zero as well, and Eq. (125) is reduced to

$$\frac{\partial H_z}{\partial n} \bigg|_C = 0.$$ \hfill (7.126)

Let us see how does all this machinery work for a simple but practically important case of a metallic-wall waveguide with a rectangular cross-section – see Fig. 22

In the natural Cartesian coordinates, shown in this figure, both Eqs. (101) take the simple form

$$\left(\frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} + k_t^2\right)f = 0,$$

where $f = \begin{cases} E_z, & \text{for } E\text{-modes,} \\ H_z, & \text{for } H\text{-modes.} \end{cases}$ \hfill (7.127)

From Chapter 2 we know that the most effective way of solution of such equations in a rectangular region is the variable separation, in which the general solution is represented as a sum of partial solutions of the type

$$f = X(x)Y(y).$$ \hfill (7.128)

Plugging this expression into Eq. (127), and dividing each term by $XY$, we get the equation,

$$\frac{1}{X} \frac{d^2X}{dx^2} + \frac{1}{Y} \frac{d^2Y}{dy^2} + k_t^2 = 0,$$ \hfill (7.129)

which should be satisfied for all values of $x$ and $y$ within the waveguide’s interior. This is only possible if each term of the sum equals a constant. Taking the $X$-term and $Y$-term constants in the form $(-k_x^2)$ and
(\(-k_i^2\)), respectfully, and solving the corresponding ordinary differential equations,\(^{54}\) for the eigenfunction (128) we get
\[
f = (c_x \cos k_x x + s_x \sin k_x x)(c_y \cos k_y y + s_y \sin k_y y), \quad \text{with } k_x^2 + k_y^2 = k_i^2,
\] (7.130)
where the constants \(c\) and \(s\) should be found from the boundary conditions. Here the difference between the \(H\)-modes and \(E\)-modes comes in.

For the \(H\)-modes, Eq. (130) is valid for \(Hz\), and we should use the boundary condition (126) on all metallic walls of the waveguide, i.e. at \(x = 0\) and \(a\); and \(y = 0\) and \(b\) – see Fig. 22. As a result, we get very simple expressions for eigenfunctions and eigenvalues:
\[
(H_z)_{nm} = H_z \cos \frac{\pi nx}{a} \cos \frac{\pi my}{b},
\] (7.131)
\[
k_x = \frac{\pi n}{a}, \quad k_y = \frac{\pi m}{b}, \quad \text{so that } (k_i)_{nm} = (k_x^2 + k_y^2)^{1/2} = \pi \left[ \left( \frac{n}{a} \right)^2 + \left( \frac{m}{b} \right)^2 \right]^{1/2},
\] (7.132)
where \(H_z\) is the longitudinal field’s amplitude, and \(n\) and \(m\) are two integer numbers – arbitrary besides that they cannot be equal to zero simultaneously.\(^{55}\) Assuming, for certainty, that \(a \geq b\) (as shown in Fig. 22), we see that the lowest eigenvalue of \(k_i\), and hence the lowest cutoff frequency (123), is achieved for the so-called \(H_{10}\) mode with \(n = 1\) and \(m = 0\), and hence with
\[
(k_i)_{10} = \frac{\pi}{a},
\] (7.133)
thus confirming our prior estimate of \(k_i\).

Depending on the \(a/b\) ratio, the second-lowest \(k_i\) (and hence \(\omega_k\)) belong to either the \(H_{11}\) mode with \(n = 1\) and \(m = 1\):
\[
(k_i)_{11} = \pi \left( \frac{1}{a^2} + \frac{1}{b^2} \right)^{1/2} \equiv \left[ 1 + \left( \frac{a}{b} \right)^2 \right]^{1/2} (k_i)_{10},
\] (7.134)
or to the \(H_{20}\) mode with \(n = 2\) and \(m = 0\):
\[
(k_i)_{20} = \frac{2\pi}{a} \equiv 2(k_i)_{10}.
\] (7.135)
These values become equal at \(a/b = \sqrt{3} \approx 1.7\); in practical waveguides, the \(a/b\) ratio is not too far from this value. For example, in the standard X-band (~10-GHz) waveguide WR90, \(a \approx 2.3\) cm (\(f_{c} \equiv \omega_k/2\pi \approx 6.5\) GHz), and \(b \approx 1.0\) cm.

Now let us have a look at the alternative \(E\)-modes. For them, we still should use the general solution (130) with \(f = Ez\), but now with the boundary condition (124). This gives us the eigenfunctions

\(^{54}\) Let me hope that the solution of equations of the type \(d^2X/dx^2 + k_x^2X = 0\) does not present any problem for the reader, at least due to their prior experience with problems such as standing waves on a guitar string, wavefunctions in a flat 1D quantum well, or (with the replacement \(x \rightarrow t\)) a classical harmonic oscillator.

\(^{55}\) Otherwise, the function \(H_z(x,y)\) would be constant, so that, according to Eq. (121), the transverse components of the electric and magnetic field would equal zero. As a result, as the last two lines of Eqs. (100) show, the whole field would be zero for any \(k_z \neq 0\).
\[
(E_z)_{nm} = E_i \sin \frac{\pi nx}{a} \sin \frac{\pi my}{b},
\]
(7.136)

and the same eigenvalue spectrum (132) as for the \( H \) modes. However, now neither \( n \) nor \( m \) can be equal to zero; otherwise Eq. (136) would give the trivial solution \( E_z(x,y) = 0 \). Hence the lowest cutoff frequency of \( TM \) waves is achieved at the so-called \( E_{11} \) mode with \( n = 1 \), \( m = 1 \), and with the eigenvalue given by Eq. (134), always higher than \( (k_t)_{10} \).

Thus the fundamental \( H_{10} \) mode is certainly the most important wave in rectangular waveguides; let us have a better look at its field distribution. Plugging the corresponding solution (131) with \( n = 1 \) and \( m = 0 \) into the general relation (121), we easily get

\[
(H_x)_{10} = -i \frac{k_z a}{\pi} H_i \sin \frac{\pi x}{a}, \quad (H_y)_{10} = 0,
\]
(7.137)

\[
(E_z)_{10} = 0, \quad (E_y)_{10} = i \frac{ka}{\pi} Z H_i \sin \frac{\pi x}{a}.
\]
(7.138)

This field distribution is (schematically) shown in Fig. 22. Neither of the fields depends on the coordinate \( y \) – the feature very convenient, in particular, for microwave experiments with small samples. The electric field has only one (in Fig. 22, vertical) component that vanishes at the side walls and reaches its maximum at the waveguide’s center; its field lines are straight, starting and ending on wall surface charges (whose distribution propagates along the waveguide together with the wave). In contrast, the magnetic field has two non-vanishing components \( (H_x \) and \( H_z) \), and its field lines are shaped as horizontal loops wrapped around the electric field maxima.

An important question is whether the \( H_{10} \) wave may be usefully characterized by a unique impedance introduced similarly to \( Z_W \) of the TEM modes – see Eq. (115). The answer is \textit{not}, because the main value of \( Z_W \) is a convenient description of the impedance matching of a transmission line with a lumped load – see Fig. 19 and Eq. (118). As was discussed above, such a simple description is possible (i.e., does not depend on the exact geometry of the connection) only if both dimensions of the line’s cross-section are much less than \( \lambda \). But for the \( H_{10} \) wave (and more generally, any non-TEM mode) this is impossible – see, e.g., Eq. (129): its lowest frequency corresponds to the TEM wavelength \( \lambda_{max} = 2 \pi (k_t)_{min} = 2 \pi (k_t)_{10} = 2a \). (The reader is challenged to find a simple interpretation of this equality.)

Now let us consider metallic-wall waveguides with a round cross-section (Fig. 23a). In this single-connected geometry, the TEM waves are impossible again, while for the analysis of \( H \)-modes and \( E \)-modes, the polar coordinates \( \{\rho, \varphi\} \) are most natural. In these coordinates, the 2D Helmholtz equation (101) takes the following form:

\[
\left[ \frac{1}{\rho} \frac{\partial}{\partial \rho} \left( \rho \frac{\partial}{\partial \rho} \right) + \frac{1}{\rho^2} \frac{\partial^2}{\partial \varphi^2} + k_i^2 \right] f = 0,
\]
where \( f = \begin{cases} E_z, & \text{for } E \text{- modes,} \\ H_z, & \text{for } H \text{- modes.} \end{cases} \)
(7.139)

Separating the variables as \( f = R(\rho) A(\varphi) \), we get

\[
\frac{1}{\rho R} \frac{d}{d \rho} \left( \rho \frac{d R}{d \rho} \right) + \frac{1}{\rho^2 A} \frac{d^2 A}{d \varphi^2} + k_i^2 = 0.
\]
(7.140)

But this is exactly the Eq. (2.127) that was studied in Sec. 2.7 in the context of electrostatics, just with a replacement of notation: \( \gamma \rightarrow k_i \). So we already know that in order to have \( 2 \pi \)-periodic functions \( A(\varphi) \),
and finite values \( R(0) \) (which are evidently necessary for our current case – see Fig. 23a), the general solution must have the form given by Eq. (2.136), i.e. the eigenfunctions are expressed via integer-order Bessel functions of the first kind:

\[
f_{nm} = J_n(k_{nm}\rho)(c_n \cos n\varphi + s_n \sin n\varphi) \equiv \text{const} \times J_n(k_{nm}\rho)\cos(n\varphi - \varphi_0),
\]

with the eigenvalues \( k_{nm} \) of the transverse wave number \( k_t \) to be determined from appropriate boundary conditions, and an arbitrary constant \( \varphi_0 \).

As for the rectangular waveguide, let us start from the \( H \)-modes (\( f = H_z \)). Then the boundary condition on the wall surface (\( \rho = R \)) is given by Eq. (126), which, for the solution (141), takes the form

\[
\frac{d}{d\xi} J_n(\xi) = 0, \quad \text{where} \quad \xi \equiv kR.
\]

This means that eigenvalues of Eq. (139) are

\[
k_i = k_{nm} = \frac{\xi'_{nm}}{R},
\]

where \( \xi'_{nm} \) is the \( m \)th zero of the function \( dJ_n(\xi)/d\xi \). The approximate values of these zeros for several lowest \( n \) and \( m \) may be read out from Fig. 2.18; their more accurate values are given in Table 1 below.

The table shows, in particular, that the lowest of the zeros is \( \xi'_{11} \approx 1.84 \). Thus, perhaps a bit counter-intuitively, the fundamental mode, providing the lowest cutoff frequency \( \omega_c = \nu k_{nm} \), is \( H_{11} \), corresponding to \( n = 1 \) rather than \( n = 0 \):

\[\text{Mathematically, the lowest root of Eq. (142) with } n = 0 \text{ equals } 0. \text{ However, it would yield } k = 0 \text{ and hence a constant field } H_z, \text{ which, according to the first of Eqs. (121), would give vanishing electric field.}\]
It has the transverse wave number is \( k_t = k_{11} = \xi'_{11}/R \approx 1.84/R \), and hence the cutoff frequency corresponding to the TEM wavelength \( \lambda_{\text{max}} = 2\pi k_{11} \approx 3.41 \, R \). Thus the ratio of \( \lambda_{\text{max}} \) to waveguide’s diameter \( 2R \) is about 1.7, i.e. is close to the ratio \( \lambda_{\text{max}}/a = 2 \) for the rectangular waveguide. The origin of this proximity is clear from Fig. 24, which shows the transverse field distribution in the \( H_{11} \) mode. (It may be readily calculated from Eqs. (121) with \( E_z = 0 \), and \( H_z \) given by Eq. (144).)

Fig. 7.24. Transverse field components in the fundamental \( H_{11} \) mode of a metallic, circular waveguide (schematically).

One can see that the field structure is actually very similar to that of the fundamental mode in the rectangular waveguide, shown in Fig. 22, despite the different nomenclature (which is due to the different coordinates used for the solution). However, note the arbitrary constant angle \( \varphi_0 \), indicating that in circular waveguides the transverse field’s polarization is arbitrary. For some practical applications, such degeneracy of these “quasi-linearly-polarized” waves creates problems; they may be avoided by using waves with circular polarization.

As Table 1 shows, the next lowest \( H \)-mode is \( H_{21} \), for which \( k_t = k_{21} = \xi'_{21}/R \approx 3.05/R \), almost twice larger than that of the fundamental mode, and only then comes the first mode with no angular dependence of any field, \( H_{01} \), with \( k_t = k_{01} = \xi'_{01}/R \approx 3.83/R \).

For the \( E \) modes, we may still use Eq. (141) (with \( f = E_z \)), but with the boundary condition (124) at \( \rho = R \). This gives the following equation for the problem eigenvalues:

\[
J_n(k_{nm}R) = 0, \quad \text{i.e.} \quad k_{nm} = \frac{\xi_{nm}}{R},
\]

where \( \xi_{nm} \) is the \( m \)-th zero of function \( J_n(\xi) \) – see Table 2.1. The table shows that the lowest \( k_t \) equals to \( \xi_{01}/R \approx 2.405/R \). Hence the corresponding mode \( (E_{01}) \), with

\[
E_z = E_iJ_0(\xi_{01}\frac{\rho}{R}),
\]

has the second-lowest cutoff frequency, ~30% higher than that of the fundamental mode \( H_{11} \).

Finally, let us discuss one more topic of general importance – the number \( N \) of electromagnetic modes that may propagate in a waveguide within a certain range of relatively large frequencies \( \omega >> \omega_k \).

\[\text{footnote continued}\]

57 The electric field lines in the \( H_{01} \) mode (as well as all higher \( H_{0m} \) modes) are directed straight from the symmetry axis to the walls, reminding those of the TEM waves in the coaxial cable. Due to this property, these modes provide, at \( \omega >> \omega_k \), much lower energy losses (see Sec. 9 below) than the fundamental \( H_{11} \) mode, and are sometimes used in practice, despite the inconvenience of working in the multimode frequency range.
It is easy to calculate for a rectangular waveguide, with its simple expressions (132) for the eigenvalues of \( \{k_x, k_y\} \). Indeed, these expressions describe a rectangular mesh on the \([k_x, k_y]\) plane, so that each point corresponds to the plane area \( \Delta A_k = (\pi/a)(\pi/b) \), and the number of modes in a large \( k \)-plane area \( A_k \gg \Delta A_k \) is \( N = A_k/\Delta A_k = abA_k/\pi^2 = AA_k/\pi^2 \), where \( A \) is the waveguide’s cross-section area.\(^{58}\) However, it is frequently more convenient to discuss transverse wave vectors \( \mathbf{k}_t \) of arbitrary direction, i.e. with an arbitrary sign of their components \( k_x \) and \( k_y \). Taking into account that the opposite values of each component actually give the same wave, the actual number of different modes of each type (\( E \)- or \( H \)-) is a factor of \( 2^2 = 4 \) lower than was calculated above. This means that the number of modes of both types is

\[
N = \frac{2 A_k A}{(2\pi)^2}.
\]

(7.147)

Let me leave it for the reader to find hand-waving (but convincing :-) arguments that this \textit{mode counting rule} is valid for waveguides with cross-sections of any shape, and any boundary conditions on the walls, provided that \( N \gg 1 \).

\subsection*{7.7. Dielectric waveguides, optical fibers, and paraxial beams}

Now let us discuss electromagnetic wave propagation in \textit{dielectric waveguides}. The simplest, \textit{step-index} waveguide (see Figs. 23b and 25) consists of an inner \textit{core} and an outer shell (in the optical fiber technology lingo, called \textit{cladding}) with a higher wave propagation speed, i.e. lower index of refraction:

\[
v_+ > v_- \quad \text{i.e.} \quad n_+ < n_- \quad k_+ < k_- \quad \epsilon_+ \mu_+ < \epsilon_- \mu_-.
\]

(7.148)

at the same frequency. (In most cases the difference is achieved due to that in the electric permittivity, \( \epsilon_- < \epsilon_+ \), while magnetically both materials are virtually passive: \( \mu_+ \approx \mu_\perp \approx \mu_0 \), so that their refraction indices \( n_\pm \), defined by Eq. (84), are very close to \( (\epsilon_\pm/\epsilon_0)^{1/2} \); I will limit my discussion to this approximation.)

The basic idea of the waveguide operation may be readily understood in the limit when the wavelength \( \lambda \) is much smaller than the characteristic size \( R \) of the core’s cross-section. If this “geometric optics” limit, at the distances of the order of \( \lambda \) from the core-to-cladding interface, which determines the wave reflection, we can approximate the interface with a plane. As we know from Sec. 4, if the angle \( \theta \) of the wave’s incidence on such an interface is larger than the critical value \( \theta_c \) specified by Eq. (85), the wave is totally reflected. As a result, the waves launched into the fiber core at such “grazing” angles, propagate inside the core, repeatedly reflected from the cladding – see Fig. 25.

\[\text{"cladding" } \epsilon_+, \mu_+ \]  
\[\text{"core" } \epsilon_-, \mu_- \]  
\[\theta \]

Fig. 7.25. Wave propagation in a thick optical fiber.

\(^{58}\) This formula ignores the fact that, according to our analysis, some modes (with \( n = 0 \) and \( m = 0 \) for \( H \) modes, and \( n = 0 \) or \( m = 0 \) for \( E \) modes) are forbidden. However, for \( N \gg 1 \), the associated corrections of Eq. (147) are negligible.
The most important type of dielectric waveguides are optical fibers.\(^{59}\) Due to a heroic technological effort, in about three decades starting from the mid-1960s, the attenuation of such fibers has been decreased from the values of the order of 20 db/km (typical for the window glass) to the fantastically low values about 0.2 db/km (meaning virtually perfect transparency of 10-km-long fiber segments!), combined with the extremely low plane-wave (so-called chromatic) dispersion below 10 ps/km-nm.\(^{60}\) In conjunction with the development of inexpensive erbium-based quantum amplifiers, this breakthrough has enabled inter-city and inter-continental (undersea), broadband\(^{61}\) optical cables, which are the backbone of all the modern telecommunication infrastructure.

The only bad news is that these breakthroughs were achieved for just one kind of materials (silica-based glasses)\(^{62}\) within a very narrow range of their chemical composition. As a result, the dielectric constants \(\kappa_\pm \equiv \varepsilon_\pm/\varepsilon_0\) of the cladding and core of practical optical fibers are both close to 2.2 \((n_\pm \approx 1.5)\) and hence very close to each other, so that the relative difference of the refraction indices,

\[
\Delta \equiv \frac{n_+ - n_-}{n_-} = \frac{\sqrt{\epsilon_+} - \sqrt{\epsilon_-}}{\sqrt{\epsilon_-}} \approx \frac{\epsilon_- - \epsilon_+}{2\epsilon_-},
\]

is typically below 0.5%. This factor limits the fiber bandwidth. Indeed, let us use the geometric-optics picture to calculate the number of quasi-plane-wave modes that may propagate in the fiber. For the complementary angle (Fig. 25)

\[
\vartheta \equiv \frac{\pi}{2} - \vartheta, \quad \text{so that} \quad \sin \vartheta = \cos \vartheta,
\]

Eq. (85) gives the following propagation condition:

\[
\cos \vartheta > \frac{n_+}{n_-} = 1 - \Delta.
\]

In the limit \(\Delta \ll 1\), when the incidence angles \(\theta > \theta_c\) of all propagating waves are very close to \(\pi/2\), and hence the complementary angles are small, we can keep only two first terms in the Taylor expansion of the left-hand side of Eq. (151) and get

\[
\vartheta_{\text{max}}^2 \approx 2\Delta.
\]

\(^{60}\) Both these parameters have the best values not in the visible light range (from 380 to 740 nm), but in the near-infrared, with the attenuation lowest between approximately 1,500 and 1,630 nm. As a result, two windows – the so-called C-band (1,530-1,565 nm) and L-band (1,570-1,610 nm) – are used in modern communication systems.

\(^{61}\) Each of the frequency bands mentioned above, at a typical signal-to-noise ratio \(S/N > 10^5\), corresponds to the Shannon bandwidth \(\Delta f \log_2(S/N)\) exceeding \(10^{14}\) bits per second, some five orders of magnitude (!) higher than that of a modern Ethernet cable. The practically usable bandwidth of each fiber is somewhat lower, but an optical cable, with many fibers in parallel, has a proportionately higher aggregate bandwidth. A recent (circa 2017) example is the C-band transatlantic (6,600-km-long) cable *Marea*, with eight fiber pairs and the aggregate useable bandwidth of 160 Tbits per second.

\(^{62}\) The silica-based fibers were developed in 1966 by an industrial group led by C. Kao (who shared the 2009 Nobel Prize in physics), but the very idea of using optical fibers for long-range communications may be traced back at least to the 1963 work by J. Nishizawa – who also invented semiconductor lasers.
(Even for the higher-end value $\Delta = 0.005$, this critical angle is only $\sim 0.1$ radian, i.e. close to $5^\circ$.) Due to this smallness, we may approximate the maximum transverse component of the wave vector as

$$(k_x)_{\text{max}} = k(\sin \theta)_{\text{max}} \approx k \theta_{\text{max}} \approx \sqrt{2} k \Delta,$$

and use Eq. (147) to calculate the number $N$ of propagating modes:

$$N \approx \frac{2(\pi R^2)(\pi k^2 \theta_{\text{max}}^2)}{(2\pi)^2} = (kR)^2 \Delta. \quad (7.154)$$

For typical values $k = 0.73 \times 10^7$ m$^{-1}$ (corresponding to the free-space wavelength $\lambda_0 = n \lambda = 2 \pi n / k \approx 1.3 \mu$m), $R = 25 \mu$m, and $\Delta = 0.005$, this formula gives $N \approx 150$.

Now we can calculate the \textit{geometric dispersion} of such a fiber, i.e. the difference of the mode propagation speed, which is commonly characterized in terms of the difference between the wave delay times (traditionally measured in picoseconds per kilometer) of the fastest and the slowest mode. Within the geometric optics approximation, the difference of time delays of the fastest mode (with $k_z = k$) and the slowest mode (with $k_z = k \sin \theta_c$) at distance $l$ is

$$\Delta t = \Delta \left( \frac{l}{v_z} \right) = \Delta \left( \frac{k l}{\omega} \right) = \frac{l}{\omega} \Delta k_z = \frac{l}{v} (1 - \sin \theta_c) = \frac{l}{v} \left( 1 - \frac{n_z}{n_c} \right) = \frac{l}{v} \Delta. \quad (7.155)$$

For the example considered above, the TEM wave speed in the glass, $v = c/n \approx 2 \times 10^8$ m/s, and the geometric dispersion $\Delta t / l$ is close to 25 ps/m, i.e. 25,000 ps/km. (This means, for example, that a 1-ns pulse, being distributed between the modes, would spread to a $\sim 25$-ns pulse after passing a just 1-km fiber segment.) This result should be compared with chromatic dispersion mentioned above, below 10 ps/km-nm, which gives $\Delta t / l$ is of the order of only 1,000 ps/km in the whole communication band $\Delta \lambda \sim 100$ nm. Due to this reason, such relatively thick ($2R \sim 50 \mu$m) \textit{multi-mode fibers}, with high geometric dispersion, are used for the transfer of signals power over only short distances below $\sim 100$ m. (In return, they may carry relatively large power, beyond 10 mW.)

Long-range telecommunications are based on \textit{single-mode fibers}, with thin cores (typically with diameters $2R \sim 5 \mu$m, i.e. of the order of $\lambda / \Delta_{1/2}^{1/2}$). For such structures, Eq. (154) yields $N \sim 1$, but in this case the geometric optics approximation is not quantitatively valid, and for the fiber analysis, we should get back to the Maxwell equations. In particular, this analysis should take into an explicit account the evanescent wave in the cladding, because its penetration depth may be comparable with $R$.\textsuperscript{63}

Since the cross-section of an optical fiber lacks metallic walls, the Maxwell equations describing them cannot be exactly satisfied with either TEM-wave, or $H$-mode, or $E$-mode solutions. Instead, the fibers can carry the so-called $HE$ and $EH$ modes, with both vectors $\mathbf{H}$ and $\mathbf{E}$ having longitudinal components simultaneously. In such modes, both $E_z$ and $H_z$ inside the core ($\rho \leq R$) have a form similar to Eq. (141):

\textsuperscript{63} The following quantitative analysis of the single-mode fibers is very valuable – both for practice, and as a very good example of Maxwell equations’ solution. However, its results will not be used in the following parts of the course, so that if the reader is not interested in this topic, she or he may safely jump to the text following Eq. (181). (I believe that the discussion of the angular momentum of electromagnetic radiation, starting at that point, is compulsory for every professional physicist.)
\[ f_- = f_+ J_n(k, \rho) \cos(\phi - \phi_0), \quad \text{where} \quad k^2_- = k^2_z - k^2_+ > 0, \quad \text{and} \quad k^2_- \equiv \omega^2 \varepsilon_\mu - \mu, \quad (7.156) \]

where the constant angles \( \phi_0 \) may be different for each field. On the other hand, for the evanescent wave in the cladding, we may rewrite Eqs. (101) as

\[ (\nabla^2 - \kappa^2) f_+ = 0, \quad \text{where} \quad \kappa^2_\pm = k^2_z - k^2_\pm > 0, \quad \text{and} \quad k^2_\pm \equiv \omega^2 \varepsilon_\pm \mu. \tag{7.157} \]

Figure 26 illustrates these relations between \( k_0, \kappa, k_z, \) and \( k_\pm \); note that the following sum,

\[ k^2_\pm + \kappa^2_\pm = \omega^2 (\varepsilon_- - \varepsilon_+) \mu_0 \sim 2k^2\Delta, \tag{7.158} \]

is fixed (at a given frequency) and, for typical fibers, is very small \( \ll k^2_\pm \). In particular, Fig. 26 shows that neither of \( k_\pm \) and \( \kappa \) can be larger than \( \phi [(\varepsilon_- - \varepsilon_+) \mu_0]^{1/2} = (2\Delta)^{1/2} k \). This means that the depth \( \delta = 1/\kappa \) of the wave penetration into the cladding is at least \( 1/(2\Delta)^{1/2} = \lambda/2\pi(2\Delta)^{1/2} \gg \lambda/2\pi \). This is why the cladding layers in practical optical fibers are made as thick as \( \sim 50 \mu \text{m} \), so that only a negligibly small tail of this evanescent wave field reaches their outer surfaces.

In the polar coordinates, Eq. (157) becomes

\[ \left[ \frac{1}{\rho} \frac{\partial}{\partial \rho} \left( \rho \frac{\partial}{\partial \rho} \right) + \frac{1}{\rho^2} \frac{\partial^2}{\partial \phi^2} - \kappa^2_\pm \right] f_+ = 0, \quad (7.159) \]

- the equation to be compared with of Eq. (139) for the circular metallic-wall waveguide. From Sec. 2.7 we know that the eigenfunctions of Eq. (159) are the products of the sine and cosine functions of \( n\phi \) by a linear combination of the modified Bessel functions \( I_n \) and \( K_n \), shown in Fig. 2.22, now of the argument \( \kappa \rho \). The fields have to vanish at \( \rho \to \infty \), so that only the latter functions (of the second kind) can participate in the solution:

\[ f_+ \propto K_n(\kappa \rho) \cos(\phi - \phi_0). \tag{7.160} \]

Now we have to reconcile Eqs. (156) and (160), using the boundary conditions at \( \rho = R \) for both longitudinal and transverse components of both fields, with the latter components first calculated using Eqs. (121). Such a conceptually simple, but a bit bulky calculation (which I am leaving for the reader’s exercise), yields a system of two linear, homogeneous equations for the complex amplitudes \( E_1 \) and \( H_1 \), which are compatible if

\[ \left( \frac{k^2}{k_1} J_n' + \frac{k^2}{\kappa_1} K_n' \right) \left( \frac{1}{k_1} J_n' + \frac{1}{\kappa_1} K_n' \right) = \frac{n^2}{R^2} \left( \frac{k^2}{k_1} + \frac{k^2}{\kappa_1} \right) \left( \frac{1}{k_1} + \frac{1}{\kappa_1} \right), \quad (7.161) \]

where the prime signs (as a rare exception in this series) denote the derivatives of each function over its full argument: \( k_1 \rho \) for \( J_n \), and \( \kappa_1 \rho \) for \( K_n \).
For any given frequency \( \omega \), the system of equations (158) and (161) determines the values of \( k_t \) and \( \kappa_t \), and hence \( k_z \). Actually, for any \( n > 0 \), this system provides two different solutions: one corresponding to the so-called \( HE \) wave, with a larger ratio \( E_z/H_z \), and the \( EH \) wave, with a smaller value of that ratio. For angular-symmetric modes with \( n = 0 \) (for whom we might naively expect the lowest cutoff frequency), the equations may be satisfied by the fields having just one non-zero longitudinal component (either \( E_z \) or \( H_z \)), so that the \( HE \) modes are the usual \( E \) waves, while the \( EH \) modes are the \( H \) waves. For the \( H \) modes, the characteristic equation is reduced to the requirement that the second parentheses on the left-hand side of Eq. (161) equals to zero. Using the Bessel function identities \( J'_0 = -J_1 \) and \( K'_0 = -K_1 \), this equation may be rewritten in a simpler form:

\[
\frac{1}{k_t} \frac{J_1(k_tR)}{J_0(k_tR)} = -\frac{1}{\kappa_t} \frac{K_1(\kappa_tR)}{K_0(\kappa_tR)}.
\]  

(7.162)

Using the simple relation between \( k_t \) and \( \kappa_t \), given by Eq. (158), we may plot both sides of Eq. (162) as functions of the same argument, say, \( \xi = k_tR \) – see Fig. 27.

![Fig. 7.27. Two sides of the characteristic equation (162), plotted as functions of \( k_tR \), for two values of its dimensionless parameter: \( \varphi = 8 \) (blue line) and \( \varphi = 3 \) (red line). Note that according to Eq. (158), the argument of the functions \( K_0 \) and \( K_1 \) is \( k_tR = [\varphi^2 - (k_tR)^2]^{1/2} = (\varphi^2 - \xi^2)^{1/2}. \)

The right-hand side of Eq. (162) depends not only on \( \xi \), but also on the dimensionless parameter \( \varphi \) defined as the normalized right-hand side of Eq. (158):

\[
\varphi^2 \equiv \omega^2 (\varepsilon_+ - \varepsilon_-) \mu_0 R^2 \approx 2\Delta k_+^2 R^2.
\]  

(7.163)

(According to Eq. (154), if \( \varphi >> 1 \), it gives twice the number \( N \) of the fiber modes – the conclusion confirmed by Fig. 27, taking into account that it describes only the \( H \) modes.) Since the ratio \( K_1/K_0 \) is positive for all values of the functions’ argument (see, e.g., the right panel of Fig. 2.22), the right-hand side of Eq. (162) is always negative, so that the equation may have solutions only in the intervals where the ratio \( J_1/J_0 \) is negative, i.e. at

\[
\xi_{01} < k_tR < \xi_{11}, \quad \xi_{02} < k_tR < \xi_{12},...,\]

(7.164)

where \( \xi_{nm} \) is the \( m \)-th zero of the function \( J_n(\xi) \) – see Table 2.1. The right-hand side of the characteristic equation (162) diverges at \( \kappa_tR \to 0 \), i.e. at \( k_tR \to \varphi \), so that no solutions are possible if \( \varphi \) is below the critical value \( \varphi_c = \xi_{01} \approx 2.405 \). At this cutoff point, Eq. (163) yields \( k_+ \approx \xi_{01}/R(2\Delta)^{1/2}. \) Hence, the cutoff frequency of the lowest \( H \) mode corresponds to the TEM wavelength
For typical parameters $\Delta = 0.005$ and $R = 2.5 \ \mu m$, this result yields $\lambda_{\text{max}} \approx 0.65 \ \mu m$, corresponding to the free-space wavelength $\lambda_0 \approx 1 \ \mu m$. A similar analysis of the first parentheses on the left-hand side of Eq. (161) shows that at $\Delta \to 0$, the cutoff frequency for the $E$ modes is similar.

This situation may look exactly like that in metallic-wall waveguides, with no waves possible at frequencies below $\omega_c$, but this is not so. The basic reason for the difference is that in the metallic waveguides, the approach to $\omega_c$ results in the divergence of the longitudinal wavelength $\lambda_z \equiv 2\pi/k_z$. On the other hand, in dielectric waveguides, the approach leaves $\lambda_z$ finite ($k_z \to k$). Due to this difference, a certain linear superposition of $HE$ and $EH$ modes with $n = 1$ can propagate at frequencies well below the cutoff frequency for $n = 0$, which we have just calculated.\textsuperscript{64} This mode, in the limit $\varepsilon_+ \approx \varepsilon_-$ (i.e. $\Delta \ll 1$) allows a very interesting and simple description using the Cartesian (rather than polar) components of the fields, but still expressed as functions of the polar coordinates $\rho$ and $\phi$. The reason is that this mode is very close to a linearly polarized TEM wave. (Due to this reason, this mode is referred to as $LP_{01}$.)

Let us select the $x$-axis parallel to the transverse component of the magnetic field vector at $\rho = 0$, so that $E_x|_{\rho = 0} = 0$, but $E_y|_{\rho = 0} \neq 0$, and $H_x|_{\rho = 0} \neq 0$, but $H_y|_{\rho = 0} = 0$. The only suitable solutions of the 2D Helmholtz equation (that should be obeyed not only by $z$-components of the field, but also their $x$- and $y$-components) are proportional to $J_0(k_\rho \rho)$, with zero coefficients for $E_x$ and $H_y$:

$$E_x = 0, \quad E_y = E_0 J_0(k_\rho \rho), \quad H_z = H_0 J_0(k_\rho \rho), \quad H_y = 0, \quad \text{for } \rho \leq R.$$  \hspace{1cm} (7.166)\textsuperscript{LP$_{01}$ mode}

Now we can use the last two equations of Eqs. (100) to calculate the longitudinal components of the fields:

$$E_z = \frac{1}{-ik_z} \frac{\partial E_y}{\partial \rho} = -i \frac{k_z}{k_\rho} E_0 J_1(k_\rho \rho) \sin \phi, \quad H_z = \frac{1}{-ik_z} \frac{\partial H_x}{\partial \rho} = -i \frac{k_z}{k_\rho} H_0 J_1(k_\rho \rho) \cos \phi,$$

where I have used the mathematical identities $J'_0 = -J_1$, $\partial \rho / \partial x = x/\rho = \cos \phi$, and $\partial \rho / \partial y = y/\rho = \sin \phi$. As a sanity check, we see that the longitudinal component or each field is a (legitimate!) eigenfunction of the type (141), with $n = 1$. Note also that if $k_\rho \ll k_z$ (this relation is always true if $\Delta \ll 1$ -- see either Eq. (158) or Fig. 26), the longitudinal components of the fields are much smaller than their transverse counterparts, so that the wave is indeed very close to the TEM one. Because of that, the ratio of the electric and magnetic field amplitudes is also close to that in the TEM wave: $E_0/H_0 \approx Z \approx Z_r$.

Now in order to satisfy the boundary conditions at the core-cladding interface ($\rho = R$), we need to have a similar angular dependence of these components at $\rho \geq R$. The longitudinal components of the fields are tangential to the interface and thus should be continuous. Using the solutions similar to Eq. (160) with $n = 1$, we get

$$E_z = -i \frac{k_z}{k_\rho} J_1(k_\rho R) E_0 K_1(\kappa R) \sin \phi, \quad H_z = -i \frac{k_z}{k_\rho} J_1(k_\rho R) H_0 K_1(\kappa R) \cos \phi, \quad \text{for } \rho \geq R. \quad (7.168)$$

\textsuperscript{64} This fact becomes less surprising if we recall that in the circular metallic waveguide, discussed in Sec. 6, the fundamental mode ($H_{11}$, see Fig. 23) also corresponded to $n = 1$ rather than $n = 0$.\hspace{1cm}
For the transverse components, we should require the continuity of the normal magnetic field $\mu H_n$, for our simple field structure equal to just $\mu H_x \cos \varphi$, of the tangential electric field $E_\tau = E_y \sin \varphi$, and of the normal component of $D_n = \varepsilon E_n = \varepsilon E_y \cos \varphi$. Assuming that $\mu = \mu_+ = \mu_0$, and $\varepsilon \approx \varepsilon_-$, we can satisfy these conditions with the following solutions:

$$E_x = 0, \quad E_y = \frac{J_0(k_y R)}{K_0(\kappa R)} E_0 K_0(\kappa, \rho), \quad H_x = \frac{J_0(k_y R)}{K_0(\kappa R)} H_0 K_0(\kappa, \rho), \quad H_y = 0, \quad \text{for } \rho \geq R. \quad (7.169)$$

From here, we can calculate components from $E_z$ and $H_z$, using the same approach as for $\rho \leq R$:

$$E_z = \frac{1}{-ik_z} \frac{\partial E_y}{\partial \varphi} = -i \frac{k_z}{k_y} J_0(k_y R) E_0 K_1(\kappa, \rho) \sin \varphi,$$

$$H_z = \frac{1}{-ik_z} \frac{\partial H_x}{\partial \varphi} = -i \frac{k_z}{k_y} J_0(k_y R) H_0 K_1(\kappa, \rho) \cos \varphi, \quad \text{for } \rho \geq R. \quad (7.170)$$

We see that these relations provide the same functional dependence of the fields as Eqs. (167), i.e. the internal and external fields are compatible, but their amplitudes at the interface coincide only if

$$J_1(k_y R) / J_0(k_y R) = K_1(\kappa R) / K_0(\kappa R). \quad (7.171)$$

This characteristic equation (which may be also derived from Eq. (161) with $n = 1$ in the limit $\Delta \to 0$) looks close to Eq. (162), but functionally is much different from it – see Fig. 28.

![Fig. 7.28. Two sides of the characteristic equation (171) for the \textit{LP}_{01} mode, plotted as a function of $k_y R$, for two values of the dimensionless parameter: $\varphi = 8$ (blue line) and $\varphi = 1$ (red line).](image)

Indeed, its right-hand side is always positive, and the left-hand side tends to zero at $k_y R \to 0$. As a result, Eq. (171) may have a solution for arbitrary small values of the parameter $\varphi$, defined by Eq. (163), i.e. for \textit{arbitrary low frequencies} (large wavelengths). This is why this mode is used in practical

---

65 It is the core assumption of this approximate theory, which accounts only for the most important effect of the small difference of dielectric constants $\varepsilon_+$ and $\varepsilon_-$. For more discussion of the accuracy of this approximation and some exact results, let me refer the interested reader either to the monograph by A. Snyder and D. Love, \textit{Optical Waveguide Theory}, Chapman and Hill, 1983, or to Chapter 3 and Appendix B in the monograph by Yariv and Yeh, which was cited above.
single-mode fibers: there are no other modes with wavelength larger than $\lambda_{\text{max}}$ given by Eq. (165), so that they cannot be unintentionally excited on small inhomogeneities of the fiber.

It is easy to use the Bessel function approximations by the first terms of the Taylor expansions (2.132) and (2.157) to show that in the limit $\mathcal{V} \to 0$, $\kappa R$ tends to zero much faster than $k R \approx \mathcal{V}$: $\kappa R \to 2\exp\{-1/\mathcal{V}\} \ll \mathcal{V}$. This means that the scale $\rho_c \equiv 1/\kappa$ of the radial distribution of the $LP_{01}$ wave’s fields in the cladding becomes very large. In this limit, this mode may be interpreted as a virtually TEM wave propagating in the cladding, just slightly deformed (and guided) by the fiber’s core. The drawback of this feature is that it requires a very thick cladding, to avoid energy losses in its outer (“buffer” and “jacket”) layers that defend the silica layers from the elements, but lack their low optical absorption. Due to this reason, the core radius is usually selected so that the parameter $\mathcal{V}$ is just slightly less than the critical value $\mathcal{V}_c = \mathcal{V}_{01} \approx 2.4$ for higher modes, thus ensuring the single-mode operation.

In order to reduce the field spread into the cladding, the step-index fibers discussed above may be replaced with graded-index fibers whose dielectric constant $\varepsilon$ is gradually and slowly decreased from the center to the periphery. 66 Keeping only the main two terms in the Taylor expansion of the function $s(\rho)$ at $\rho = 0$, we may approximate such reduction as

$$\varepsilon(\rho) \approx \varepsilon(0)(1 - \zeta \rho^2), \quad (7.172)$$

where $\zeta = -[(d^2\varepsilon/d\rho^2)/2\varepsilon]_{\rho=0}$ is a positive constant characterizing the fiber composition gradient.67 Moreover, if this constant is sufficiently small ($\zeta \ll k^2$), the field distribution across the fiber’s cross-section may be described by the same 2D Helmholtz equation (101), but with the space-dependent transverse wave vector: 68

$$[V_i^2 + k_i^2(\rho)]f = 0, \quad (7.173)$$

where

$$k_i^2(\rho) = k_i^2(\rho) - k_i^2(0) \equiv k_i^2(0) - k_i^2(0)\zeta \rho^2, \quad \text{and} \quad k_i^2(0) \equiv \omega^2\varepsilon(0)\mu_0.$$

Surprisingly for such an axially-symmetric problem, because of its special dependence on the radius, this equation may be most readily solved in Cartesian coordinates. Indeed, rewriting it as

$$\left[\frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} + k_i^2(0) - k_i^2(0)\zeta (x^2 + y^2)\right]f = 0, \quad (7.174)$$

and separating the variables as $f = X(x)Y(y)$, we get

$$\frac{1}{X} \frac{d^2X}{d x^2} + \frac{1}{Y} \frac{d^2Y}{d y^2} + k_i^2(0) - k_i^2(0)\zeta (x^2 + y^2) = 0, \quad (7.175)$$

so that the functions $X$ and $Y$ obey similar differential equations, for example

66 Due to difficulties of fabrication of graded-index fibers with wave attenuation below a few dm/km, they are not used as broadly as the step-index ones.

67 For an axially-symmetric smooth function $s(\rho)$, the first derivative $ds/d\rho$ always vanishes at $\rho = 0$, so that Eq. (172) does not have a term linear in $\rho$.

68 Such approach is invalid at arbitrary (large) $\zeta$, because in the macroscopic Maxwell equations, $s(\mathbf{r})$ is under the differentiation sign, and the exact Helmholtz-type equations for fields have additional terms containing $\nabla s$. 
\[
\frac{d^2 X}{dx^2} + \left[ k_x^2 - k^2(0) \zeta^2 \right] X = 0, \quad (7.176)
\]

with the separation constants satisfying the following relation:
\[
k_x^2 + k_y^2 = k_z^2(0) \equiv k^2(0) - k_x^2. \quad (7.177)
\]

The ordinary differential equation (176) is well known from the elementary quantum mechanics, because the Schrödinger equation for the perhaps most important basic quantum system, a 1D harmonic oscillator, may be rewritten in this form. Its eigenvalues are described by a simple formula
\[
(k_n^2) = k(0) \zeta^{1/2} (2n + 1), \quad (k_m^2) = k(0) \zeta^{1/2} (2m + 1), \quad \text{with } n, m = 0, 1, 2, ..., \quad (7.178)
\]
but eigenfunctions \(X_n(x)\) and \(Y_m(y)\) have to be expressed via not quite elementary functions – the Hermite polynomials.\(^{69}\) For most practical purposes, however, the lowest eigenfunctions \(X_0(x)\) and \(Y_0(y)\) are sufficient, because they correspond to the lowest \(k_{x,y}\) and hence the lowest
\[
\left[ k_x^2(0) \right]_{\text{min}} = (k_x^2)_0 + (k_y^2)_0 = 2k(0) \zeta^{1/2}, \quad (7.179)
\]
and the lowest cutoff frequency. As may be readily verified by substitution to Eq. (176), the eigenfunctions corresponding to this fundamental mode are simple:
\[
X_0(x) = \text{const} \times \exp \left\{ - \frac{k(0) \zeta^{1/2} x^2}{2} \right\}, \quad (7.180)
\]
and similarly for \(Y_0(y)\), so that the field distribution follows the Gaussian function
\[
f_0(\rho) = f_0(0) \exp \left\{ - \frac{k(0) \zeta^{1/2} \rho^2}{2} \right\} = f_0(0) \exp \left\{ - \frac{\rho^2}{2a^2} \right\}, \quad \text{with } a \equiv [k(0)]^{-1/2} \zeta^{-1/4}, \quad (7.181)
\]
where \(a >> 1/k(0)\) has the sense of the effective width of the field’s extension in the radial direction, normal to the wave propagation axis \(z\). This is the so-called \(\text{Gaussian beam}\), very convenient for some applications.

The Gaussian beam (181) is just one example of the so-called \(\text{paraxial beams}\), which may be represented as a result of modulation of a plane wave with a wave number \(k\), by an axially-symmetric \(\text{envelope function} f(\rho)\), where \(\rho = \{x, y\}\), with a relatively large effective radius \(a >> 1/k\).\(^{70}\) Such beams give me a convenient opportunity to deliver on the promise made in Sec. 1: calculate the angular momentum \(L\) of a circularly polarized wave, propagating in free space, and prove its fundamental relation to the wave’s energy \(U\). Let us start from the calculation of \(U\) for a paraxial beam (with an arbitrary, but spatially-localized envelope \(f\)) of the circularly polarized waves, with the transverse electric field components given by Eq. (19):
\[
E_x = E_0 f(\rho) \cos \psi, \quad E_y = \mp E_0 f(\rho) \sin \psi, \quad (7.182a)
\]

\(^{69}\) See, e.g., QM Sec. 2.9.

\(^{70}\) Note that propagating in a uniform medium, i.e. outside of grade-index fibers or other focusing systems, such beams gradually increase their width \(a\) due to diffraction – the effect to be analyzed in the next chapter.
where \(E_0\) is the real amplitude of the wave’s electric field at the propagation axis, \(\psi \equiv kz - \omega t + \varphi\) is its total phase, and the two signs correspond to two possible directions of the circular polarization. According to Eq. (6), the corresponding transverse components of the magnetic field are

\[
H_x = \pm \frac{E_0}{Z_0} f(\rho) \sin \psi, \quad H_y = \frac{E_0}{Z_0} f(\rho) \cos \psi. \tag{7.182b}
\]

These expressions are sufficient to calculate the energy density (6.113) of the wave,

\[
u = \frac{\varepsilon_0}{2} \left( \frac{E_x^2 + E_y^2}{2} + \frac{\mu_0}{2}(H_x^2 + H_y^2) \right) = \frac{\varepsilon_0}{2} \frac{E_0^2}{Z_0^2} f^2 + \frac{\mu_0}{2} \frac{E_0^2}{Z_0^2} f^2 = \varepsilon_0 \frac{E_0^2}{Z_0^2} f^2, \tag{7.183}
\]

and hence the full energy (per unit length in the direction \(z\) of the wave’s propagation) of the beam:

\[
U = \int ud^2r = 2\pi \int_0^\infty \nu \rho d\rho = 2\pi \varepsilon_0 E_0^2 \int_0^\infty f^2 \rho d\rho. \tag{7.184}
\]

However, the transverse fields (182) are insufficient to calculate a non-vanishing average of \(L\). Indeed, following the angular moment’s definition in mechanics, \(L \equiv \mathbf{r} \times \mathbf{p}\), where \(\mathbf{p}\) is a particle’s (linear) momentum, we may use Eq. (6.115) for the electromagnetic field momentum’s density \(\mathbf{g}\) in free space, to define the field’s angular momentum’s density as

\[
\mathbf{l} \equiv \mathbf{r} \times \mathbf{g} \equiv \frac{1}{c^2} \mathbf{r} \times \mathbf{S} \equiv \frac{1}{c^2} \mathbf{r} \times (\mathbf{E} \times \mathbf{H}). \tag{7.185}
\]

Let us use the familiar \textit{bac minus cab} rule of the vector algebra to transform this expression to

\[
\mathbf{l} = \frac{1}{c^2} \left[ \mathbf{E}(\mathbf{r} \cdot \mathbf{H}) - \mathbf{H}(\mathbf{r} \cdot \mathbf{E}) \right] = \frac{1}{c^2} \left[ n_z [E_z(\mathbf{r} \cdot \mathbf{H}) - H_z(\mathbf{r} \cdot \mathbf{E})] + [E_y(\mathbf{r} \cdot \mathbf{H}) - H_y(\mathbf{r} \cdot \mathbf{E})] \right]. \tag{7.186}
\]

If the field is purely transverse \((E_z = H_z = 0)\), as it is in a strictly plane wave, the first square brackets in the last expression vanish, while the second bracket gives an azimuthal component of \(\mathbf{l}\), which oscillates in time, and vanishes at its time averaging. (This is exactly the reason why I have not tried to calculate \(L\) at our first discussion of the circularly-polarized waves in Sec. 1.)

Fortunately, our discussion of optical fibers, in particular, the derivation of Eqs. (167), (168), and (170), gives us a clear clue on how to solve this paradox. If the envelope function \(f(\rho)\) differs from a constant, the transverse wave components (182) alone do not satisfy the Maxwell equations (2b), which necessitate longitudinal components \(E_z\) and \(H_z\) of the fields, with

71 For our task of calculation of two \textit{quadratic} forms of the fields (\(L\) and \(U\)), their real representation (182) is more convenient than the complex-exponent one. However, for \textit{linear} manipulations, the latter representation of the circularly-polarized waves, \(E_x = E_0 f(\rho) \text{Re}(n_x + i n_y) \exp \{i \psi\})\), \(H_x = (E_0/Z_0) f(\rho) \text{Re}(\bar{\mathbf{n}}_x + n_y) \exp \{i \psi\})\), is usually more convenient, and is broadly used.
72 Note that, in contrast to a linearly-polarized wave (16), the energy density of a circularly-polarized wave does not depend on the full phase \(\psi\) – in particular, on \(t\) at fixed \(z\), or vice versa. This is natural, because its field vectors rotate (keeping their magnitude) rather than oscillate – see Fig. 3b.
73 See, e.g., CM Eq. (1.31).
74 See, e.g., MA Eq. (7.5).
75 The complex-exponential versions of these equalities are given by the bottom line of Eq. (100).
\[
\frac{\partial E_z}{\partial z} = -\frac{\partial E_y}{\partial x} - \frac{\partial E_x}{\partial y}, \quad \frac{\partial H_y}{\partial z} = -\frac{\partial H_z}{\partial x} - \frac{\partial H_x}{\partial y}.
\] (7.187)

However, as these expressions show, if the envelope function \( f \) changes very slowly in the sense \( df/d\rho \sim f/\rho << kf \), the longitudinal components are very small and do not have a back effect on the transverse components, so that the above calculation of \( U \) is still valid (asymptotically, at \( ka \to 0 \)). Hence, we may still use Eqs. (182) on the right-hand side of Eqs. (187),

\[
\frac{\partial E_z}{\partial z} = E_0 \left(-\frac{\partial f}{\partial x} \cos \psi \pm \frac{\partial f}{\partial y} \sin \psi \right), \quad \frac{\partial H_y}{\partial z} = \frac{E_0}{Z_0} \left(\mp \frac{\partial f}{\partial x} \sin \psi - \frac{\partial f}{\partial y} \cos \psi \right),
\] (7.188)

and integrate them over \( z \) as

\[
E_z = E_0 \int \left(-\frac{\partial f}{\partial x} \cos \psi \pm \frac{\partial f}{\partial y} \sin \psi \right) \, dz = E_0 \left(-\frac{\partial f}{\partial x} \int \cos \psi \, d\psi \pm \frac{\partial f}{\partial y} \int \sin \psi \, d\psi \right)
\] (7.189a)

Here the integration constant is taken for zero, because no wave field component may have a time-independent part. Integrating, absolutely similarly, the second of Eqs. (188), we get

\[
E_z = \frac{E_0}{k} \left(-\frac{\partial f}{\partial x} \sin \psi \mp \frac{\partial f}{\partial y} \cos \psi \right).
\] (7.189b)

With the same approximation, we may calculate the longitudinal (\( z \)-) component of \( l \), given by the first term of Eq. (186), keeping only the dominating, transverse fields (182) in the scalar products:

\[
l_z = E_z (\mathbf{r} \cdot \mathbf{H}_z) - H_z (\mathbf{r} \cdot \mathbf{E}_z) \equiv E_z (xH_z + yH_y) - H_z (xE_x + yE_y).
\] (7.190)

Plugging in Eqs. (182) and (189), and taking into account that in free space, \( k = \omega / c \), and hence \( 1/Z_0 c^2 k = \epsilon / \omega^2 \), we get:

\[
l_z = \mp \frac{E_0 E_0^2}{2\omega} \left[ \frac{\partial}{\partial x} \left( f^2 \right) + \frac{\partial}{\partial y} \left( f^2 \right) \right] \equiv \mp \frac{E_0 E_0^2}{2\omega} \mathbf{p} \cdot \nabla (f^2) \equiv \mp \frac{E_0 E_0^2}{2\omega} \rho \frac{d(f^2)}{d\rho}.
\] (7.191)

Hence the total angular momentum of the beam (per unit length), is

\[
L_z = \int l_z d^2r = 2\pi \int_0^\infty l_z \rho d\rho = \mp \frac{E_0 E_0^2}{\omega} \int_0^\infty \rho^2 \frac{d(f^2)}{d\rho} d\rho = \mp \frac{E_0 E_0^2}{\omega} \int_0^\infty \rho^2 f^2 d\rho.
\] (7.192)

Taking this integral by parts, with the assumption that \( \rho f \to 0 \) at \( \rho \to 0 \) and \( \rho \to \infty \) (at it is true for the Gaussian beam (181) and all realistic paraxial beams), we finally get

\[
L_z = \pm \frac{\pi E_0 E_0^2}{\omega} \int_0^\infty f^2 d(\rho^2) \equiv \pm \frac{\pi E_0 E_0^2}{\omega} \int_0^\infty f^2 \rho^2 d\rho.
\] (7.193)

Now comparing this expression with Eq. (184), we see that remarkably, the ratio \( L_z/U \) does not depend on the shape and the width of the beam (and of course on the wave’s amplitude \( E_0 \)), so these parameters are very simply and universally related:
\[ L_z = \pm \frac{U}{\omega}. \] (7.194)

Since this relation is valid in the plane-wave limit \( a \to \infty \), it may be attributed to plane waves as well, with the understanding that in real life they always have sort of the wave width ("aperture") restriction.

As the reader certainly knows, in quantum mechanics the energy excitations of any harmonic oscillator of frequency \( \omega \) are quantized in the units of \( \hbar \omega \), while the components of the internal angular momentum of a particle are quantized in the units of \( s \hbar \), where \( s \) is its spin. In this context, the classical relation (194) is used in quantum electrodynamics as the basis for treating the electromagnetic field excitation quanta (photons) as a sort of quantum particles with spin \( s = 1 \). (Such integer spin also fits the Bose-Einstein statistics of the electromagnetic radiation.)

Unfortunately, I do not have time for a further discussion of the (very interesting) physics of paraxial beams, but cannot help noticing, at least in passing, the very curious effect of helical waves – the beams carrying not only the “spin” momentum (194), but also an additional “orbital” angular momentum. The distribution of their energy in space is not monotonic, as in the Gaussian beam (181), but reminds several threads twisted around the propagation axis – hence the term “helical”.

Mathematically, this structure is described by the associate Laguerre polynomials – the same special functions that are used for the quantum-mechanical description of hydrogen-like atoms. Presently there are efforts to use such beams for the so-called orbital angular momentum (OAM) multiplexing for high-rate information transmission.

7.8. Resonators

Resonators are distributed oscillators, i.e. structures that may sustain standing waves (in electrodynamics, oscillations of the electromagnetic field) even without a source, until the oscillation amplitude slowly decreases in time due to unavoidable energy losses. If the resonator quality (described by the so-called Q-factor, which will be defined and discussed in the next section) is high, \( Q \gg 1 \), this decay takes many oscillation periods. Alternatively, high-Q resonators may sustain oscillating fields permanently, if fed with a relatively weak incident wave.

Conceptually the simplest resonator is the Fabry-Pérot interferometer that may be obtained by placing two well-conducting planes parallel to each other. Indeed, in Sec. 3 we have seen that if a plane wave is normally incident on such a “perfect mirror”, located at \( z = 0 \), its reflection, at negligible skin depth, results in a standing wave described by Eq. (61b):

\[ E(z,t) = \text{Re}\left(2E_0e^{-i\omega t+i\frac{\pi}{2}}\right)\sin kz. \] (7.195)

\[ \text{Noticing such solutions of the Maxwell equations may be traced back to at least the 1943 theoretical work by J. Humblet; however, this issue had not been discussed in literature too much until experiments carried out in 1992 – see, e.g., L. Allen et al., Optical Angular Momentum; IOP, 2003.} \]

\[ \text{See, e.g., QM Sec. 3.7.} \]

\[ \text{See, e.g., J. Wang et al., Nature Photonics 6, 488 (2012).} \]

\[ \text{The device is named after its inventors, Charles Fabry and Alfred Pérot; is also called the Fabry-Pérot etalon (meaning “gauge”), because of its initial usage for the light wavelength measurements.} \]

\[ \text{The resonators formed by well conducting (usually, metallic) walls are frequently called the resonant cavities.} \]
Hence the wave would not change if we had suddenly put the second mirror (isolating the segment of length \( l \) from the external wave source) at any position \( z = l \) with \( \sin kl = 0 \), i.e. with

\[
kl = p\pi, \quad \text{where } p = 1, 2, \ldots.
\]

This condition, which determines the spectrum of eigen- (or own-, or resonance-) frequencies of the resonator of fixed length \( l \),

\[
\omega_p = v k_p = \frac{\pi v}{a} p, \quad \text{with } v = \frac{1}{(\varepsilon\mu)^{1/2}},
\]

has a simple physical sense: the resonator’s length \( l \) equals exactly \( p \) half-waves of the frequency \( \omega_p \).

Though this is all very simple, please note a considerable change of philosophy from what we have been doing in the previous sections: the main task of resonator’s analysis is finding its eigenfrequencies \( \omega_p \) that are now determined by the system geometry rather than by an external wave source.

Before we move to more complex resonators, let us use Eq. (62) to represent the magnetic field in the Fabry-Pérot interferometer:

\[
H(z,t) = \Re \left( 2 \frac{E_\omega}{Z} e^{-i\omega t} \right) \cos k z.
\]

Expressions (195) and (198) show that in contrast to traveling waves, each field of the standing wave changes simultaneously (proportionately) at all points of the Fabry-Pérot resonator, turning to zero everywhere twice a period. At the instants when the energy of the corresponding field vanishes, but the total energy of oscillations stays constant, because the counterpart field oscillates with the phase shift \( \pi/2 \). Such behavior is typical for all electromagnetic resonators.

Another, more technical remark is that we can readily get the same results (195)-(198) by solving the Maxwell equations from scratch. For example, we already know that in the absence of dispersion, losses, and sources, they are reduced to the wave equations (3) for any field components. For the Fabry-Pérot resonator’s analysis, we can use the 1D form of these equations, say, for the transverse component of the electric field:

\[
\left( \frac{\partial^2}{\partial z^2} - \frac{1}{v^2} \frac{\partial^2}{\partial t^2} \right) E = 0,
\]

and solve it as a part of an eigenvalue problem with the corresponding boundary conditions. Indeed, separating time and space variables as \( E(z, t) = Z(z) \tilde{\tau}(t) \), we get

\[
\frac{1}{Z} \frac{d^2 Z}{dz^2} - \frac{1}{v^2} \frac{1}{\tilde{\tau}} \frac{d^2 \tilde{\tau}}{dt^2} = 0.
\]

Calling the separation constant \( k^2 \), we get two similar ordinary differential equations,

\[
\frac{d^2 Z}{dz^2} + k^2 Z = 0, \quad \frac{d^2 \tilde{\tau}}{dt^2} + k^2 v^2 \tilde{\tau} = 0,
\]

both with sinusoidal solutions, so that the product \( Z(z) \tilde{\tau}(t) \) is a standing wave with the wave vector \( k \) and frequency \( \omega = kv \). (In this form, the equations are valid even in the presence of dispersion, but with a
frequency-dependent wave speed: \( v^2 = 1/\varepsilon(\omega)\mu(\omega) \). Now using the boundary conditions \( E(0, t) = E(l, t) = 0 \), we get the eigenvalue spectrum for \( k_p \) and hence for \( \omega_p = vk_p \), given by Eqs. (196) and (197).

Lessons from this simple case study may be readily generalized for an arbitrary resonator: there are (at least :-) two approaches to finding the eigenfrequency spectrum:

(i) We may look at a traveling wave solution and find where reflecting mirrors may be inserted without affecting the wave’s structure. Unfortunately, this method is limited to simple geometries.

(ii) We may solve the general 3D wave equations,

\[
\left( \nabla^2 - \frac{1}{v^2} \frac{\partial^2}{\partial t^2} \right) f(\mathbf{r}, t) = 0, \quad (7.202)
\]

for field components, as an eigenvalue problem with appropriate boundary conditions. If system parameters (and hence the coefficient \( v \)) do not change in time, the spatial and temporal variables of Eq. (202) may be always separated by taking

\[
f(\mathbf{r}, t) = \mathcal{R}(\mathbf{r}) \mathcal{T}(t), \quad (7.203)
\]

where the function \( \mathcal{T}(t) \) always obeys the same equation as in Eq. (201), having the sinusoidal solution of frequency \( \omega = vk \). Plugging this solution back into Eqs. (202), for the spatial distribution of the field, we get the 3D Helmholtz equation,

\[
\left( \nabla^2 + k^2 \right) \mathcal{R}(\mathbf{r}) = 0, \quad (7.204)
\]

whose solution (for non-symmetric geometries) may be much more complex.

Let us use these approaches to find the eigenfrequency spectrum of a few simple, but practically important resonators. First of all, the first method is completely sufficient for the analysis of any resonator formed as a fragment of a uniform TEM transmission line (e.g., a coaxial cable), confined with two conducting lids normal to the line’s direction. Indeed, since in such lines \( k_z = k = \omega/c \), and the electric field is perpendicular to the propagation axis, e.g., parallel to the lid surface, the boundary conditions are exactly the same as in the Fabry-Pérot resonator, and we again arrive at the eigenfrequency spectrum (197).

Now let us analyze a slightly more complex system: a rectangular metallic-wall cavity of volume \( a \times b \times l \) – see Fig. 29.

\[
81 \text{ This is of course the expression of the first of the general boundary conditions (104). The second of these conditions (for the magnetic field) is satisfied automatically for the transverse waves we are considering.}
\]
To use the first approach outlined above, let us consider the resonator as a finite-length ($\Delta z = l$) section of the rectangular waveguide stretched along axis $z$, which was analyzed in detail in Sec. 6. As a reminder, at $a < b$, in the fundamental $H_{10}$ traveling wave mode, both vectors $\mathbf{E}$ and $\mathbf{H}$ do not depend on $y$, with $\mathbf{E}$ having only a $y$-component. In contrast, $\mathbf{H}$ has two components, $H_x$ and $H_z$, with the phase shift $\pi/2$ between them, and with $H_z$ having the same phase as $E_y$ – see Eqs. (131), (137), and (138). Hence, if a plane, perpendicular to the $z$-axis, is placed so that the electric field vanishes on it, $H_z$ also vanishes, so that both boundary conditions (104), pertinent to a perfect metallic wall, are fulfilled simultaneously.

As a result, the $H_{10}$ wave would not be perturbed by two metallic walls separated by an integer number of half-wavelengths $\lambda/2$ corresponding to the wave number given by the combination of Eqs. (102) and (133):

$$k_z = \left( k^2 - k_1^2 \right)^{1/2} = \left( \frac{\omega^2}{v^2} - \frac{\pi^2}{a^2} \right),$$

Using this expression, we see that the smallest of these distances, $l = \lambda/2 = \pi k_z$, gives the resonance frequency$^{82}$

$$\omega_{101} = \sqrt{\left( \frac{\pi}{a} \right)^2 + \left( \frac{\pi}{l} \right)^2}^{1/2},$$

where the indices of $\omega$ show the numbers of half-waves along each dimension of the system, in the order $[a, b, l]$. This is the lowest (fundamental) eigenfrequency of the resonator (if $b < a, l$).

The field distribution in this mode is close to that in the corresponding waveguide mode $H_{10}$ (Fig. 22), with the important difference that the magnetic and electric fields are now shifted by phase $\pi/2$ both in space and time, just as in the Fabry-Pérot resonator – see Eqs. (195) and (198). Such a time shift allows for a very simple interpretation of the $H_{101}$ mode, which is especially adequate for very flat resonators, with $b << a, l$. At the instant when the electric field reaches its maximum (Fig. 30a), i.e. when the magnetic field vanishes in the whole volume, the surface electric charge of the walls (with the areal density $\sigma = E_x/\epsilon$) is largest, being localized mostly in the middle of the broadest (in Fig. 30, horizontal) faces of the resonator. At the immediate later times, the walls start to recharge via surface currents whose density $J$ is largest in the side walls, and reaches its maximal value in a quarter of the oscillation period $T = 2\pi/\omega_{101}$ – see Fig. 30b.

---

$^{82}$ In most electrical engineering handbooks, the index corresponding to the shortest side of the resonator is listed last, so that the fundamental mode is nominated as $H_{110}$ and its eigenfrequency as $\omega_{110}$. 

---
The currents generate the vortex magnetic field, with looped field lines in the plane of the broadest face of the resonator. The surface currents continue to flow in this direction until (in one more quarter period) the broader walls of the resonator are fully recharged in the polarity opposite to that shown in Fig. 30a. After that, the surface currents start to flow in the direction opposite to that shown in Fig. 30b. This process, which repeats again and again, is conceptually similar to the well-known oscillations in a lumped $LC$ circuit, with the role of (now, distributed) capacitance played mostly by the broadest faces of the resonator, and that of (now, distributed) inductance, mostly by its narrower walls.

In order to generalize the result (206) to higher oscillation modes, the second of the approaches discussed above is more prudent. Separating the variables as $\xi(\mathbf{r}) = X(x)Y(y)Z(z)$ in the Helmholtz equation (204), we see that $X$, $Y$, and $Z$ have to be either sinusoidal or cosinusoidal functions of their arguments, with wave vector components satisfying the characteristic equation

$$k_x^2 + k_y^2 + k_z^2 = k^2 \equiv \frac{\omega^2}{v^2}.$$  \hfill (7.207)

In contrast to the wave propagation problem, now we are dealing with standing waves along all three dimensions, and have to satisfy the macroscopic boundary conditions (104) on all sets of parallel walls. It is straightforward to check that these conditions ($E_x = 0$, $H_n = 0$) are fulfilled at the following field component distribution:

\[
\begin{align*}
E_x &= E_1 \cos k_x x \sin k_y y \sin k_z z, & H_x &= H_1 \sin k_x x \cos k_y y \cos k_z z, \\
E_y &= E_2 \sin k_x x \cos k_y y \sin k_z z, & H_y &= H_2 \cos k_x x \sin k_y y \cos k_z z, \\
E_z &= E_3 \sin k_x x \sin k_y y \cos k_z z, & H_z &= H_3 \cos k_x x \cos k_y y \sin k_z z,
\end{align*}
\]

with each of the wave vector components having an equidistant spectrum, similar to Eq. (196):

\[
k_x = \frac{\pi n}{a}, \quad k_y = \frac{\pi m}{b}, \quad k_z = \frac{\pi p}{l}, \quad \text{so that the full spectrum of eigenfrequencies is given by the following formula,}
\]

\[
\omega_{\text{osc}} = vk = v \left[ \left( \frac{\pi n}{a} \right)^2 + \left( \frac{\pi m}{b} \right)^2 + \left( \frac{\pi p}{l} \right)^2 \right]^{1/2}, \quad \text{(7.210)}
\]

which is a natural generalization of Eq. (206). Note, however, that of 3 integers $m$, $n$, and $p$ at least two have to be different from zero, to keep the fields (206) from vanishing at all points.

We may use Eq. (210), in particular, to evaluate the number of different modes in a relatively small range $d^3k \ll k^3$ of the wave vector space, which is, on the other hand, much larger than the reciprocal volume, $1/V = 1/abl$, of the resonator. Taking into account that each eigenfrequency (210), with $nmpl \neq 0$, corresponds to two field modes with different polarizations,\(^{83}\) the argumentation absolutely similar to the one used at the end of Sec. 7 for the 2D case yields

\[
dN = 2V \frac{d^3k}{(2\pi)^3}. \quad \text{(7.211)}
\]

\(^{83}\) This fact becomes evident from plugging Eqs. (208) into the Maxwell equation $\nabla \cdot \mathbf{E} = 0$. The resulting equation, $k_x E_1 + k_y E_2 + k_z E_3 = 0$, with the discrete, equidistant spectrum (209) for each wave vector component, may be satisfied by two linearly independent sets of the constants $E_{1,2,3}$. \hfill Oscillation mode density
This property, valid for resonators of arbitrary shape, is broadly used in classical and quantum statistical physics,\textsuperscript{84} in the following form. If some electromagnetic mode functional, \( f(\mathbf{k}) \), is a smooth function of the wave vector \( \mathbf{k} \), and the volume \( V \) is large enough, then Eq. (211) may be used to approximate the sum of the functional’s values over the modes by an integral:

\[
\sum_{k} f(\mathbf{k}) \approx \int f(\mathbf{k}) dN = \int_{k} f(\mathbf{k}) \frac{dN}{d^3 k} d^3 k = 2 \frac{V}{(2\pi)^3} \int_{k} f(\mathbf{k}) d^3 k.
\]  

(7.212)

Leaving the similar analyses of resonant cavities of other shapes for the reader’s exercise, let me finish this section by noting that low-loss resonators may be also formed by finite-length sections of not only metallic-wall waveguides of various cross-sections, but also of the dielectric waveguides. Moreover, even a simple slab of a dielectric material with a \( \mu/\varepsilon \) ratio substantially different from that of its environment (say, the free space) may be used as a high-\( Q \) Fabry-Pérot interferometer (Fig. 31), due to an effective wave reflection from its surfaces at normal and especially inclined incidence – see, respectively, Eqs. (68), and Eqs. (91) and (95).

Actually, such dielectric Fabry-Pérot interferometers are frequently more convenient for practical purposes than metallic-wall resonators, not only due to possibly lower losses (especially in the optical range), but also due to a natural coupling to the environment, that enables a ready way of wave insertion and extraction – see Fig. 31 again. The backside of the same medal is that this coupling to the environment provides an additional mechanism of power losses, limiting the resonance quality – see the next section.

7.9. Energy loss effects

The inevitable energy losses (“dissipation”) in passive media lead, in two different situations, to two different effects. In a long transmission line fed by a constant wave source at one end, the losses lead to a gradual attenuation of the wave, i.e. to a decrease of its amplitude, and hence its power \( \mathcal{P} \), with the distance \( z \) along the line. In linear materials, the time-averaged power losses \( \mathcal{P}_{\text{loss}} \) are proportional to the time-averaged power \( \mathcal{P} \) carried by the wave, so that the energy balance on a small segment \( dz \) takes the form

\[
d\mathcal{P} = -\frac{d\mathcal{P}_{\text{loss}}}{dz} dz \equiv -\alpha \mathcal{P} dz.
\]  

(7.213)

The coefficient \( \alpha \), participating in the last form of Eq. (213) and defined by that relation:

\textsuperscript{84} See, e.g., QM Sec. 1.1 and SM Sec. 2.6.
\[ \alpha \equiv \frac{d\mathcal{R}_{\text{loss}}}{dz} \tag{7.214} \]

is called the attenuation constant.\(^{85}\) Comparing the solution of Eq. (213),

\[ \mathcal{P}(z) = \mathcal{P}(0)e^{-\alpha z} \tag{7.215} \]

with Eq. (29), where \( k \) is replaced with \( k_z \), we see that \( \alpha \) may be expressed as

\[ \alpha = 2\text{Im}k_z, \tag{7.216} \]

where \( k_z \) is the component of the wave vector along the transmission line. In the most important limit when the losses are low in the sense \( \alpha \ll |k_z| \approx \text{Re}k_z \), its effects on the field distribution along the line’s cross-section are negligible, making the calculation of \( \alpha \) rather straightforward. In particular, in this limit the contributions to attenuation from two major sources, energy losses in the filling dielectric, and the skin effect-losses in conducting walls, are independent and additive.

The dielectric losses are especially simple to describe. Indeed, a review of our calculations in Secs. 5-7 shows that all of them remain valid if either \( \varepsilon(\omega) \), or \( \mu(\omega) \), or both, and hence \( k(\omega) \), have small imaginary parts:

\[ k'' = \omega\text{Im}\left[\varepsilon^{1/2}(\omega)\mu^{1/2}(\omega)\right] \ll k'. \tag{7.217} \]

In TEM transmission lines, \( k_z = k \), and hence Eq. (216) yields

\[ \alpha_{\text{filling}} = 2k'' = 2\omega\text{Im}\left[\varepsilon^{1/2}(\omega)\mu^{1/2}(\omega)\right] \tag{7.218} \]

For dielectric waveguides, in particular optical fibers, these losses are the main attenuation mechanism. As we already know from Sec. 7, in practical optical fibers \( \kappa R >> 1 \), i.e. most of the field propagates (as an evanescent wave) in the cladding, with a field distribution very close to the TEM wave. This is why Eq. (218) is approximately valid if it is applied to the cladding material alone. In waveguides with non-TEM waves, we can readily use the relations between \( k_z \) and \( k \), derived in the previous sections, to re-calculate \( k'' \) into \( \text{Im}k_z \). (Note that at such a re-calculation, the values of \( k_t \) have to be kept real, because they are just the eigenvalues of the Helmholtz equation (101), which does not include the filling media parameters.).

In transmission lines and waveguides and with metallic walls, much higher energy losses may come from the skin effect. If the wavelength \( \lambda \) is much larger than \( \delta_s \), as it usually is,\(^{86}\) the losses may be readily evaluated using Eq. (6.36):

\[ \frac{d\mathcal{R}_{\text{loss}}}{dA} = H_{\text{wall}}^2 \frac{\mu_0 \delta_s^2}{4}, \tag{7.219} \]

\(^{85}\) In engineering, attenuation is frequently measured in decibels per meter, abbreviated as dB/m (not to be confused with dBm, standing for decibel-milliwatt):

\[ \alpha_{\text{db/m}} \equiv 10 \log_{10} \left| \frac{\mathcal{P}(z = 0)}{\mathcal{P}(z = 1 \text{m})} \right| = 10 \log_{10} e^{\alpha[1/\text{m}]} = \frac{10}{\ln 10} \alpha \left[ \text{m}^{-1} \right] \approx 4.34 \alpha \left[ \text{m}^{-1} \right]. \]

\(^{86}\) As follows from Eq. (78), which may be used for crude estimates even in cases of arbitrary incidence, this condition is necessary for low attenuation: \( \alpha \ll k \) only if \( \mathcal{J} \ll 1 \).
where \( H_{\text{wall}} \) is the real amplitude of the tangential component of the magnetic field at the wall’s surface. The total power loss \( \mathcal{P}_{\text{loss}}/dz \) per unit length of a waveguide, i.e. the right-hand side of Eq. (213), now may be calculated by the integration of this \( d\mathcal{P}_{\text{loss}}/dA \) along the contour(s) limiting the cross-section of all conducting walls. Since our calculation is only valid for low losses, we may ignore their effect on the field distribution, so that the unperturbed distributions may be used both in Eq. (219), i.e. in the numerator of Eq. (214), and also for the calculation of the average propagating power, i.e. the denominator of Eq. (214) – as the integral of the Poynting vector over the cross-section of the waveguide.

Let us see how this approach works for the TEM mode in one of the simplest transmission lines, the coaxial cable (Fig. 20). As we already know from Sec. 5, in the coarse-grain approximation (implying negligible power loss), the distribution of TEM mode fields is the same as in statics, namely:

\[
H_z = 0, \quad H_\rho = 0, \quad H_\varphi (\rho) = H_0 \frac{a}{\rho}, \quad (7.220)
\]

where \( H_0 \) is the field’s amplitude on the surface of the inner conductor, and

\[
E_z = 0, \quad E_\rho (\rho) = ZH_\varphi (\rho) = ZH_0 \frac{a}{\rho}, \quad E_\varphi = 0, \quad \text{where} \quad Z \equiv \left( \frac{\mu}{\varepsilon} \right)^{1/2}. \quad (7.221)
\]

Now we can, neglecting power losses for now, plug these expressions into Eq. (42) to calculate the time-averaged Poynting vector:

\[
\overline{S} = \frac{Z|H_\varphi(\rho)|^2}{2} = \frac{Z|H_0|^2}{2} \left( \frac{a}{\rho} \right)^2, \quad (7.222)
\]

and from it, the total wave power flow through the cross-section:

\[
\mathcal{P} = \int_A \overline{S} d^2 r = \frac{Z|H_0|^2}{2} a^2 2\pi \int_a^b d\rho \rho^2 = \pi Z|H_0|^2 a^2 \ln \frac{b}{a}. \quad (7.223)
\]

Next, for the particular case of the coaxial cable (Fig. 20), the contours limiting the wall cross-section are circles of radii \( \rho = a \) (where the surface field amplitude \( H_{\text{wall}} \) equals, in our notation, \( H_0 \)), and \( \rho = b \) (where, according to Eq. (214), the field is a factor of \( b/a \) lower). As a result, for the power loss per unit length, Eq. (219) yields

\[
\frac{d\mathcal{P}_{\text{loss}}}{dz} = \int_{C_a+C_b} \frac{d\mathcal{P}_{\text{loss}}}{dA} dl = \left( 2\pi|H_0|^2 + 2\pi b \frac{a}{b} H_0 \left( \frac{a}{b} \right)^2 \right) \frac{\mu_0 \omega \delta_s}{4} = \frac{\pi a}{2} \left( 1 + \frac{a}{b} \right) \mu_0 \omega \delta_s |H_0|^2. \quad (7.224)
\]

Note that at \( a \ll b \), the losses in the inner conductor dominate, despite its smaller surface, because of the higher surface field.

Now we may plug Eqs. (223) and (224) into the definition (214) of \( \alpha \), to calculate the skin-effect contribution to the attenuation constant:

\[
\alpha_{\text{skin}} \equiv \frac{d\mathcal{P}_{\text{loss}}/dz}{\mathcal{P}} = \frac{1}{2\ln(b/a)} \left( \frac{1}{a} + \frac{1}{b} \right) \frac{\mu_0 \omega \delta_s}{Z} \equiv \frac{k \delta_s}{2\ln(b/a)} \left( \frac{1}{a} + \frac{1}{b} \right). \quad (7.225)
\]
We see that the relative (dimensionless) attenuation, \( \alpha/k \), scales approximately as the ratio \( \delta_s/\min[a, b] \), in a semi-quantitative agreement with Eq. (78) for the normal incidence of a plane wave on a conducting surface.

Let us use this result to evaluate \( \alpha \) for the standard TV cable RG-6/U, with copper conductors of diameters \( 2a = 1 \) mm, \( 2b = 4.7 \) mm, and \( \varepsilon \approx 2.2\varepsilon_0, \mu \approx \mu_0 \). According to Eq. (6.33), for frequency \( f = 100 \) MHz (\( \omega \approx 6.3\times10^8 \text{ s}^{-1} \)) the skin depth of pure copper at room temperature (with \( \sigma \approx 6.0\times10^7 \text{ S/m} \)) is close to \( 6.5\times10^{-6} \) m, while \( k = \omega(\varepsilon_0\mu)^{1/2} = (\varepsilon_0\varepsilon)^{1/2}(\omega\mu/c) \approx 3.1 \) m\(^{-1} \). As a result, the attenuation is rather low: \( \alpha_{\text{skin}} \approx 0.016 \text{ m}^{-1} \), so that the attenuation length scale \( l_d \equiv 1/\alpha \) is about 60 m. Hence the attenuation in a cable connecting a roof TV antenna to a TV set in the same house is not a big problem, though using a worse conductor, e.g., steel, would make the losses rather noticeable. (Hence the current worldwide shortage of copper.) However, the use the same cable in the X-band (\( f \sim 10 \) GHz) is more problematic. Indeed, though the skin depth \( \delta_s \propto \omega^{-1/2} \) decreases with frequency, the wavelength drops, i.e. \( k \) increases, even faster (\( k \propto \omega \)), so that the attenuation \( \alpha_{\text{skin}} \propto \omega^{1/2} \) becomes close to 0.16 m\(^{-1} \), i.e. \( l_d \) to ~6 m. This is why at such frequencies, it may be necessary to use rectangular waveguides, with their larger internal dimensions \( a, b \sim 1/k \), and hence lower attenuation. Let me leave the calculation of this attenuation, using Eq. (219) and the results derived in Sec. 7, for the reader’s exercise.

The power loss effect on free oscillations in resonators is different: here it leads to a gradual decay of the oscillating fields’ energy \( U \) in time. A useful dimensionless measure of this decay, called the \( Q \) factor, may be introduced by writing the temporal analog of Eq. (213):

\[
\frac{dU}{dt} = -\frac{\omega}{Q} U dt \tag{7.226}
\]

where \( \omega \) in the eigenfrequency in the loss-free limit, and

\[
\frac{\omega}{Q} \equiv \frac{\alpha_{\text{loss}}}{U} \tag{7.227}
\]

is the temporal analog of Eq. (214). The solution of Eq. (226),

\[
U(t) = U(0)e^{-t/\tau}, \quad \text{with} \quad \tau \equiv \frac{Q}{\omega} = \frac{Q/2\pi}{\omega/2\pi} = \frac{Q\pi}{2\pi}, \tag{7.228}
\]

which is the temporal analog of Eq. (215), shows the physical meaning of the \( Q \)-factor: the characteristic time \( \tau \) of the oscillation energy’s decay is \( (Q/2\pi) \) times longer than the oscillation period \( T = 2\pi/\omega \).

(Another useful interpretation of \( Q \) comes from the relation\( Q = \frac{\omega}{\Delta\omega} \),\( \Delta\omega \) being the so-called \textit{FWHM} \( \textit{bandwidth} \) of the resonance, namely the difference between the two values of the external signal frequency, one above and one below \( \omega \), at which the energy of the forced oscillations induced in the resonator by an input signal is twice lower than its resonance value.)

---

87 As losses grow, the oscillation waveform deviates from sinusoidal one, and the very notion of “oscillation frequency” becomes vague. As a result, the parameter \( Q \) is well defined only if it is much higher than 1.
88 See, e.g., CM Sec. 5.1.
89 This is the acronym for “Full Width at Half-Maximum.”
In the important particular case of resonators formed by the insertion of metallic walls into a TEM transmission line of small cross-section (with the linear size scale \( a \) much less than the wavelength \( \lambda \)), there is no need to calculate the \( Q \)-factor directly, provided that the line attenuation coefficient \( \alpha \) is already known. In fact, as was discussed in Sec. 8 above, the standing waves in such a resonator, of the length given by Eq. (196): \( l = p(\lambda/2) \) with \( p = 1, 2, \ldots \), may be understood as an overlap of two TEM waves running in opposite directions, or in other words, a traveling wave plus its reflection from one of the ends, the whole roundtrip taking time \( \Delta t = 2l/v = p\lambda/v = 2\pi p/\omega = p\tau \). According to Eq. (215), at this distance, the wave’s power drops by the factor of \( \exp\{-2\alpha l\} = \exp\{-p\alpha \lambda\} \). On the other hand, the same decay may be viewed as taking place in time, and according to Eq. (228), results in the drop by \( \exp\{-\Delta t/\tau\} = \exp\{-p\tau/(Q/\omega)\} = \exp\{-2\pi p/Q\} \). Comparing these two exponents, we get

\[
Q = \frac{2\pi}{\alpha \lambda} = \frac{k}{\alpha} .
\]  

(7.230)

This simple relation neglects the losses at the wave reflection from the walls limiting the resonator length. Such approximation is indeed legitimate at \( a \ll \lambda \); if this relation is violated, or if we are dealing with more complex resonator modes (such as those based on the reflection of \( E \) or \( H \) waves), the \( Q \)-factor may be smaller than that given by Eq. (230), and needs to be calculated directly. A substantial relief for such a direct calculation is that, just at the calculation of small attenuation in waveguides, in the low-loss limit \( (Q >> 1) \), both the numerator and denominator of the right-hand side of Eq. (227) may be calculated neglecting the effects of the power loss on the field distribution in the resonator. I am leaving such a calculation, for the simplest (rectangular and circular) resonators, for the reader’s exercise.

To conclude this chapter, let me make the last remark: in some resonators (including certain dielectric resonators and metallic resonators with holes in their walls), additional losses due to the wave radiation into the environment are also possible. In some simple cases (say, the Fabry-Pérot interferometer shown in Fig. 31) the calculation of these radiative losses is straightforward, but sometimes it requires more elaborated approaches, which will be discussed in the next chapter.

### 7.10. Exercise problems

**7.1.** Find the temporal Green’s function of a medium whose complex dielectric constant obeys the Lorentz oscillator model given by Eq. (32), using:

- (i) the Fourier transform, and
- (ii) the direct solution of Eq. (30).

*Hint:* For the Fourier-transform approach, you may like to use the Cauchy integral.\(^{90}\)

**7.2.** The electric polarization of some material responds in the following way to an electric field step.\(^{91}\)

---

90 See, e.g., MA Eq. (15.2).

91 This function \( E(t) \) is of course proportional to the well-known step function \( \theta(t) \) – see, e.g., MA Eq. (14.3). I am not using this notion just to avoid possible confusion between two different uses of the Greek letter \( \theta \).
where \( \tau \) is a positive constant. Calculate the complex permittivity \( \varepsilon(\omega) \) of this material, and discuss a possible simple physical model giving such dielectric response.

7.3. Calculate the complex dielectric constant \( \varepsilon(\omega) \) for a material whose dielectric-response Green’s function, defined by Eq. (23), is

\[
G(\theta) = G_0 \left[ 1 - e^{-\theta/\tau} \right],
\]

with some positive constants \( G_0 \) and \( \tau \). What is the difference between this dielectric response and the apparently similar one considered in the previous problem?

7.4. Use the Lorentz oscillator model of an atom, given by Eq. (30), to calculate the average potential energy of the atom in a uniform, sinusoidal ac electric field, and use the result to calculate the potential profile created for the atom by a standing electromagnetic wave with the electric field amplitude \( E_\omega(r) \).

7.5. The solution of the previous problem shows that a standing plane wave exerts a time-averaged force on a non-relativistic charged particle. Reveal the physics of this force by writing and solving the equations of motion of a free, charged particle in:

(i) a linearly-polarized, monochromatic, plane traveling wave, and
(ii) a similar but standing wave.

7.6. Calculate, sketch, and discuss the dispersion relation for electromagnetic waves propagating in a medium described by Eq. (32), for the case of negligible damping.

7.7. As was briefly discussed in Sec. 2,\(^\text{92}\) a wave pulse of a finite but relatively large spatial extension \( \Delta z \gg \lambda \equiv 2\pi/k \) may be formed as a wave packet – a sum of sinusoidal waves with wave vectors \( k \) within a relatively narrow interval. Consider an electromagnetic plane wave packet of this type, with the electric field distribution

\[
E(r,t) = \text{Re} \int_{-\infty}^{\infty} E_k e^{i(kz - \omega_k t)} dk, \quad \text{with} \quad \omega_k \left[ \varepsilon(\omega_k) \mu(\omega_k) \right]^{1/2} \equiv |k|,
\]

propagating along the \( z \)-axis in an isotropic, linear, and loss-free (but not necessarily dispersion-free) medium. Express the full energy of the packet (per unit area of wave’s front) via the complex amplitudes \( E_k \), and discuss its dependence of time.

7.8.\(^\ast\) Analyze the effect of a constant, uniform magnetic field \( B_0 \), parallel to the direction \( \mathbf{n} \) of electromagnetic wave propagation, on the wave’s dispersion in plasma, within the same simple model that was used in Sec. 2 for the derivation of Eq. (38). (Limit your analysis to relatively weak waves, whose magnetic field is negligible in comparison with \( B_0 \).)

\(^{92}\) And in more detail in CM Sec. 5.3, and especially in QM Sec. 2.2.
Hint: You may like to represent the incident wave as a linear superposition of two circularly polarized waves, with opposite polarization directions.

7.9. A monochromatic, plane electromagnetic wave is normally incident, from free space, on a uniform slab of a material with electric permittivity $\varepsilon$ and magnetic permeability $\mu$, with the slab thickness $d$ comparable with the wavelength.

(i) Calculate the power transmission coefficient $\mathcal{T}$, i.e. the fraction of the incident power, that is transmitted through the slab.

(ii) Assuming that $\varepsilon$ and $\mu$ are frequency-independent and positive, analyze in detail the frequency dependence of $\mathcal{T}$. In particular, how does the function $\mathcal{T}(\omega)$ depend on the slab’s thickness $d$ and the wave impedance $Z = (\mu/\varepsilon)^{1/2}$ of its material?

7.10. A monochromatic, plane electromagnetic wave, with free-space wave number $k_0$, is normally incident on a plane, conducting film of thickness $d \sim \delta_s << 1/k_0$. Calculate the power transmission coefficient of the system, i.e. the fraction of incident wave’s power propagating beyond the film. Analyze the result in the limits of small and large ratio $d/\delta_s$.

7.11. A plane wave of frequency $\omega$ is normally incident, from free space, on a plane surface of a material with real electric permittivity $\varepsilon'$ and magnetic permeability $\mu'$. To minimize the wave reflection from the surface, you may cover it with a layer, of thickness $d$, of another transparent material – see the figure on the right. Calculate the optimal values of $\varepsilon$, $\mu$, and $d$.

7.12. A monochromatic, plane wave is incident from inside a medium with $\varepsilon\mu > \varepsilon_0\mu_0$ onto its plane surface, at an angle of incidence $\theta$ larger than the critical angle $\theta_c = \sin^{-1}(\varepsilon_0\mu_0/\varepsilon\mu)^{1/2}$. Calculate the depth $\delta$ of the evanescent wave penetration into the free space, and analyze its dependence on $\theta$. Does the result depend on the wave’s polarization?

7.13. Analyze the possibility of propagation of surface electromagnetic waves along a plane boundary between a plasma and the free space. In particular, calculate and analyze the dispersion relation of the waves.

Hint: Assume that the magnetic field of the wave is parallel to the boundary and perpendicular to the wave’s propagation direction. (After solving the problem, justify this mode choice.)
7.14. Light from a very distant source arrives to an observer through a plane layer of nonuniform medium with a certain refraction index distribution, \( n(z) \), at angle \( \theta_0 \) – see the figure on the right. What is the genuine direction \( \theta_i \) to the source, if \( n(z) \to 1 \) at \( z \to \infty \)? (This problem is evidently important for high-precision astronomical measurements from the Earth surface.)

7.15. Calculate the impedance \( Z_W \) of the long, straight TEM transmission lines formed by metallic electrodes with the cross-sections shown in the figure below:

(i) two round, parallel wires, separated by distance \( d \gg R \),
(ii) a microstrip line of width \( w \gg d \),
(iii) a stripline with \( w \gg d_1 \sim d_2 \),
in all cases using the coarse-grain boundary conditions on metallic surfaces. Assume that the conductors are embedded into a linear dielectric with constant \( \varepsilon \) and \( \mu \).

7.16. Modify the solution of Task (ii) of the previous problem for a superconductor microstrip line, taking into account the magnetic field penetration into both the strip and the ground plane.

7.17. What lumped ac circuit would be equivalent to the TEM-line system shown in Fig. 19, with an incident wave’s power \( P_i \)? Assume that the wave reflected from the lumped load circuit does not return to it.

7.18. Find the lumped ac circuit equivalent to a loss-free TEM transmission line of length \( l \sim \lambda \), with a small cross-section area \( A \ll \lambda^2 \), as “seen” (measured) from one end, if the line’s conductors are galvanically connected (“shortened”) at the other end – see the figure on the right. Discuss the result’s dependence on the signal frequency.

7.19. Represent the fundamental \( H_{10} \) wave in a rectangular waveguide (Fig. 22) with a sum of two plane waves, and discuss the physics behind such a representation.

7.20. For a metallic coaxial cable with the circular cross-section (Fig. 20), find the lowest non-TEM mode and calculate its cutoff frequency.
7.21. Two coaxial cable sections are connected coaxially – see the figure on the right, which shows the cut along the system’s symmetry axis. Relations (118) and (120) seem to imply that if the ratios \( b/a \) of these sections are equal, their impedance matching is perfect, i.e. a TEM wave incident from one side on the connection would pass it without any reflection at all: \( R = 0 \). Is this statement correct?

7.22. Prove that TEM-like waves may propagate, in the radial direction, in the free space between two coaxial, round, metallic cones – see the figure on the right. Can this system be characterized by a certain transmission line impedance \( Z_W \), as defined by Eq. (7.115)?

7.23. * Use the recipe outlined in Sec. 7 to prove the characteristic equation (161) for the \( HE \) and \( EH \) modes in a round, step-index optical fiber.

7.24. Neglecting the skin-effect depth \( \delta \), find the lowest eigenfrequencies, and the corresponding field distributions, of the standing electromagnetic waves inside a round cylindrical resonant cavity – see the figure on the right.

7.25. A plane, monochromatic wave propagates through a medium with an Ohmic conductivity \( \sigma \), and negligible electric and magnetic polarization effects. Calculate the wave’s attenuation, and relate the result with a certain calculation carried out in Chapter 6.

7.26. Generalize the telegrapher’s equations (110)-(111) by accounting for small energy losses:

(i) in the transmission line’s conductors, and

(ii) in the medium separating the conductors,

using their simplest (Ohmic) models. Formulate the conditions of validity of the resulting equations.

7.27. Calculate the skin-effect contribution to the attenuation coefficient \( \alpha \), defined by Eq. (214), for the fundamental \( (H_{10}) \) mode propagating in a metallic-wall waveguide with a rectangular cross-section – see Fig.22. Use the results to evaluate the wave decay length \( l_d \equiv 1/\alpha \) of a 10 GHz wave in the standard X-band waveguide WR-90 (with copper walls, \( a = 23 \) mm, \( b = 10 \) mm, and no dielectric filling), at room temperature. Compare the result with that, obtained in Sec. 9, for the standard TV coaxial cable, at the same frequency.

7.28. * Calculate the skin-effect contribution to the attenuation coefficient \( \alpha \) of

(i) the fundamental \( (H_{11}) \) wave, and

(ii) the \( H_{01} \) wave,

in a metallic-wall waveguide with the circular cross-section (see Fig. 23a), and analyze the low-frequency \( (\omega \rightarrow \omega_k) \) and high-frequency \( (\omega \gg \omega_k) \) behaviors of \( \alpha \) for each of these modes.
7.29. For a rectangular metallic-wall resonator with dimensions $a \times b \times l$ ($b \leq a, l$), calculate the $Q$-factor in the fundamental oscillation mode, due to the skin-effect losses in the walls. Evaluate the factor for a 23×23×10 mm$^3$ resonator with copper walls, at room temperature.

7.30. Calculate the lowest eigenfrequency and the $Q$-factor (due to the skin-effect losses) of the toroidal (axially-symmetric) resonator with metallic walls, and interior’s cross-section shown in the figure on the right, in the case when $d << r, R$.

7.31. Express the contribution to the damping coefficient (the reciprocal $Q$-factor) of a resonator, from small energy losses in the dielectric that fills it, via the complex functions $\varepsilon(\omega)$ and $\mu(\omega)$ of the material.

7.32. For the dielectric Fabry-Pérot resonator (Fig. 31) with the normal wave incidence, calculate the $Q$-factor due to radiation losses, in the limit of a strong impedance mismatch ($Z > Z_0$), using two approaches:

(i) from the energy balance, using Eq. (227), and
(ii) from the frequency dependence of the power transmission coefficient, using Eq. (229).

Compare the results.
Chapter 8. Radiation, Scattering, Interference, and Diffraction

This chapter continues the discussion of the electromagnetic wave propagation, now focusing on the results of wave incidence on various objects of more complex shapes. Depending on the shape, the result of this interaction is called either scattering, or diffraction, or interference. However, as the reader will see, the boundaries between these effects are blurry, and their mathematical description may be conveniently based on a single key calculation – the electric dipole radiation of a spherical wave by a localized source. Naturally, I will start the chapter from this calculation, deriving it from an even more general result – the “retarded-potential” solution of the Maxwell equations.

8.1. Retarded potentials

Let us start from finding the general solution of the macroscopic Maxwell equations (6.99) in a dispersion-free, linear, uniform, isotropic medium, characterized by frequency-independent, real ε and μ. The easiest way to perform this calculation is to use the scalar (φ) and vector (A) potentials of the electromagnetic field, that are defined via the electric and magnetic fields by Eqs. (6.7):

\[ \mathbf{E} = -\nabla \phi - \frac{\partial \mathbf{A}}{\partial t}, \quad \mathbf{B} = \nabla \times \mathbf{A}. \]  

As was discussed in Sec. 6.8, by imposing upon the potentials the Lorenz gauge condition (6.117),

\[ \nabla \cdot \mathbf{A} + \frac{1}{v^2} \frac{\partial \phi}{\partial t} = 0, \quad \text{with } v^2 \equiv \frac{1}{\varepsilon \mu}, \]  

which does not affect the fields \( \mathbf{E} \) and \( \mathbf{B} \), the Maxwell equations may be used to get a pair of very similar, simple equations (6.118) for the potentials:

\[ \nabla^2 \phi - \frac{1}{v^2} \frac{\partial^2 \phi}{\partial t^2} = -\frac{\rho}{\varepsilon}, \]  

\[ \nabla^2 \mathbf{A} - \frac{1}{v^2} \frac{\partial^2 \mathbf{A}}{\partial t^2} = -\mu \mathbf{j}. \]  

Let us find the general solution of these equations, thinking of the densities \( \rho(\mathbf{r}, t) \) and \( \mathbf{j}(\mathbf{r}, t) \) of the stand-alone charges and currents as of known functions. (This will not prevent the results from being valid for the cases when \( \rho(\mathbf{r}, t) \) and \( \mathbf{j}(\mathbf{r}, t) \) should be calculated self-consistently.) The idea of such solution may be borrowed from electro- and magnetostatics. Indeed, for the stationary case (\( \partial / \partial t = 0 \)), the solutions of Eqs. (8.3) are given, by the ready generalization of, respectively, Eqs. (1.38) and (5.28) to a uniform, linear medium:

\[ \phi(\mathbf{r}) = \frac{1}{4\pi\varepsilon} \int \rho(\mathbf{r'}) \frac{d^3 r'}{|\mathbf{r} - \mathbf{r}'|}, \]  

When necessary (e.g., at the discussion of the Cherenkov radiation in Sec. 10.5), it will be not too hard to generalize the results to a dispersive medium.
As we know, these expressions may be derived by, first, calculating the potential of a point source, and then using the linear superposition principle for a system of such sources.

Let us do the same for the time-dependent case, starting from the field induced by a time-dependent point charge at the origin:

\[ \rho(r,t) = q(t) \delta(r), \]  

In this case, Eq. (3a) is homogeneous everywhere but the origin:

\[ \nabla^2 \phi - \frac{1}{v^2} \frac{\partial^2 \phi}{\partial t^2} = 0, \quad \text{at } r \neq 0. \]  

Due to the spherical symmetry of the problem, it is natural to look for a spherically-symmetric solution to this equation. Thus, we may simplify the Laplace operator correspondingly, and reduce Eq. (6) to

\[ \left[ \frac{1}{r^2} \frac{\partial}{\partial r} \left( r^2 \frac{\partial}{\partial r} \right) - \frac{1}{v^2} \frac{\partial^2}{\partial t^2} \right] \phi = 0, \quad \text{at } r \neq 0. \]  

If we now introduce a new variable \( \chi = r \phi \), Eq. (7) is reduced to a 1D wave equation

\[ \left( \frac{\partial^2}{\partial r^2} - \frac{1}{v^2} \frac{\partial^2}{\partial t^2} \right) \chi = 0, \quad \text{at } r \neq 0. \]  

From discussions in Chapter 7, we know that its general solution may be represented as

\[ \chi(r,t) = \chi_{\text{out}} \left( t - \frac{r}{v} \right) + \chi_{\text{in}} \left( t + \frac{r}{v} \right), \]  

where \( \chi_{\text{in}} \) and \( \chi_{\text{out}} \) are (so far) arbitrary functions of one variable. The physical sense of \( \phi_{\text{out}} = \chi_{\text{out}} / r \) is a spherical wave propagating from our source (at \( r = 0 \)) to outer space, i.e. exactly the solution we are looking for. On the other hand, \( \phi_{\text{in}} = \chi_{\text{in}} / r \) describes a spherical wave that could be created by some distant spherically-symmetric source, that converges exactly on our charge located at the origin – evidently not the effect we want to consider here. Discarding this term, and returning to \( \phi = \chi / r \), we can write the solution (9) as

\[ \phi(r,t) = \frac{1}{r} \chi_{\text{out}} \left( t - \frac{r}{v} \right). \]  

---

2 Admittedly, this expression does not satisfy the continuity equation (4.5), but this deficiency will be corrected imminently, at the linear superposition stage – see Eq. (17) below.

3 Let me confess that this is not the general solution to Eq. (6). For example, it does not describe the possible waves created by other sources, that pass by the considered charge \( q(t) \). However, such fields are irrelevant for our current task: to calculate the field created by the charge \( q(t) \). The solution becomes general when it is integrated (as it will be) over all charges of interest.

4 See, e.g., MA Eq. (10.9).

5 See also CM Sec. 6.3.
In order to calculate the function $\chi_{\text{out}}$, let us consider the solution (10) at distances $r$ so small that the time-derivative term in Eq. (3a), with the right-hand side (5),

$$\nabla^2 \phi - \frac{1}{v^2} \frac{\partial^2 \phi}{\partial t^2} = -\frac{q(t)}{\varepsilon} \delta(r),$$  

is much smaller than the spatial derivative term (which diverges at $r \to 0$). Then Eq. (11) is reduced to the electrostatic equation, whose solution (4a), for the source (5), is

$$\phi(r \to 0, t) = \frac{q(t)}{4\pi\varepsilon r}.$$  

Now requiring the two solutions, (10) and (12), to coincide at $r \ll vt$, we get $\chi_{\text{out}}(t) = q(t)/4\pi\varepsilon r$, so that Eq. (10) becomes

$$\phi(r, t) = \frac{1}{4\pi\varepsilon r} q\left(t - \frac{r}{v}\right).$$  

Just as had been done in statics, this result may be readily generalized for the arbitrary position $r'$ of the point charge:

$$\rho(r, t) = q(t)\delta(r - r') \equiv q(t)\delta(R),$$  

where $R$ is the distance between the field observation point $r$ and the source position point $r'$, i.e. the length of the vector,

$$R \equiv r - r',$$  

connecting these points – see Fig. 1.

![Fig. 8.1. Calculating the retarded potentials of a localized source.](image)

Obviously, now Eq. (13) becomes

$$\phi(r, t) = \frac{1}{4\pi\varepsilon R} q\left(t - \frac{R}{v}\right).$$  

Finally, we may use the linear superposition principle to write, for the arbitrary charge distribution,

$$\phi(r, t) = \frac{1}{4\pi\varepsilon} \int \rho(r', t - \frac{R}{v}) d^3r' \frac{1}{R},$$  

where $\rho(r', t - \frac{R}{v})$ is the charge density at the retarded time $t - \frac{R}{v}$, and $R = r - r'$ is the distance between the observation point and the source point.
where the integration is extended over all charges of the system under analysis. Acting absolutely similarly, for the vector potential we get\(^6\)

\[
A(r, t) = \frac{\mu}{4\pi} \int \frac{\left( r' - \frac{R}{v} \right) d^3r'}{R}.
\]

(8.17b)

The solutions (17) are called the **retarded potentials**,\(^7\) the name signifying the fact that the observed fields are “retarded” (delayed) in time by \(\Delta t = R/v\) relative to the source variations – physically, because of the finite speed \(v\) of the electromagnetic wave propagation. These solutions are so important that they deserve at least a couple of general remarks.

First, very remarkably, these simple expressions are **exact** solutions of the macroscopic Maxwell equations (in a uniform, linear, dispersion-free) medium for an arbitrary distribution of stand-alone charges and currents. They also may be considered as the general solutions of these equations, provided that the integration is extended over all field sources in the Universe – or at least in its part that affects our observations.

Second, due to the mathematical similarity of the microscopic and macroscopic Maxwell equations, Eqs. (17) are valid, with the coefficient replacement \(\varepsilon \rightarrow \varepsilon_0\) and \(\mu \rightarrow \mu_0\), for the exact, rather than the macroscopic fields, provided that the functions \(\rho(r, t)\) and \(j(r, t)\) describe not only stand-alone but all charges and currents in the system. (Alternatively, this statement may be formulated as the validity of Eqs. (17), with the same coefficient replacement, in free space.)

Finally, Eqs. (17) may be plugged into Eqs. (1), giving (after an explicit differentiation) the so-called **Jefimenko equations** for fields \(E\) and \(B\) – similar in structure to Eqs. (17), but more cumbersome. Conceptually, the existence of such equations is good news, because they are free from the gauge ambiguity pertinent to the potentials \(\phi\) and \(A\). However, the practical value of these explicit expressions for the fields is not too high: for all applications I am aware of, it is easier to use Eqs. (17) to calculate the particular expressions for the potentials first, and only then calculate the fields from Eqs. (1). Let me now present an (apparently, the most important) example of this approach.

### 8.2. Electric dipole radiation

Consider again the problem that was discussed in electrostatics (Sec. 3.1), namely the field of a localized source with linear dimensions \(a \ll r\) (see Fig. 1 again), but now with time-dependent charge and/or current distributions. Using the arguments of that discussion, in particular the condition expressed by Eq. (3.1), \(r' \ll r\), we may apply the Taylor expansion (3.3), truncated to two leading terms,

\[
f(R) = f(r) - r' \cdot \nabla f(r) + \ldots, \tag{8.18}
\]

to the function \(f(R) \equiv R\) (for which \(\nabla f(r) = \nabla R = \mathbf{n}\), where \(\mathbf{n} \equiv r/r\) is the unit vector directed toward the observation point – see Fig. 1) to approximate the distance \(R\) as

---

\(^6\) Now nothing prevents the functions \(\rho(r, t)\) and \(j(r, t)\) from satisfying the continuity relation.

\(^7\) As should be clear from the analogy of Eqs. (17) with their stationary forms (4), which were discussed, respectively, in Chapters 1 and 5, in the Gaussian units the retarded potential formulas are valid with the coefficient \(1/4\pi\) dropped in Eq. (17a), and replaced with the coefficient \(1/c\) in Eq. (17b).
\[ R \approx r - r' \cdot \mathbf{n} . \] (8.19)

In each of the retarded potential formulas (17), \( R \) participates in two places: in the denominator and in the source’s time argument. If \( \rho \) and \( \mathbf{j} \) change in time on the scale \( \sim 1/\omega \), where \( \omega \) is some characteristic frequency, then any change of the argument \( (t - R/v) \) on that time scale, for example due to a change of \( R \) on the spatial scale \( \sim v/\omega = 1/k \), may substantially change these functions. Thus, the expansion (19) may be applied to \( R \) in the argument \( (t - R/v) \) only if \( ka \ll 1 \), i.e. if the system’s size \( a \) is much smaller than the radiation wavelength \( \lambda = 2\pi/k \). On the other hand, the function \( 1/R \) changes relatively slowly, and for it even the first term of the expansion (19) gives a good approximation as soon as \( a \ll r, R \). In this approximation, Eq. (17a) yields

\[
\phi(\mathbf{r}, t) \approx \frac{1}{4\pi \varepsilon r} \int \rho \left( \mathbf{r}' - \frac{R}{v} \right) d^3 r' \equiv \frac{1}{4\pi \varepsilon r} Q \left( t - \frac{R}{v} \right),
\] (8.20)

where \( Q(t) \) is the net electric charge of the localized system. Due to the charge conservation, this charge cannot change with time, so that the approximation (20) describes just a static Coulomb field of our localized source, rather than a radiated wave.

Let us, however, apply the similar approximation to the vector potential (17b):

\[
\mathbf{A}(\mathbf{r}, t) \approx \frac{\mu}{4\pi r} \int \mathbf{j} \left( \mathbf{r}' - \frac{R}{v} \right) d^3 r'.
\] (8.21)

According to Eq. (5.87), in statics the right-hand side of this expression would vanish, but in dynamics this is no longer true. For example, if the current is due to a non-relativistic motion\(^8\) of a system of point charges \( q_k \), we can write

\[
\int \mathbf{j}(\mathbf{r}', t) d^3 r' = \sum_k q_k \dot{\mathbf{r}}_k(t) = \frac{d}{dt} \sum_k q_k \mathbf{r}_k(t) = \mathbf{p}(t),
\] (8.22)

where \( \mathbf{p}(t) \) is the dipole moment of the localized system, defined by Eq. (3.6). Now, after the integration, we may keep only the first term of the approximation (19) in the argument \( (t - R/v) \) as well, getting

\[
\mathbf{A}(\mathbf{r}, t) \approx \frac{\mu}{4\pi r} \mathbf{p} \left( t - \frac{r}{v} \right).
\] (8.23)

Let us analyze what exactly does this result, valid in the limit \( ka \ll 1 \), describe. The second of Eqs. (1) allows us to calculate the magnetic field by the spatial differentiation of \( \mathbf{A} \). At large distances \( r >> \lambda \) (i.e. in the so-called far-field zone), where Eq. (23) describes a virtually plane wave, the main contribution into this derivative is given by the dipole moment factor:

\[
\mathbf{B}(\mathbf{r}, t) = -\frac{\mu}{4\pi r} \mathbf{v} \times \mathbf{p} \left( t - \frac{r}{v} \right) = -\frac{\mu}{4\pi rv} \mathbf{n} \times \dot{\mathbf{p}} \left( t - \frac{r}{v} \right).
\] (8.24)

This expression means that the magnetic field, at the observation point, is perpendicular to the vectors \( \mathbf{n} \) and (the retarded value of) \( \dot{\mathbf{p}} \), and its magnitude is

---

\(^8\) For relativistic particles, moving with velocities of the order of speed of light, one has to be more careful. As the result, I will postpone the discussion of their radiation until Chapter 10, i.e. until after the detailed discussion of special relativity in Chapter 9.
where $\Theta$ is the angle between those two vectors – see Fig. 2.9.

The most important feature of this result is that the time-dependent field decreases very slowly (only as $1/r$) with the distance from the source, so that the radial component of the corresponding Poynting vector (7.9b),

$$S_r = ZH^2 = \frac{Z}{(4\pi vr)^2} \left| \hat{p} \left( t - \frac{r}{v} \right) \right|^2 \sin^2 \Theta \tag{8.26}$$

drops as $1/r^2$, i.e. the full instant power $\mathcal{P}$ of the emitted wave,

$$\mathcal{P} \equiv \int_{r=\text{const}} S_r d^2 r = \frac{Z}{(4\pi v)^2} \hat{p}^2 2\pi \int_0^{\pi} \sin^3 \Theta d\Theta = \frac{Z}{6\pi v^2} \hat{p}^2. \tag{8.27}$$

This is the famous Larmor formula\(^\text{12}\) for the electric dipole radiation; it is the dominating component of radiation by a localized system of charges – unless $\hat{p} = 0$. Please notice its angular dependence: the radiation vanishes at the axis of the retarded vector $\hat{p}$ (where $\Theta = 0$), and reaches its maximum in the plane perpendicular to that axis.

In order to find the average power, Eq. (27) has to be averaged over a sufficiently long time. In particular, if the source is monochromatic, $\mathbf{p}(t) = \text{Re} \{ \mathbf{p}_e \exp \{-i\omega t\} \}$, with a time-independent vector $\mathbf{p}_e$, such averaging may be carried out just over one period, giving an extra factor 2 in the denominator:

\(^9\)From the first of Eqs. (1), for the electric field, in the first approximation (23), we would get $-\partial \mathbf{A}/\partial t = -(1/4\pi vr\nu) \hat{p} \left( t - \frac{r}{v} \right)$. The transverse component of this vector (see Fig. 2) is the proper electric field $E = Z\mathbf{H} \times \mathbf{n}$ of the radiated wave, while its longitudinal component is exactly compensated by $(-\nabla \phi)$ in the next term of the expansion of Eq. (17a) with respect to the small parameter $r/\lambda \ll 1$.

\(^{10}\)Note the “doughnut” dependence of $S_r$ on the direction $\mathbf{n}$, frequently used to visualize the dipole radiation.

\(^{11}\)In the Gaussian units, for free space ($v = c$), Eq. (27) reads $\mathcal{P} = (2/3c^3) \hat{p}^2$.

\(^{12}\)Named after Joseph Larmor, who was first to derive it (in 1897) for the particular case of a single point charge $q$ moving with acceleration $\mathbf{a}$, when $\hat{p} = q\mathbf{a}$. 

\[^{11}\] In the Gaussian units, for free space ($v = c$), Eq. (27) reads $\mathcal{P} = (2/3c^3) \hat{p}^2$.

\[^{12}\] Named after Joseph Larmor, who was first to derive it (in 1897) for the particular case of a single point charge $q$ moving with acceleration $\mathbf{a}$, when $\hat{p} = q\mathbf{a}$.
The easiest application of this formula is to a point charge oscillating, with frequency \( \omega \), along a straight line (which we may take for the \( z \)-axis), with amplitude \( a \). In this case, \( \mathbf{p} = qz(t)\mathbf{n}_z = qa \, \text{Re}\{\exp\{-i\omega t\}\} \mathbf{n}_z \), and if the charge velocity amplitude, \( a\omega \), is much less than the wave speed \( v \), we may use Eq. (28) with \( p_\omega = qa \), giving

\[
\mathcal{P} = \frac{Z \omega^4}{12\pi v^2} |p_\omega|^2. \tag{8.28}
\]

Applied to an electron \((q = -e \approx -1.6 \times 10^{-19} \text{ C})\), initially rotating about a nucleus at an atomic distance \( a \sim 10^{-10} \text{ m} \), the Larmor formula shows\(^{13}\) that the energy loss due to the dipole radiation is so large that it would cause the electron to collapse on the atom’s nuclei in just \( \sim 10^{-10} \text{ s} \). In the beginning of the 1900s, this classical result was one of the main arguments for the development of quantum mechanics, which prevents such collapse of electrons in their lowest-energy (ground) quantum state.

Another useful application of Eq. (28) is the radio wave radiation by a short, straight, symmetric antenna which is fed, for example, by a TEM transmission line such as a coaxial cable – see Fig. 3.

The exact solution of this problem is rather complicated, because the law \( I_\omega(z) \) of the current variation along the antenna’s length should be calculated self-consistently with the distribution of the electromagnetic field induced by the current in the surrounding space. (This fact is unfortunately ignored in some textbooks.) However, one may argue that at \( l \ll \lambda \), the current should be largest in the feeding point (in Fig. 3, taken for \( z = 0 \)), vanish at antenna’s ends \((z = \pm l/2)\), and that the only possible scale of the current variation in the antenna is \( l \) itself, so that the linear function,

\[
I_\omega(z) = I_\omega(0) \left(1 - \frac{2}{l}|z|\right), \tag{8.30}
\]

should give a good approximation of the actual distribution – as it indeed does. Now we can use the continuity equation \( \partial Q/\partial t = I \), i.e. \(-i\omega Q_\omega = I_\omega \) to calculate the complex amplitude \( Q_\omega(z) = i I_\omega(z) \text{sgn}(z)/\omega \) of the electric charge \( Q(z, t) = \text{Re}\{Q_\omega \exp\{-i\omega t\}\} \) of the wire beyond point \( z \), and from it, the amplitude of the linear density of charge

\(^{13}\) Actually, the formula needs a numerical coefficient adjustment to account for electron’s orbital (rather than linear) motion – the task left for reader’s exercise. However, this adjustment does not affect the order-of-magnitude estimate given above.
\[ \lambda_{\omega}(z) \equiv \frac{dQ_{\omega}(z)}{dz} = -i \frac{2I_{\omega}(0)}{\omega l} \text{sgn} z. \]  

(8.31)

From here, the dipole moment's amplitude is

\[ p_{\omega} = 2 \int_0^{l/2} \lambda_{\omega}(z) z dz = -i \frac{L_{\omega}(0)}{2\omega} l, \]  

(8.32)

so that Eq. (28) yields

\[ \mathcal{P} = Z \frac{\omega^4}{12\pi v^2} \left| I_{\omega}(0) \right|^2 \left( \frac{Z}{24\pi} \right) \left| I_{\omega}(0) \right|^2, \]  

(8.33)

where \( k = \omega v \). The analogy between this result and the dissipation power, \( \mathcal{P} = \text{Re} \left| Z \frac{I_{\omega}(0)}{2\omega} \right|^2 \), in a lumped linear circuit element, allows the interpretation of the first fraction in the last form of Eq. (33) as the real part of the antenna's impedance:

\[ \text{Re} Z_A = \frac{Z(kl)^2}{24\pi}, \]  

(8.34)

as felt by the transmission line.

According to Eq. (7.118), the wave traveling along the line toward the antenna is fully radiated, i.e. not reflected back, only if \( Z_A \) equals to \( Z_W \) of the line. As we know from Sec. 7.5 (and the solution of the related problems), for typical TEM lines, \( Z_W \sim Z_0 \), while Eq. (34), which is only valid in the limit \( kl \ll 1 \), shows that for radiation into the free space \( (Z = Z_0) \), \( \text{Re} Z_A \) is much less than \( Z_0 \). Hence to reach the impedance matching condition \( Z_W = Z_A \), the antenna’s length should be increased – as a more involved theory shows, to \( l \approx \lambda/2 \). However, in many cases, practical considerations make short antennas necessary. The example most often met nowadays is the cell phone antennas, which use frequencies close to 1 or 2 GHz, with free-space wavelengths \( \lambda \) between 15 and 30 cm, i.e. much larger than the phone size.\(^{14}\) The quadratic dependence of the antenna’s efficiency on \( l \), following from Eq. (34), explains why every millimeter counts in the design of such antennas, and why the designs are carefully optimized using software packages for the (virtually exact) numerical solution of the Maxwell equations for the specific shape of the antenna and other phone parts.\(^{15}\)

To conclude this section, let me note that if the wave source is not monochromatic, so that \( p(t) \) should be represented as a Fourier series,

\[ p(t) = \text{Re} \sum_{\omega} p_{\omega} e^{-i\omega t}, \]  

(8.35)

the terms corresponding to the interference of spectral components with different frequencies \( \omega \) are averaged out at the time averaging of the Poynting vector, so that the average radiated power is just a sum of contributions (28) from all substantial frequency components.

\(^{14}\) The situation will be partly remedied by the current transfer of the wireless mobile technology to its next (5G) generation, with the frequencies moved up to the 28 GHz, 37-39 GHz, and possibly even the 64-71 GHz bands.

\(^{15}\) A partial list of popular software packages of this kind includes both publicly available codes such as NEC -2 (whose various versions are available online, e.g., at http://www.qsl.net/4nec2/), and proprietary packages – such as Momentum from Agilent Technologies (now owned by Hewlett-Packard), FEKO from EM Software & Systems, and XFdit from Remcom.
8.3. Wave scattering

The formalism described above may be immediately used in the theory of scattering – the phenomenon illustrated by Fig. 4. Generally, scattering is a complex problem. However, in many cases it allows the so-called Born approximation, in which scattered wave field’s effect on the scattering object is assumed to be much weaker than that of the incident wave, and is neglected.

As the first example of this approach, let us consider the scattering of a plane wave, propagating in free space ($Z = Z_0$, $v = c$), by a free charged particle whose motion may be described by non-relativistic classical mechanics. (This requires, in particular, the incident wave not to be too powerful, so that the speed of the induced charge motion remains much lower than the speed of light.) As was already discussed at the derivation of Eq. (7.32), in this case, the magnetic component of the Lorentz force (5.10) is negligible in comparison with the force $F_e = qE$ exerted by its electric field. Thus, assuming that the incident wave is linearly polarized along some axis $x$, the equation of particle’s motion in the Born approximation is just $m \ddot{x} = qE(t)$, so that for the $x$-component $p_x = qx$ of its dipole moment we can write

$$\dot{p} = q\dot{x} = \frac{q^2}{m} E(t). \quad (8.36)$$

As we already know from Sec. 2, oscillations of the dipole moment lead to radiation of a wave with a wide angular distribution of intensity; in our case, this is the scattered wave – see Fig. 4. Its full power may be found by plugging Eq. (36) into Eq. (27):

$$\mathcal{P} = \frac{Z_0}{6\pi c^2} \dot{p}^2 = \frac{Z_0 q^4}{6\pi c^2 m^2} E^2(t), \quad (8.37)$$

so that for the average power we get

$$\overline{\mathcal{P}} = \frac{Z_0 q^4}{12\pi c^2 m^2} |E_0|^2. \quad (8.38)$$

---

16 Named after Max Born, one of the founding fathers of quantum mechanics. Note, however, the basic idea of this approach was developed, in the electromagnetic theory, much earlier (in 1881) by Lord Rayleigh (born John William Strutt) – whose numerous contributions to science include the discovery of argon.

17 As Eq. (7.30) shows, this calculation is also valid for an oscillator with a low own frequency, $\omega_0 << \omega$. 
Since the power is proportional to the incident wave’s intensity $S$, it is customary to characterize the scattering ability of the object by the ratio,

$$
\sigma \equiv \frac{\overline{P}}{S_{\text{incident}}} = \frac{\overline{P}}{|E_{\text{in}}|^2 / 2Z_0},
$$

which has the dimension of area, and is called the total cross-section of scattering.\(^{18}\) For this measure, Eq. (38) yields the famous result

$$
\sigma = \frac{Z^2 q^4}{6\pi e^2 m^2} = \frac{\mu_0^2 q^4}{6\pi m^2},
$$

which is called the Thomson scattering formula,\(^{19}\) especially when applied to an electron. This relation is most frequently represented in the form\(^{20}\)

$$
\sigma = \frac{8\pi}{3} r_c^2, \quad \text{with} \quad r_c \equiv \frac{q^2}{4\pi\varepsilon_0}, \frac{1}{mc^2}.
$$

This constant $r_c$ is called the classical radius of the particle (or sometimes the “Thomson scattering length”); for the electron ($q = -e$, $m = m_e$) it is close to $2.82\times10^{-15}$ m. Its possible interpretation is evident from the latter of Eqs. (41) for $r_c$: at that distance between two similar particles, the potential energy $q^2/4\pi\varepsilon_0r$ of their electrostatic interaction is equal to particle’s rest-mass energy $mc^2$.\(^{21}\)

Now we have to go back and establish the conditions at which the Born approximation, when the field of the scattered wave is negligible, is indeed valid for a point-object scattering. Since the scattered wave’s intensity, described by Eq. (26), diverges as $1/r^2$, according to the definition (39) of the cross-section, it may become comparable to $S_{\text{incident}}$ at $r^2 \sim \sigma$. However, Eq. (38) itself is only valid if $r \gg \lambda$, so that the Born approximation does not lead to a contradiction only if

$$
\sigma \ll \lambda^2.
$$

For the Thompson scattering by an electron, this condition means $\lambda \gg r_c \sim 3\times10^{-15}$ m and is fulfilled for all frequencies up to very hard $\gamma$-rays with energies $\sim 100$ MeV.

Possibly the most notable feature of result (40) is its independence of the wave frequency. As it follows from its derivation, particularly from Eq. (37), this independence is intimately related to the unbound character of charge motion. For bound charges, say for electrons in gas molecules, this result is

\(^{18}\) This definition parallels those accepted in the classical and quantum theories of particle scattering – see, e.g., respectively, CM Sec. 3.5 and QM Sec. 3.3.

\(^{19}\) Named after Sir Joseph John (“JJ”) Thomson, the discoverer of the electron – and isotopes as well! He should not be confused with his son, G. P. Thomson, who discovered (simultaneously with C. Davission and L. Germer) quantum-mechanical wave properties of the same electron.

\(^{20}\) In the Gaussian units, this formula looks like $r_c = q^2/mc^2$ (giving, of course, the same numerical values: for the electron, $r_c \approx 2.82\times10^{-13}$ cm). This classical expression should not be confused with the particle’s Compton wavelength $\lambda_c = 2\pi\hbar/mc$ (for the electron, close to $2.24\times10^{-12}$ m), which naturally arises in quantum electrodynamics – see a brief discussion in the next chapter, and also QM Sec. 1.1.

\(^{21}\) It is fascinating how smartly has the relativistic expression $mc^2$ sneaked into the result (40)-(41), which was obtained using the non-relativistic equation (36) of the particle motion. This was possible because the calculation engaged electromagnetic waves, which propagate with the speed of light, and whose quanta (photons), as a result, may be frequently treated as relativistic (moreover, ultra-relativistic) particles – see the next chapter.
only valid if the wave frequency $\omega$ is much higher than all eigenfrequencies $\omega_j$ of molecular resonances. In the opposite limit, $\omega \ll \omega_j$, the result is dramatically different. Indeed, in this limit we can approximate the molecule’s dipole moment by its static value (3.48):

$$\mathbf{p} = \alpha \mathbf{E}.$$  \hfill (8.43)

In the Born approximation, and in the absence of the molecular field effects mentioned in Sec. 3.3, $\mathbf{E}$ in this expression is just the incident wave’s field, and we can use Eq. (28) to calculate the power of the wave scattered by a single molecule:

$$\mathcal{P} = \frac{Z_0 \omega^4}{4\pi c^2} \alpha^2 |E_\omega|^2.$$  \hfill (8.44)

Now, using the last form of the definition (39) of the cross-section, we get a very simple result,

$$\sigma = \frac{Z_0^2 \omega^4}{6\pi c^2} \alpha^2,$$  \hfill (8.45)

showing that in contrast to Eq. (40), at low frequencies $\sigma$ changes as fast as $\omega^4$.

Now let us explore the effect of such Rayleigh scattering on wave propagation in a gas, with a relatively low volumic density $n$. We may expect (and will prove in the next section) that due to the randomness of molecule positions, the waves scattered by individual molecules may be treated as incoherent ones, so that the total scattering power may be calculated just as the sum of those scattered by each molecule. We can use this fact to write the balance of the incident’s wave intensity in a small volume $dV$ of length (along the incident wave direction) $dz$, and area $A$ across it. Since such a segment includes $ndV = nAdz$ molecules, and, according to definition (39), each of them scatters power $S\sigma = \mathcal{P}\sigma A$, the total scattered power is $n\mathcal{P}\sigma dz$; hence the incident power’s change is

$$d\mathcal{P} \equiv -n\sigma \mathcal{P} dz.$$  \hfill (8.46)

Comparing this equation with the definition (7.213) of the wave attenuation constant, applied to the scattering, \hfill (8.46)

$$d\mathcal{P} \equiv -\alpha_{\text{scat}} \mathcal{P} dz.$$  \hfill (8.47)

we see that this effect gives the following contribution to attenuation: $\alpha_{\text{scat}} = n\sigma$. From here, using Eq. (3.50) to write $\alpha = \varepsilon_0(\kappa - 1)/n$, where $\kappa$ is the dielectric constant, and Eq. (45) for $\sigma$, we get

$$\alpha_{\text{scat}} = \frac{k^4}{6\pi n} (\kappa - 1)^2, \quad \text{where} \quad k \equiv \frac{2\pi}{\lambda_0} = \frac{\omega}{c}.$$  \hfill (8.48)

This is the famous Rayleigh scattering formula, which in particular explains the colors of blue sky and red sunsets. Indeed, through the visible light spectrum, $\omega$ changes almost two-fold; as a result, the scattering of blue components of sunlight is an order of magnitude higher than that of its red components. More quantitatively, for the air near the Earth’s surface, $\kappa - 1 \approx 6 \times 10^4$, and $n \sim 2.5 \times 10^{25}$

\footnotesize{\textsuperscript{22} I am sorry for using the same letter ($\alpha$) for both the molecular polarizability and the wave attenuation, but both notations are traditional. Hopefully, the subscript “scat”, marking $\alpha$ in the latter meaning, excludes any possibility of confusion.}
m$^{-3}$ – see Sec. 3.3. Plugging these numbers into Eq. (47), we see that the effective length $l_{\text{scat}} \equiv 1/\alpha_{\text{scat}}$ of scattering is $\sim 30$ km for the blue light and $\sim 200$ km for the red light.\footnote{These values are approximate, because both $n$ and $(\kappa - 1)$ vary through the atmosphere’s thickness.} The effective thickness $h$ of the Earth’s atmosphere is $\sim 10$ km, so that the Sun looks just a bit yellowish during most of the day. However, an elementary geometry shows that on the sunset, the light should pass the length $l \sim (R_Eh)^{1/2} \approx 300$ km to reach an Earth-surface observer; as a result, the blue components of Sun’s light spectrum are almost completely scattered out, and even the red components are weakened substantially.

8.4. Interference and diffraction

Now let us discuss scattering by objects with size of the order of, or even larger than $\lambda$. For such extended objects, the phase difference factors (neglected above) step in, leading in particular to the important effects of interference and diffraction. These effects show up not as much in the total power of the scattered radiation, as in its angular distribution. It is traditional to characterize this distribution by the differential cross-section defined as

$$\frac{d\sigma}{d\Omega} \equiv \frac{\overline{S}_r r^2}{S_{\text{incident}}}, \quad (8.49)$$

where $r$ is the distance from the scatterer, at which the scattered wave is observed.\footnote{Just as in the case of the total cross-section, this definition is also similar to that accepted at the particle scattering – see, e.g., CM Sec. 3.5 and QM Sec. 3.3.} Both the definition and the notation may become more clear if we notice that according to Eq. (26), at large distances ($r \gg a$), the numerator on the right-hand side of Eq. (49), and hence the differential cross-section as the whole, do not depend on $r$, and that its integral over the total solid angle $\Omega = 4\pi$ coincides with the total cross-section defined by Eq. (39):

$$\int d\Omega \sigma = \frac{1}{S_{\text{incident}}} \int d\Omega \frac{\overline{S}_r r^2}{S_{\text{incident}}} = \frac{1}{S_{\text{incident}}} \int_{r=\text{const}} d^2r = \frac{\overline{P}}{S_{\text{incident}}} \equiv \sigma. \quad (8.50)$$

For example, according to Eq. (26), the angular distribution of the radiation scattered by a single dipole is rather broad; in particular, in the quasistatic case (43), and in the Born approximation,

$$\frac{d\sigma}{d\Omega} = \left( \frac{\alpha k^2}{4\pi\varepsilon_0} \right)^2 \sin^2 \Theta. \quad (8.51)$$

If the wave is scattered by a small dielectric body, with a characteristic size $a \ll \lambda$ (i.e., $ka \ll 1$), then all its parts re-radiate the incident wave coherently. Hence, we can calculate it similarly, just replacing the molecular dipole moment (43) with the total dipole moment of the object – see Eq. (3.45):

$$\mathbf{p} = \mathbf{P}V = (\kappa - 1)\varepsilon_0\mathbf{E}V, \quad (8.52)$$

where $V \sim a^3$ is the body’s volume. As a result, the differential cross-section may be obtained from Eq. (51) with the replacement $\alpha_{\text{mol}} \rightarrow (\kappa - 1)\varepsilon_0 V$: \vspace{1cm}

\footnote{Just as in the case of the total cross-section, this definition is also similar to that accepted at the particle scattering – see, e.g., CM Sec. 3.5 and QM Sec. 3.3.}
\[
\frac{d\sigma}{d\Omega} = \left(\frac{k^2 V}{4\pi}\right)^2 (\kappa - 1)^2 \sin^2 \Theta, \tag{8.53}
\]
i.e. follows the same \(\sin^2 \Theta\) law.

The situation for extended objects, with at least one dimension of the order, or larger than the wavelength, is different: here we have to take into account the phase shifts introduced by various parts of the body. Let us analyze this issue first for an arbitrary collection of similar point scatterers located at points \(r_j\). If the wave vector of the incident plane wave is \(k_0\), the wave’s field has the phase factor \(\exp\{ik_0 \cdot r\}\) – see Eq. (7.79). At the location of \(j^{th}\) scattering center, the factor equals to \(\exp\{ik_0 \cdot r_j\}\), so that the local dipole vectors \(p_j\), and the scattered wave they create, are proportional to this factor. On its way to the observation point \(r\), the scattered wave, with the wave vector \(k\) (with \(k = k_0\)), acquires an additional phase factor \(\exp\{ik \cdot (r - r_j)\}\), so that the scattered wave field is proportional to

\[
\exp[ik \cdot r_j + i\mathbf{k} \cdot (r - r_j)] \equiv e^{ik \cdot r_j} \exp\{-i(k - k_0) \cdot r_j\}. \tag{8.54}
\]

Since the first factor in the last expression does not depend on \(r_j\), in order to calculate the total scattering wave, it is sufficient to sum up the last phase factors, \(\exp\{-i\mathbf{q} \cdot r_j\}\), where the vector \(\mathbf{q} = k - k_0\) has the physical sense of the wave vector change at scattering.\(^{25}\) It may look like the phase factor depends on the choice of the reference frame. However, according to Eq. (7.42), the average intensity of the scattered wave is proportional to \(E_\omega E_\omega^*\), i.e. to the following real scalar function of the vector \(\mathbf{q}\):

\[
F(\mathbf{q}) = \left( \sum_j \exp\{-i\mathbf{q} \cdot r_j\} \right) \left( \sum_j \exp\{-i\mathbf{q} \cdot r_j'\} \right)^* = \sum_{j,j'} \exp\{i\mathbf{q} \cdot (r_j - r_j')\} \equiv |I(\mathbf{q})|^2, \tag{8.56}
\]

where the complex function

\[
I(\mathbf{q}) \equiv \sum_j \exp\{-i\mathbf{q} \cdot r_j\} \tag{8.57}
\]
is called the \textit{phase sum}, and may be calculated in any reference frame, without affecting the final result (56).

So, besides the \(\sin^2 \Theta\) factor, the differential cross-section (49) of scattering by an extended object is also proportional to the scattering function (56). Its double-sum form is convenient to notice that for a system of \textit{many} \((N >> 1)\) of similar but randomly located scatterers, only the terms with \(j = j'\) accumulate at summation, so that \(F(\mathbf{q})\), and hence \(d\sigma/d\Omega\), scale as \(N\), rather than \(N^2\) – thus justifying again our treatment of the Rayleigh scattering problem in the previous section.

Let us start using Eq. (56) by applying it to a simple problem of just \textit{two} similar small scatterers, separated by a fixed distance \(a\):

\(^{25}\) In quantum mechanics, \(h\mathbf{q}\) has a very clear sense of the momentum transferred from the scattering object to the scattered particle (for example, a photon), and this terminology is sometimes smuggled even into classical electrodynamics texts.
\[ F(\mathbf{q}) = \sum_{j,i=1}^{2} \exp\{i\mathbf{q} \cdot (\mathbf{r}_j - \mathbf{r}_i)\} = 2 + \exp\{-iq_a a\} + \exp\{iq_a a\} = 2(1 + \cos q_a a) = 4 \cos^2 \frac{q_a a}{2}, \]  

(8.58)

where \( q_a \equiv \mathbf{q} \cdot \mathbf{a}/a \) is the component of the vector \( \mathbf{q} \) along the vector \( \mathbf{a} \) connecting the scatterers. The apparent simplicity of this result may be a bit misleading, because the mutual plane of the vectors \( \mathbf{k} \) and \( \mathbf{k}_0 \) (and hence of the vector \( \mathbf{q} \)) does not necessarily coincide with the mutual plane of the vectors \( \mathbf{k}_0 \) and \( \mathbf{E}_{\text{obs}} \) so that the scattering angle \( \theta \) between \( \mathbf{k} \) and \( \mathbf{k}_0 \) is generally different from \((\pi/2 - \Theta)\) – see Fig. 5.

Moreover, the angle between the vectors \( \mathbf{q} \) and \( \mathbf{a} \) (within their common plane) is one more parameter independent of both \( \theta \) and \( \Theta \). As a result, the angular dependence of the scattered wave’s intensity (and hence \( d\sigma/d\Omega \)), that depends on all three angles, may be rather involved,\(^\text{26}\) but some of its details do not affect the basic physics of the interference/diffraction. This is why let me consider only the simple case when the vectors \( \mathbf{k}, \mathbf{k}_0, \) and \( \mathbf{a} \) all lie in the same plane (Fig. 6a), with \( \mathbf{k}_0 \) normal to \( \mathbf{a} \).

Then, with our choice of coordinates, \( q_a = q_x = k \sin \theta \), and Eq. (58) is reduced to

\[ F(\mathbf{q}) = 4 \cos^2 \frac{ka \sin \theta}{2}. \]  

(8.59)

This function always has two maxima, at \( \theta = 0 \) and \( \theta = \pi \), and, if the product \( ka \) is large enough, other maxima at the special angles \( \theta_n \) that satisfy the simple condition

\[ ka \sin \theta_n = 2\pi n, \quad \text{i.e. } a \sin \theta_n = n\lambda. \]  

(8.60)

As Fig. 6a shows, this condition may be readily understood as that of the in-phase addition (the constructive interference) of two coherent waves scattered from the two points, when the difference

\(^{26}\) In optics, such patterns, observed as dark and bright spots on a screen, are called interference fringes.
between their paths toward the observer, \( a \sin \theta \), equals to an integer number of wavelengths. At each such maximum, \( F = 4 \), due to the doubling of the wave amplitude and hence quadrupling its power.

If the distance between the point scatterers is large (\( ka >> 1 \)), the first maxima (60) correspond to small scattering angles, \( \theta << 1 \). For this region, Eq. (59) is reduced to a simple periodic dependence of function \( F \) on the angle \( \theta \). Moreover, within the range of small \( \theta \), the wave polarization factor \( \sin^2 \Theta \) is virtually constant, so that the scattered wave intensity, and hence the differential cross-section are also very simple:

\[
\frac{d\sigma}{d\Omega} \propto F(q) = 4 \cos^2 \left( \frac{ka\theta}{2} \right). \tag{8.61}
\]

This simple interference pattern is well known from Young’s two-slit experiment.\(^{27}\) (As will be discussed in the next section, the theoretical description of the two-slit experiment is more complex than that of the Born scattering, but is preferable experimentally, because at such scattering, the wave of intensity (61) has to be observed on the backdrop of a much stronger incident wave that propagates in almost the same direction, \( \theta = 0 \).)

A very similar analysis of scattering from \( N \geq 2 \) similar, equidistant scatterers, located along the same straight line shows that the positions (60) of the constructive interference maxima do not change (because the derivation of this condition is still applicable to each pair of adjacent scatterers), but the increase of \( N \) makes these peaks sharper and sharper. Leaving the quantitative analysis of this system for the reader’s exercise, let me jump immediately to the limit \( N \to 0 \), in which we may ignore the scatterers’ discreteness. The resulting pattern is similar to that at scattering by a continuous thin rod (see Fig. 6b), so let us first spell out the Born scattering formula by an arbitrary an extended, continuous, uniform dielectric body. Transferring Eq. (56) from the sum to an integral, for the differential cross-section we get

\[
\frac{d\sigma}{d\Omega} = \left( \frac{k^2}{4\pi} \right)^2 (\kappa - 1)^2 F(q) \sin^2 \Theta \equiv \left( \frac{k^2}{4\pi} \right)^2 (\kappa - 1)^2 |I(q)|^2 \sin^2 \Theta, \tag{8.62}
\]

where \( I(q) \) now becomes the phase integral,\(^{28}\)

\[
I(q) = \int \exp \left\{ -i q \cdot r' \right\} d^3 r', \tag{8.63}
\]

with the dimensionality of volume.

\(^{27}\) This experiment was described in 1803 by Thomas Young – one more universal genius of science, who has also introduced the Young modulus in the elasticity theory (see, e.g., CM Chapter 7), besides numerous other achievements – including deciphering Egyptian hieroglyphs! It is fascinating that the first clear observation of wave interference was made 100 years earlier by another genius, Isaac Newton, in the form of so-called Newton rings. Unbelievably, Newton failed to give the most natural explanation of his observations – perhaps because he was violently opposed the idea of light as a wave, which was promoted in his times by others, notably including Christian Huygens. Due to Newton’s authority, only Young’s two-slit experiments have firmly established the wave picture of light, to be replaced by the dualistic photon/wave picture, formalized by quantum electrodynamics, only 100+ years later – see, e.g., QM Ch. 9.

\(^{28}\) Since the observation point’s position \( r \) does not participate in this formula explicitly, the prime sign in \( r' \) could be dropped, but I keep it as a reminder that the integral is taken over points \( r' \) of the scattering object.
Now we may return to the particular case of a thin rod (with both dimensions of the cross-section’s area $A$ much smaller than $\lambda$, but an arbitrary length $a$), otherwise keeping the same simple geometry as for two-point scatterers – see Fig. 6b. In this case, the phase integral is just

$$I(q) = A \int_{-a/2}^{a/2} \exp\{-iq \cdot x\}dx = \frac{\exp\{-iq \cdot a/2\} - \exp\{-iq \cdot a/2\}}{-iq} = V \frac{\sin \xi}{\xi}, \quad (8.64)$$

where $V = Aa$ is the volume of the rod, and $\xi$ is the dimensionless argument defined as

$$\xi = \frac{q \cdot a}{2} \equiv \frac{ka \sin \theta}{2}. \quad (8.65)$$

The fraction participating in the last form of Eq. (64) is met in physics so frequently that it has deserved the special name of the \textit{sinc} (not "sync", please!) function (see Fig. 7):

$$\text{sinc} \xi \equiv \frac{\sin \xi}{\xi}, \quad (8.66)$$

which vanishes at all points $\xi_n = \pi n$, with integer $n$, besides the point with $n = 0$: $\text{sinc} 0 \equiv \text{sinc} 0 = 1$.

The function $F(q) = V^2 \text{sinc}^2 \xi$, resulting from Eq. (64), is plotted with the red line in Fig. 8, and is called the \textit{Fraunhofer diffraction pattern}.\footnote{It is named after Joseph von Fraunhofer (1787-1826) – who has invented the spectroscope, developed the diffraction grating (see below), and also discovered the dark \textit{Fraunhofer lines} in Sun’s spectrum.}
Note that it oscillates with the same argument period $\Delta(k\sin\theta) = 2\pi/ka$ as the interference pattern (61) from two-point scatterers (shown with the blue line in Fig. 8). However, at the interference, the scattered wave intensity vanishes at angles $\theta_n'$ that satisfy the condition

$$\frac{ka\sin\theta_n'}{2\pi} = n + \frac{1}{2},$$

(8.67)

i.e. when the optical paths difference $as\alpha$ equals to a semi-integer number of wavelengths $\lambda/2 = \pi/k$, and hence the two waves from the scatterers arrive to the observer in anti-phase – the so-called destructive interference. On the other hand, for the diffraction on a continuous rod the minima occur at a different set of scattering angles:

$$\frac{ka\sin\theta_n}{2\pi} = n,$$

(8.68)

i.e. exactly where the two-point interference pattern has its maxima – see Fig. 8 again. The reason for this relation is that the wave diffraction on the rod may be considered as a simultaneous interference of waves from all its elementary fragments, and exactly at the observation angles when the rod edges give waves with phases shifted by $2\pi m$, the interior points of the rod give waves with all possible phases, with their algebraic sum equal to zero. As even more visible in Fig. 8, at the diffraction, the intensity oscillations are limited by a rapidly decreasing envelope function $1/\xi^2$ (while at the two-point interference, the oscillations retain the same amplitude). The reason for this fast decrease is that with each Fraunhofer diffraction period, a smaller and smaller fraction of the road gives an unbalanced contribution to the scattered wave.

If rod’s length is small ($ka \ll 1$, i.e. $a \ll \lambda$), then the sinc function’s argument $\xi$ is small at all scattering angles $\theta$, so $I(q) \approx V$, and Eq. (62) is reduced to Eq. (53). In the opposite limit, $a >> \lambda$, the first zeros of the function $I(q)$ correspond to very small angles $\theta$, for which $\sin\theta \approx 1$, so that the differential cross-section is just

$$\frac{d\sigma}{d\Omega} = \left(\frac{k^2}{4\pi}\right) (\kappa - 1)^2 \text{sinc}^2 \frac{ka\theta}{2},$$

(8.69)

i.e. Fig. 8 shows the scattering intensity as a function of the direction toward the observation point – if this point is within the plane containing the rod.

Finally, let us discuss a problem of large importance for applications: calculate the positions of the maxima of the interference pattern arising at the incidence of a plane wave on a very large 3D periodic system of point scatterers. For that, first of all, let us quantify the notion of 3D periodicity. The periodicity in one dimension is simple: the system we are considering (say, the positions of point scatterers) should be invariant with respect to the linear translation by some period $a$, and hence by any multiple $sa$ of this period, where $s$ is any integer. Anticipating the 3D generalization, we may require any of the possible translation vectors $\mathbf{R}$ to be equal $sa$, where the primitive vector $a$ is directed along the (only) axis of the 1D system.

Now we are ready for the common definition of the 3D periodicity – as the invariance of the system with respect to the translation by any vector of the following set:

$$\mathbf{R} = \sum_{i=1}^{3} s_i \mathbf{a}_i,$$

(8.70)
where \( s_i \) are 3 independent integers, and \( \{a_i\} \) is a set of 3 linearly-independent primitive vectors. The set of geometric points described by Eq. (70) is called the Bravais lattice (first analyzed in detail, circa 1850, by Auguste Bravais); perhaps the most nontrivial feature of this relation is that the vectors \( a_i \) should not necessarily be orthogonal to each other. (That requirement would severely restrict the set of possible lattices, and make it unsuitable for the description, for example, of many solid-state crystals.) For the scattering problem we are considering, let us assume that the position \( r_j \) of each scatterer coincides with one of the points \( R \) of some Bravais lattice, with a given set of primitive vectors \( a_i \), so that the index \( j \) is coding the set of integers \( \{s_1, s_2, s_3\} \).

Now let us consider a similarly defined Bravais lattice, but in the reciprocal (wave-number) space, numbered by independent integers \( \{t_1, t_2, t_3\} \):

\[
Q = \sum_{m=1}^{3} t_m b_m, \quad \text{with} \quad b_m = 2\pi \frac{a_m \times a_{m'}}{a_m \cdot (a_m \times a_{m'})},
\]  

where in the last expression, the indices \( m, m' \), and \( m'' \) are all different. This is the so-called reciprocal lattice, which plays an important role in all physics of periodic structures, in particular in the quantum energy-band theory.\(^{30}\) To reveal its most important property, and thus justify the above definition of the primitive vectors \( b_m \), let us calculate the following scalar product:

\[
R \cdot Q = \sum_{l,m=1}^{3} s_l t_m a_i \cdot b_m \equiv 2\pi \sum_{l,m=1}^{3} s_l t_m a_i \cdot \frac{a_m \times a_{m'}}{a_m \cdot (a_m \times a_{m'})} \equiv 2\pi \sum_{l,m=1}^{3} s_l t_k a_i \cdot \frac{(a_m \times a_{m'})}{a_m \cdot (a_m \times a_{m'})}.
\]  

(8.72)

Applying to the numerator of the last fraction the operand rotation rule of vector algebra,\(^{31}\) we see that it is equal to zero if \( l \neq m \), while for \( l = m \) the whole fraction is evidently equal to 1. Thus the double sum (72) is reduced to a single sum:

\[
R \cdot Q = 2\pi \sum_{l=1}^{3} s_l t_l = 2\pi \sum_{l=1}^{3} n_l,
\]  

(8.73)

where each of the products \( n_l \equiv s_l t_l \) is an integer, and hence their sum,

\[
n \equiv \sum_{l=1}^{3} n_l \equiv s_1 t_1 + s_2 t_2 + s_3 t_3,
\]  

(8.74)

is an integer as well, so that the main property of the direct/reciprocal lattice couple is very simple:

\[
R \cdot Q = 2\pi n, \quad \text{and} \quad \exp\left\{-i\mathbf{R} \cdot \mathbf{Q}\right\} = 1.
\]  

(8.75)

Now returning to the scattering function (56), we see that if the vector \( q \equiv k - k_0 \) coincides with any vector \( Q \) of the reciprocal lattice, then all terms of the phase sum (57) take their largest possible values (equal to 1), and hence the sum as the whole is largest as well, giving a constructive interference maximum. This equality, \( q = Q \), where \( Q \) is given by Eq. (71), is called the von Laue condition (named after Max von Laue) of the constructive interference; it is, in particular, the basis of all field of the X-ray crystallography of solids and polymers – the main tool for revealing their atomic/molecular structure.\(^{32}\)

---

\(^{30}\) See, e.g., QM Sec. 3.4, where several particular Bravais lattices \( R \), and their reciprocals \( Q \), are considered.

\(^{31}\) See, e.g., MA Eq. (7.6).

\(^{32}\) For more reading on this important topic, I can recommend, for example, the classical monograph by B. Cullity, *Elements of X-Ray Diffraction*, 2nd ed., Addison-Wesley, 1978. Note that it uses the alternative popular name of the field, once again illustrating how blurry the boundary between the interference and diffraction is.
In order to recast the von Laue condition is a more vivid, geometric form, let us consider one of the vectors \( \mathbf{Q} \) of the reciprocal lattice, corresponding to a certain integer \( n \) in Eq. (75), and notice that if that relation is satisfied for one point \( \mathbf{R} \) of the direct Bravais lattice (70), i.e. for one set of integers \( \{s_1, s_2, s_3\} \), it is also satisfied for a 2D system of other integer sets, which may be parameterized, for example, by two integers \( S_1 \) and \( S_2 \):

\[
s'_1 = s_1 + S_1 t_3, \quad s'_2 = s_2 + S_2 t_3, \quad s'_3 = s_3 - S_1 t_1 - S_2 t_2.
\] (8.76)

Indeed, each of these sets has the same value of the integer \( n \), defined by Eq. (74), as the original one:

\[
n' \equiv s'_1 t_1 + s'_2 t_2 + s'_3 t_3 = (s_1 + S_1 t_1) t_1 + (s_2 + S_2 t_3) t_2 + (s_3 - S_1 t_1 - S_2 t_2) t_3 = n.
\] (8.77)

Since according to Eq. (75), the vector of the distance between any pair of the corresponding points of the direct Bravais lattice (70),

\[
\Delta \mathbf{R} = \Delta S_1 t_3 \mathbf{a}_1 + \Delta S_2 t_3 \mathbf{a}_2 - (\Delta S_1 t_1 + \Delta S_2 t_2) \mathbf{a}_3,
\] (8.78)

satisfies the condition \( \Delta \mathbf{R} \cdot \mathbf{Q} = 2\pi \Delta n = 0 \), this vector is normal to the (fixed) vector \( \mathbf{Q} \). Hence, all the points corresponding to the 2D set (76), with arbitrary integers \( S_1 \) and \( S_2 \), are located on one geometric plane, called the crystal (or “lattice”) plane. In a 3D system of \( N >> 1 \) scatterers (such as \( N \sim 10^{23} \) atoms in a \( \sim 1 \)-cm\(^3\) solid crystal), with all linear dimensions comparable, such a plane contains \( \sim N^{2/3} >> 1 \) points. As a result, the constructive interference peaks are very sharp.

Now rewriting Eq. (75) as a relation for the vector \( \mathbf{R}' \)’s component along the vector \( \mathbf{Q} \),

\[
R_{\mathbf{Q}'} = \frac{2\pi}{Q} n, \quad \text{where} \quad R_{\mathbf{Q}'} = \mathbf{R} \cdot \mathbf{n}_{\mathbf{Q}} = \mathbf{R} \cdot \frac{\mathbf{Q}}{Q}, \quad \text{and} \quad Q = |\mathbf{Q}|,
\] (8.79)

we see that the parallel crystal planes, corresponding to different numbers \( n \) (but the same \( \mathbf{Q} \)) are located in space periodically, with the smallest distance

\[
d = \frac{2\pi}{Q},
\] (8.80)

so that the von Laue condition \( \mathbf{q} = \mathbf{Q} \) may be rewritten as the following rule for the possible magnitudes of the scattering vector \( \mathbf{q} \equiv \mathbf{k} - \mathbf{k}_0 \):

\[
q = \frac{2\pi n}{d}.
\] (8.81)

Figure 9a shows the diagram of the three wave vectors \( \mathbf{k} \), \( \mathbf{k}_0 \), and \( \mathbf{q} \), taking into account the elastic scattering condition \( |\mathbf{k}| = |\mathbf{k}_0| = k \equiv 2\pi\lambda \). From the diagram, we immediately get the famous Bragg rule\(^{33}\) for the (equal) angles \( \alpha \equiv \theta/2 \) between the crystal plane and each of the vectors \( \mathbf{k} \) and \( \mathbf{k}_0 \):

\[
k \sin \alpha = \frac{q}{2} = \frac{mn}{d}, \quad \text{i.e.} \quad 2d \sin \alpha = n\lambda.
\] (8.82)

The physical sense of this relation is very simple – see Fig. 9b drawn in the “direct” space of the radius-vectors \( \mathbf{r} \), rather than in the reciprocal space of the wave vectors, as Fig. 9a. It shows that if the Bragg

\(^{33}\) Named after Sir William Bragg and his son, Sir William Lawrence Bragg, who were first to demonstrate (in 1912) the X-ray diffraction by atoms in crystals. The Braggs’ experiments have made the existence of atoms (before that, a hypothetical notion, which had been ignored by many physicists) indisputable.
condition (82) is satisfied, the total difference \(2d\sin\alpha\) of the optical paths of two waves, partly reflected from the adjacent crystal planes, is equal to an integer number of wavelengths, so these waves interfere constructively.

![Diagram](image)

Fig. 8.9. Deriving the Bragg rule: (a) from the von Laue condition (in the reciprocal space), and (b) from a direct-space diagram. Note that the scattering angle \(\theta\) equals \(2\alpha\).

Finally, note that the von Laue and Bragg rules, as well as the similar condition (60) for the 1D system of scatterers, are valid not only in the Born approximation, but also follow from any adequate theory of scattering, because the phase sum (57) does not depend on the magnitude of the wave propagating from each elementary scatterer, provided that they are all similar.

### 8.5. The Huygens principle

The Born approximation is very convenient for tracing the basic features of (and the difference between) the phenomena of interference and diffraction. Unfortunately, this approximation, based on the relative weakness of the scattered wave, cannot be used for more typical experimental implementations of these phenomena, for example, Young’s two-slit experiment, or the diffraction on a single slit or orifice – see, e.g. Fig. 10. Indeed, at such experiments, the orifice size \(a\) is typically much larger than the light’s wavelength \(\lambda\), and as a result, no clear decomposition of the fields to the “incident” and “scattered” waves is possible inside it.

![Diagram](image)

Fig. 8.10. Deriving the Huygens principle.

However, for such experiments, another approximation, called the *Huygens* (or “Huygens-Fresnel”) principle,\(^{34}\) is very instrumental. In this approach, the wave beyond the screen is represented

\(^{34}\) Named after Christian Huygens (1629-1695) who had conjectured the wave nature of light (which remained controversial for more than a century, until T. Young’s experiments), and Augustin-Jean Fresnel (1788-1827) who has developed a quantitative theory of diffraction, and in particular gave a mathematical formulation of the Huygens principle. (Note that Eq. (91), sufficient for the purposes of this course, is not its most general form.)
as a linear superposition of spherical waves of the type (17), as if they were emitted by every point of the incident wave’s front that has arrived at the orifice. This approximation is valid if the following strong conditions are satisfied:

\[ \lambda << a << r, \]  

where \( r \) is the distance of the observation point from the orifice. In addition, as we have seen in the last section, at small \( \lambda/a \) the diffraction phenomena are confined to angles \( \theta \sim 1/ka \sim \lambda/a << 1 \). For observation at such small angles, the mathematical expression of the Huygens principle, for the complex amplitude \( f_\omega(\mathbf{r}) \) of a monochromatic wave \( f(\mathbf{r}, t) = \text{Re}[f_\omega e^{i\omega t}] \), is given by the following simple formula

\[
f_\omega(\mathbf{r}) = C \int_{\text{orifice}} f_\omega(\mathbf{r}') \frac{e^{ik\mathbf{R}}}{R} d^2r'. \tag{8.84}
\]

Here \( f' \) is any transverse component of any of wave’s fields (either \( E \) or \( H \)), \( R \) is the distance between point \( \mathbf{r}' \) at the orifice and the observation point \( \mathbf{r} \) (i.e. the magnitude of vector \( \mathbf{R} \equiv \mathbf{r} - \mathbf{r}' \)), and \( C \) is a complex constant.

Before describing the proof of Eq. (84), let me carry out its sanity check – which also will give us the constant \( C \). Let us see what does the Huygens principle give for the case when the field under the integral is a plane wave with the complex amplitude \( f_\omega(\mathbf{r}) \), propagating along axis \( z \), with an unlimited \( x \)-\( y \) front, (i.e. when there is no opaque screen at all), so we should take the whole \([x, y]\) plane, say with \( z' = 0 \), as the integration area in Eq. (84) – see Fig. 11.

Then, for the observation point with coordinates \( x = 0, y = 0, \) and \( z > 0 \), Eq. (84) yields

\[
f_\omega(\mathbf{z}) = C f_\omega(0) \int dx' \int dy' \frac{\exp\left\{ik\left(x'^2 + y'^2 + z^2\right)^{1/2}\right\}}{\left(x'^2 + y'^2 + z^2\right)^{1/2}}. \tag{8.85}
\]

Before specifying the integration limits, let us consider the range \( |x'|, |y'| << z \). In this range, the square root, participating in Eq. (85) twice, may be approximated as

\[
\left(x'^2 + y'^2 + z^2\right)^{1/2} \equiv z\left(1 + \frac{x'^2 + y'^2}{z^2}\right)^{1/2} \approx z\left(1 + \frac{x'^2 + y'^2}{2z^2}\right) \equiv z + \frac{x'^2 + y'^2}{2z^2}. \tag{8.86}
\]

35 The fact that the Huygens principle is valid for any field component should not too surprising. Due to condition \( a >> \lambda \), the real boundary conditions at the orifice edges are not important; what is only important that the screen, that limits the orifice, is opaque. Because of this, the Huygens principle’s expression (84) is a part of the so-called scalar theory of diffraction. (In this course, I will not have time to discuss the more accurate, vector theory, of these effects – see, e.g. chapter 11 of the monograph by M. Born and E. Wolf, cited in the end of Sec. 7.1.)
At \( z \gg \lambda \), the denominator of Eq. (85) is a much slower function of \( x' \) and \( y' \) than the exponent in the nominator, and in the former case, it is sufficient (as we will check \textit{a posteriori}) to keep just the main, first term of the expansion (86). With that, Eq. (85) becomes

\[
\frac{f_\omega(z)}{z} = \frac{1}{z} \int dx' \int dy' \exp \left( \frac{ik(x'^2 + y'^2)}{2z} \right) = \frac{Cf_\omega(0)e^{ikz}}{z} I_x I_y, \tag{8.87}
\]

where \( I_x \) and \( I_y \) are two similar integrals; for example,

\[
I_x = \int \exp \left( \frac{ikx'^2}{2z} \right) dx' = \left( \frac{2\pi}{k} \right)^{1/2} \int \exp \left( i \frac{\xi^2}{k^2} \right) d\xi = \left( \frac{2\pi}{k} \right)^{1/2} \left[ \int \cos(\xi^2) d\xi + i \int \sin(\xi^2) d\xi \right], \tag{8.88}
\]

where \( \xi \equiv (k/2z)^{1/2} x' \). These are the so-called \textit{Fresnel integrals}. I will discuss them in more detail in the next section (see, in particular, Fig. 13), and for now, only one property\(^{36}\) of these integrals is important for us: if taken in symmetric limits \([ -\xi_0, +\xi_0 ] \), both of them rapidly converge to the same value, \((\pi/2)^{1/2}\), as soon as \( \xi_0 \) becomes much larger than 1. This means that even if we do not impose any exact limits on the integration area in Eq. (85), this integral converges to the value

\[
f_\omega(z) = \frac{Cf_\omega(0)e^{ikz}}{z} \left( \frac{2\pi}{k} \right)^{1/2} \left[ \left( \frac{\pi}{2} \right)^{1/2} + i \left( \frac{\pi}{2} \right)^{1/2} \right] \tag{8.89}
\]

due to contributions from the central area with a linear size corresponding to \( \Delta \xi \sim 1 \), i.e.

\[
\Delta x \sim \Delta y \sim \left( \frac{z}{k} \right)^{1/2} \sim (\lambda/z)^{1/2}, \tag{8.90}
\]

so that the net contribution from the front points \( r' \) well beyond the range (90) is negligible.\(^{37}\) (Within our assumptions (83), which in particular require \( \lambda \) to be much less than \( z \), the \textit{diffraction angle} \( \Delta x/z \sim \Delta y/z \sim (\lambda/z)^{1/2} \), corresponding to the important area of the front, is small.) According to Eq. (89), to sustain the unperturbed plane wave propagation, \( f_\omega(z) = f_\omega(0)e^{ikz} \), the constant \( C \) has to be taken equal to \( k/2\pi i \). Thus, the Huygens principle’s prediction (84), in its final form, reads

\[
f_\omega(r) = \frac{k}{2\pi i} \int_{\text{orifice}} \frac{f_\omega(r')e^{ikr'}}{R} d^2r', \tag{8.91}
\]

and describes, in particular, the straight propagation of the plane wave (in a uniform medium).

Let me pause to emphasize how nontrivial this result is. It would be a natural corollary of Eqs. (25) (and the linear superposition principle) if all points of the orifice were filled with point scatterers that re-emit all the incident waves into spherical waves. However, as it follows from the above example, the Huygens principle also works if there is nothing in the orifice but the free space!

---

\(^{36}\) See, e.g., MA Eq. (6.10).

\(^{37}\) This result very is natural, because the function \( \exp\{ikR\} \) oscillates fast with the change of \( r' \), so that the contributions from various front points are averaged out. Indeed, the only reason why the central part of plane \([x', \ y']\) gives a non-zero contribution (89) to \( f_\omega(z) \) is that the phase exponents stops oscillating as \((x'^2 + y'^2)\) is reduced below \( \sim z/k \) – see Eq. (86).
This is why let us discuss a proof of the principle,\footnote{This proof was given in 1882 by the same G. Kirchhoff whose circuit rules were discussed in Sec. 4.1 and 6.6.} based on Green’s theorem (2.207). Let us apply it to the function \( f = f_\omega \) where \( f_\omega \) is the complex amplitude of a scalar component of one of the wave’s fields, which satisfies the Helmholtz equation (7.204),

\[
(\nabla^2 + k^2)f_\omega(\mathbf{r}) = 0, \tag{8.92}
\]

and the function \( g = G_\omega \), which is the temporal Fourier image of the corresponding Green’s function. The latter function may be defined, as usual, as the solution to the same equation with the added delta-functional right-hand side with an arbitrary coefficient, for example,

\[
(\nabla^2 + k^2)G_\omega(\mathbf{r}, \mathbf{r'}) = -4\pi \delta(\mathbf{r} - \mathbf{r'}). \tag{8.93}
\]

Using Eqs. (92) and (93) to express the Laplace operators of the functions \( f_\omega \) and \( G_\omega \), we may rewrite Eq. (2.207) as

\[
\int_V \left[ f_\omega [-k^2G_\omega(\mathbf{r}, \mathbf{r'}) - 4\pi \delta(\mathbf{r} - \mathbf{r'})] - G_\omega(\mathbf{r}, \mathbf{r'})(-k^2f_\omega) \right] d^3r = \oint_S \left[ f_\omega \frac{\partial G_\omega(\mathbf{r}, \mathbf{r'})}{\partial n} - G_\omega(\mathbf{r}, \mathbf{r'}) \frac{\partial f_\omega}{\partial n} \right] d^2r, \tag{8.94}
\]

where \( \mathbf{n} \) is the outward normal to the surface \( S \) limiting the integration volume \( V \). Two terms in the left-hand side of this relation cancel, so that after swapping the arguments \( \mathbf{r} \) and \( \mathbf{r'} \), we get

\[
-4\pi f_\omega(\mathbf{r}) = \oint_S \left[ f_\omega(\mathbf{r'}) \frac{\partial G_\omega(\mathbf{r'}, \mathbf{r})}{\partial n'} - G_\omega(\mathbf{r}, \mathbf{r'}) \frac{\partial f_\omega(\mathbf{r'})}{\partial n'} \right] d^2r'. \tag{8.95}
\]

This relation is only correct if the selected volume \( V \) includes the point \( \mathbf{r} \) (otherwise we would not get its left-hand side from the integration of the delta-function), but does not include the genuine source of the wave – otherwise Eq. (92) would have a non-zero right-hand side. Let \( \mathbf{r} \) be the field observation point, \( V \) be all the source-free half-space (for example, the half-space right of the screen in Fig. 10), so that \( S \) is the surface of the screen, including the orifice. Then the right-hand side of Eq. (95) describes the field at the observation point \( \mathbf{r} \), induced by the wave passing through the orifice points \( \mathbf{r'} \).

Since no waves are emitted by the opaque parts of the screen, we can limit the integration by the orifice area.\footnote{Actually, this is a nontrivial point of the proof. Indeed, it may be shown that the solution of Eq. (94) identically equals to zero if \( f(\mathbf{r'}) \) and \( \partial f(\mathbf{r'})/\partial n' \) vanish together at any part of the boundary, of non-zero area. A more careful analysis of this issue (which is the task of the formal vector theory of diffraction, which I will not have time to pursue) confirms our intuition-based conclusion.} Assuming also that the opaque parts of the screen do not re-emit the waves “radiated” by the orifice, we can take the solution of Eq. (93) to be the retarded potential for the free space:40

\[
G_\omega(\mathbf{r}, \mathbf{r'}) = \frac{e^{i\mathbf{R}/R}}{R}. \tag{8.96}
\]

Plugging this expression into Eq. (82), we get

\[
-4\pi f_\omega(\mathbf{r}) = \oint_{\text{orifice}} \left[ f_\omega(\mathbf{r'}) \frac{\partial}{\partial n'} \left( \frac{e^{i\mathbf{R}/R}}{R} \right) - \frac{e^{i\mathbf{R}/R}}{R} \frac{\partial f_\omega(\mathbf{r'})}{\partial n'} \right] d^2r'. \tag{8.97}
\]

\footnote{It follows, e.g., from Eq. (16) with a monochromatic source \( q(t) = q_\omega \exp\{-i\omega t\} \), with the amplitude \( q_\omega = 4\pi\varepsilon \) that fits the right-hand side of Eq. (93).}
This is the so-called Kirchhoff (or “Fresnel-Kirchhoff”) integral. (Again, with the integration extended over all boundaries of the volume \( V \), this would be an exact mathematical result.) Now, let us make two additional approximations. The first of them stems from Eq. (83): at \( ka \gg 1 \), the wave’s spatial dependence in the orifice area may be represented as

\[ f_{\infty}(r') = (\text{a slow function of } r') \times \exp\{i(k_0 \cdot r')\}, \tag{8.98} \]

where “slow” means a function that changes on the scale of \( a \) rather than \( \lambda \). If, also, \( kR \gg 1 \), then the differentiation in Eq. (97) may be, in both instances, limited to the rapidly changing exponents, giving

\[ -4\pi f_{\infty}(r) = \oint_{\text{orifice}} i(k + k_0) \cdot n' \frac{e^{ikR}}{R} f(r')d^2r', \tag{8.99} \]

Second, if all observation angles are small, we may take \( k \cdot n' \approx k_0 \cdot n' \approx -k \). With that, Eq. (99) is reduced to Eq. (91) expressing the Huygens principle.

It is clear that the principle immediately gives a very simple description of the interference of waves passing through two small holes in the screen. Indeed, if the holes’ sizes are negligible in comparison with the distance \( a \) between them (though still much larger than the wavelength!), Eq. (91) yields

\[ f_{\infty}(r) = c_1 e^{ikR_1} + c_2 e^{ikR_2}, \quad \text{with} \quad c_{1,2} \equiv kf_{1,2}A_{1,2}/2\pi R_{1,2}, \tag{8.100} \]

where \( R_{1,2} \) are the distances between the holes and the observation point, and \( A_{1,2} \) are the hole areas. For the wave intensity, Eq. (100) yields

\[ \overline{S} \propto f_{\infty}f_{\infty}^* = |c_1|^2 + |c_2|^2 + 2|c_1||c_2|\cos[k(R_1 - R_2) + \varphi], \quad \text{where} \quad \varphi \equiv \arg c_1 - \arg c_2. \tag{8.101} \]

The first two terms in the last expression clearly represent the intensities of the partial waves passed through each hole, while the last one is the result of their interference. The interference pattern’s contrast ratio

\[ \mathcal{R} \equiv \frac{\overline{S}_{\text{max}}}{\overline{S}_{\text{min}}} = \left( \frac{|c_1| + |c_2|}{|c_1| - |c_2|} \right)^2, \tag{8.102} \]

is the largest (infinite) when both waves have equal amplitudes.

The analysis of the interference pattern is simple if the line connecting the holes is perpendicular to wave vector \( k \approx k_0 \) — see Fig. 6a. Selecting the coordinate axes as shown in that figure, and using for distances \( R_{1,2} \) the same expansion as in Eq. (86), for the interference term in Eq. (101) we get

\[ \cos[k(R_1 - R_2) + \varphi] \approx \cos\left(\frac{kxa}{z} + \varphi\right). \tag{8.103} \]

This means that the intensity does not depend on \( y \), i.e. the interference pattern in the plane of constant \( z \) is a set of straight, parallel strips, perpendicular to the vector \( a \), with the period given by Eq. (60), i.e. by the Bragg law.\footnote{The phase shift \( \varphi \) vanishes at the normal incidence of a plane wave on the holes. Note, however, that the spatial shift of the interference pattern following from Eq. (103), \( \Delta x = -(z/ka)\varphi \), is extremely convenient for the...}
the next term in the Taylor expansion (73) to show that farther on from the interference pattern center
the strips start to diverge.

8.6. Fresnel and Fraunhofer diffraction patterns

Now let us use the Huygens principle to analyze a (slightly) more complex problem: plane wave’s diffraction on a long, straight slit of a constant width $a$ (Fig. 12).

According to Eq. (83), to use the Huygens principle for the problem’s analysis we need to have $\lambda << a << z$. Moreover, the simple version (91) of the principle is only valid for small observation angles, $|x| << z$. Note, however, that the relation between two dimensionless numbers, $z/a$ and $a/\lambda$, both much less than 1, is so far arbitrary; as we will see in a minute, this relation determines the type of the observed diffraction pattern.

Let us apply Eq. (91) to our current problem (Fig. 12), for the sake of simplicity assuming the normal wave incidence, and taking $z' = 0$ at the screen plane:

$$f_0(x, z) = f_0 \frac{k}{2\pi i} \int_{-a}^{+a} dx' \int_{-\infty}^{+\infty} dy' \exp\left\{\frac{ik[(x-x')^2 + y'^2 + z^2]^{1/2}}{(x-x')^2 + y'^2 + z^2}^{1/2}\right\},$$

where $f_0 \equiv f_0(x', 0) = \text{const}$ is the incident wave’s amplitude. This is the same integral as in Eq. (85), except for the finite limits for the integration variable $x'$, and may be simplified similarly, using the small-angle condition $(x-x')^2 + y'^2 << z^2$:

$$f_0(x, z) \approx f_0 \frac{k}{2\pi i} \frac{e^{ikz}}{z} \int_{-a/2}^{+a/2} dx' \int_{-\infty}^{+\infty} dy' \exp\left\{\frac{ik[(x-x')^2 + y'^2]}{2z}\right\} \equiv f_0 \frac{k}{2\pi i} \frac{e^{ikz}}{z} I_x I_y. \quad (8.105)$$

The integral over $y'$ is the same as in the last section:

$$I_y \equiv \int_{-\infty}^{+\infty} \exp\left\{\frac{iky'^2}{2z}\right\} dy' = \left(\frac{2\pi i z}{k}\right)^{1/2}, \quad (8.106)$$

experimental measurement of the phase shift between two waves, especially if it is induced by some factor (such as insertion of a transparent object into one of interferometer’s arms, etc.) that may be turned on/off at will.
but the integral over \( x' \) is more general, because of its finite limits:

\[
I_s \equiv \int_{-a/2}^{+a/2} \exp \left( \frac{ik(x-x')^2}{2z} \right) dx'.
\]  

(8.107)

It may be simplified in the following two (opposite) limits.

(i) **Fraunhofer diffraction** takes place when \( z/a \gg a/\lambda \) – the relation which may be rewritten either as \( a \ll (z\lambda)^{1/2} \), or as \( ka^2 \ll z \). In this limit, the ratio \( k x'^2/z \) is negligibly small for all values of \( x' \) under the integral, and we can approximate it as

\[
\left( \frac{2z}{k} \right)^{1/2} \int_{-a/2}^{+a/2} \exp \left( \frac{ikx'^2}{2z} \right) \frac{dx'}{k} = \frac{2z}{k} \exp \left( \frac{ikx'^2}{2z} \right) \sin \frac{ka}{2z},
\]

so that Eq. (105) yields

\[
f_{oo}(x,z) \approx f_0 \frac{k}{2\pi i} \frac{e^{ikz}}{z} \left( \frac{2\pi iz}{k} \right)^{1/2} \exp \left( \frac{ikx'^2}{2z} \right) \sin \frac{ka}{2z},
\]

and hence the relative wave intensity is

\[
\frac{\overline{S}(x,z)}{S_0} \equiv \left| \frac{f_{oo}(x,z)}{f_0} \right|^2 = \frac{8z}{\pi kx^2} \sin^2 \frac{kxa}{2z} = \frac{2}{\pi} \sin^2 \left( \frac{ka\theta}{2} \right),
\]

(8.110)

where \( S_0 \) is the intensity of the incident wave, and \( \theta \equiv x/z \ll 1 \) is the observation angle. Comparing this expression with Eq. (69), we see that this the diffraction pattern is exactly the same as that of a similar (uniform, 1D) object in the Born approximation – see the red line in Fig. 8. Note again that the angular width \( \delta\theta \) of the Fraunhofer pattern is of the order of \( 1/ka \), so that its linear width \( \delta x = z\delta\theta \) is of the order of \( z/ka \sim \lambda/a \). Hence the condition of the Fraunhofer approximation’s validity may also be represented as \( a \ll \delta x \).

(ii) **Fresnel diffraction**. In the opposite limit of a relatively wide slit, with \( a >> \delta x = z\delta\theta \sim z/ka \sim \lambda/a \), i.e. \( ka^2 >> z \), the diffraction patterns at two slit edges are well separated. Hence, near each edge (for example, near \( x' = -a/2 \)) we may simplify Eq. (107) as

\[
I_s(x) \approx \int_{-a/2}^{+a/2} \exp \left( \frac{ik(x-x')^2}{2z} \right) dx' \equiv \left( \frac{2z}{k} \right)^{1/2} \int_{-a/2}^{+a/2} \exp \left( i\zeta^2 \right) d\zeta,
\]

(8.111)

and express it via the special functions called the Fresnel integrals:\(^43\)

\[42\] Note also that since in this limit \( ka^2 \ll z \), Eq. (97) shows that even the maximum value \( S(0,z) \) of the diffracted wave intensity is much less than the intensity \( S_0 \) of the incident wave. This is natural, because the incident power \( S_0a \) per unit length of the slit is now distributed over a much larger width \( \delta x \gg a \), so that \( S(0,z) \sim S_0 (a/\delta x) \ll S_0 \).

\[43\] Slightly different definitions of these functions, mostly affecting the constant factors, may also be met in literature.
whose plots are shown in Fig. 13a. As was mentioned above, at large values of their argument (\(\xi\)), both functions tend to \(\frac{1}{2}\).

![Graph of Fresnel integrals](image)

Fig. 8.13. (a) The Fresnel integrals and (b) their parametric representation.

Plugging this expression into Eqs. (105) and (111), for the diffracted wave intensity, in the Fresnel limit (i.e. at \(|x + a/2| \ll a\)), we get

\[
\frac{\overline{S}(x, z)}{S_0} = \frac{1}{2} \left\{ \mathcal{C} \left( \frac{k}{2z} \left( x + \frac{a}{2} \right) \right)^2 + \mathcal{F} \left( \frac{k}{2z} \left( x + \frac{a}{2} \right) \right)^2 \right\}. \tag{8.113}
\]

A plot of this function (Fig. 14) shows that the diffraction pattern is very peculiar: while in the “shade” region \(x < -a/2\) the wave intensity fades monotonically, the transition to the “light” region within the gap \((x > -a/2)\) is accompanied by intensity oscillations, just as at the Fraunhofer diffraction – cf. Fig. 8.

![Graph of Fresnel diffraction pattern](image)

Fig. 8.14. The Fresnel diffraction pattern.

This behavior, which is described by the following asymptotes,
is essentially an artifact of observing just the wave intensity (i.e. its real amplitude) rather than its phase as well. Indeed, as may be seen even more clearly from the parametric presentation of the Fresnel integrals, shown in Fig. 13b, these functions oscillate similarly at large positive and negative values of their argument. (This famous pattern is called either the Euler spiral or the Cornu spiral.) Physically, this means that the wave diffraction at the slit edge leads to similar oscillations of its phase at \( x < -a/2 \) and \( x > -a/2 \); however, in the latter region (i.e. inside the slit) the diffracted wave overlaps the incident wave passing through the slit directly, and their interference reveals the phase oscillations, making them visible in the measured intensity as well.

Note that according to Eq. (113), the linear scale \( \delta x \) of the Fresnel diffraction pattern is of the order of \((2z/k)^{1/2}\), i.e. is complies with the estimate (90). If the slit is gradually narrowed, so that its width \( a \) becomes comparable to \( \delta x \),\(^{44}\) the Fresnel diffraction patterns from both edges start to “collide” (interfere). The resulting wave, fully described by Eq. (107), is just a sum of two contributions of the type (111) from both edges of the slit. The resulting interference pattern is somewhat complicated, and only when \( a \) becomes substantially less than \( \delta x \), it is reduced to the simple Fraunhofer pattern (110). Of course, this crossover from the Fresnel to Fraunhofer diffraction may be also observed, at fixed wavelength \( \lambda \) and slit width \( a \), by increasing \( z \), i.e. by measuring the diffraction pattern farther and farther away from the slit.

Note also that the Fraunhofer limit is always valid if the diffraction is measured as a function of the diffraction angle \( \theta \) alone, i.e. effectively at infinity, \( z \to \infty \). This may be done, for example, by collecting the diffracted wave with a “positive” (converging) lens and observing the diffraction pattern in its focal plane.

8.7. Geometrical optics placeholder

Behind all these details, I would not like the reader to miss the main feature of the Fresnel diffraction, that has an overwhelming practical significance. Namely, besides narrow diffraction “cones” (actually, parabolic-shaped regions) with the lateral scale \( \delta x \sim (\lambda z)^{1/2} \), the wave far behind a slit of width \( a \gg \lambda \), \( \delta x \), repeats the field just behind the slit, i.e. reproduces the unperturbed incident wave inside the slit, and has a negligible intensity in the shade regions outside it. An evident generalization of this fact is that when a plane wave (in particular an electromagnetic wave) passes any opaque object of a large size \( a \gg \lambda \), it propagates around it, by distances \( z \) up to \( \sim a^2/\lambda \), along straight lines, with virtually negligible diffraction effects. This fact gives the strict foundation for the very notion of the wave ray (or beam), as the line perpendicular to the local front of a quasi-plane wave. In a uniform media such ray follows a straight line,\(^{45}\) but it refracts in accordance with the Snell law at the interface of two media with

\[^{44}\] Note that this condition may be also rewritten as \( a \sim \delta x \), i.e. \( z/a \sim a/\lambda \).

\[^{45}\] In application to optical waves, this notion may be traced back to at least the work by Hero (a.k.a. Heron) of Alexandria (circa 1-70 AD). Curiously, he correctly described light reflection from one or several plane mirrors, starting from the completely wrong idea of light propagation from the eye of the observer to the observed object.
different wave speed \( v \), i.e. different values of the refraction index. The notion of rays enables the whole field of geometric optics, devoted mostly to ray tracing in various (sometimes very complex) systems.

This is why, at this point, an E&M course that followed the scientific logic more faithfully than this one, would give an extended discussion of the geometric and quasi-geometric optics, including (as a minimum\(^{46}\) such vital topics as

- the so-called *lensmaker’s equation* expressing the focus length \( f \) of a lens via the curvature radii of its spherical surfaces and the refraction index of the lens material,
- the *thin lens formula* relating the image distance from the lens via \( f \) and the source distance,
- the concepts of basic optical instruments such as glasses, telescopes and microscopes,
- the concepts of the spherical, angular, and chromatic aberrations (image distortions).

However, since I have made a (possibly, wrong) decision to follow the common tradition in selecting the main topics for this course, I do not have time/space left for such discussion. Still, I am using this “placeholder” pseudo-section to relay my deep conviction that any educated physicist has to know the geometric optics basics. If the reader has not been exposed to this subject during their undergraduate studies, I highly recommend at least browsing one of the available textbooks.\(^{47}\)

8.8. Fraunhofer diffraction from more complex scatterers

So far, our quantitative analysis of diffraction has been limited to a very simple geometry – a single slit in an otherwise opaque screen (Fig. 12). However, in the most important Fraunhofer limit, \( z \gg ka^2 \), it is easy to get a very simple expression for the plane wave diffraction/interference by a plane orifice (with a linear size \( \sim a \)) of arbitrary shape. Indeed, the evident 2D generalization of the approximation (106)-(107) is

\[
I_x I_y = \int_{\text{orifice}} \exp \left( \frac{ik[(x-x')^2 +(y-y')^2]}{2z} \right) dx' dy'
\approx \exp \left( \frac{ik(x^2 + y^2)}{2z} \right) \int_{\text{orifice}} \exp \left\{ -i \frac{kxx'}{z} - i \frac{kyy'}{z} \right\} dx' dy',
\]

so that besides the inconsequential total phase factor, Eq. (105) is reduced to

\[
f(\mathbf{p}) \propto f_0 \int_{\text{orifice}} \exp \left\{ -i \mathbf{k} \cdot \mathbf{p}' \right\} d^2 \rho' \equiv f_0 \int_{\text{all screen}} T(\mathbf{p}') \exp \left\{ -i \mathbf{k} \cdot \mathbf{p}' \right\} d^2 \rho'. \tag{8.116}
\]

Here the 2D vector \( \mathbf{k} \) (not to be confused with wave vector \( \mathbf{k} \), which is virtually perpendicular to \( \mathbf{k} \)) is defined as

\(^{46}\) Admittedly, even this list leaves aside several spectacular effects, including such a beauty as conical refraction in biaxial crystals – see, e.g., Chapter 15 of the textbook by M. Born and E. Wolf, cited in the end of Sec. 7.1.

\[ \kappa \equiv \frac{k \rho}{z} \approx q = k - k_0, \quad (8.117) \]

and \( \rho = \{x, y\} \) and \( \rho' = \{x', y'\} \) are 2D radius-vectors in the, respectively, observation and orifice planes – both nearly normal to the vectors \( k \) and \( k_0 \). In the last form of Eq. (116), the function \( T(\rho') \) describes the screen’s transparency at point \( \rho' \), and the integral is over the whole screen plane \( z' = 0 \). (Though the two forms of Eq. (116) are strictly equivalent only if \( T(\rho') \) equals to either 1 or 0, its last form may be readily obtained from Eq. (91) with \( f(r') = T(\rho')\delta_0 \) for any transparency profile, provided that \( T(\rho') \) is an arbitrary function, but changes only at distances much larger than \( \lambda \equiv 2\pi/k \).)

From the mathematical point of view, the last form of Eq. (116) is just the 2D spatial Fourier transform of the function \( T(\rho') \), with the variable \( \kappa \) defined by the observation point’s position: \( \rho \equiv (z/k) \kappa = (z\lambda/2\pi) \kappa \). This interpretation is useful because of the experience we all have with the Fourier transform, mostly in the context of its time/frequency applications. For example, if the orifice is a single small hole, \( T(\rho') \) may be approximated by a delta-function, so that Eq. (116) yields \( |f(\rho)| \approx \text{const} \). This result corresponds (at least for the small diffraction angles \( \theta \equiv \rho'z \), for which the Huygens approximation is valid) to a spherical wave spreading from the point-like orifice. Next, for two small holes, Eq. (116) immediately gives the Young interference pattern (103). Let me now use Eq. (116) to analyze other simplest (and most important) 1D transparency profiles, leaving 2D cases for the reader’s exercise.

(i) A single slit of width \( a \) (Fig. 12) may be described by transparency

\[ T(\rho') = \begin{cases} 1, & \text{for } |x'| < a/2, \\ 0, & \text{otherwise}. \end{cases} \quad (8.118) \]

Its substitution into Eq. (116) yields

\[ f(\rho) \propto f_0 \int_{-a/2}^{+a/2} \exp\{-i\kappa',x'\} dx' = f_0 \frac{\exp\{-i\kappa',a/2\} - \exp\{i\kappa',a/2\}}{-i\kappa'} \propto \sin\left(\frac{\kappa'a}{2}\right) = \sin\left(\frac{kxa}{2z}\right), \quad (8.119) \]

naturally returning us to Eqs. (64) and (110), and hence to the red lines in Fig. 8 for the wave intensity. (Please note again that Eq. (116) describes only the Fraunhofer, but not the Fresnel diffraction!)

(ii) Two narrow, similar, parallel slits with a much larger distance \( a \) between them may be described by taking

\[ T(\rho') \propto \delta(x' - a/2) + \delta(x' + a/2), \quad (8.120) \]

so that Eq. (116) yields the generic 1D interference pattern,

\[ f(\rho) \propto f_0 \left[ \exp\left\{-i\kappa',a/2\right\} + \exp\left\{i\kappa',a/2\right\} \right] \propto \cos \frac{\kappa'a}{2} = \cos \frac{kxa}{2z}, \quad (8.121) \]

whose intensity is shown with the blue line in Fig. 8.

(iii) In a more realistic version of the Young-type two-slit experiment, each slit has a width (say, \( w \)) which is much larger than light wavelength \( \lambda \), but still much smaller than the slit spacing \( a \). This situation may be described by the following transparency function
\[
T(p') = \sum_{n} \left\{ \begin{array}{ll}
1, & \text{for } |x' \pm a| < w/2,
0, & \text{otherwise},
\end{array} \right.
\]

(8.122)

for which Eq. (116) yields a natural combination of the results (119) (with \(a\) replaced with \(w\)) and (121):

\[
f(r) \propto \text{sinc}\left(\frac{kxw}{2z}\right)\cos\left(\frac{kxa}{2z}\right).
\]

(8.123)

This is the usual interference pattern, modulated with a Fraunhofer-diffraction envelope (shown with the dashed blue line in Fig. 15). Since the function \(\text{sinc}^2 \xi\) decreases very fast beyond its first zeros at \(\xi = \pm \pi\), the practical number of observable interference fringes is close to \(2a/w\).

(iv) A structure very useful for experimental and engineering practice is a set of many parallel, similar slits, called the **diffraction grating**.\(^{48}\) Indeed, if the slit width is much smaller than the grating period \(d\), the grating’s transparency function may be approximated as

\[
T(p') \propto \sum_{n} \delta(x' - nd),
\]

(8.124)

and Eq. (116) yields

\[
f(p) \propto \sum_{n} \exp\left\{-i n \kappa d \right\} = \sum_{n} \exp\left\{-i \frac{nkd}{z} \right\}.
\]

(8.125)

This sum vanishes for all values of \(\kappa d\) that are not multiples of \(2\pi\), so that the result describes sharp intensity peaks at the following diffraction angles:

\[
\theta_m = \left(\frac{x}{z}\right)_m = \left(\frac{\kappa}{k}\right)_m = 2\pi k d^m = \frac{\lambda}{d} m.
\]

(8.126)

Taking into account that this result is only valid for small angles \(|\theta_m| \ll 1\), it may be interpreted exactly as Eq. (59) – see Fig. 6a. However, in contrast with the interference (121) from two slits, the destructive interference from many slits kills the net wave as soon as the angle is even slightly different from each value (60). This is very convenient for spectroscopic purposes, because the diffraction lines

\(^{48}\) The rudimentary diffraction grating effect, produced by the parallel fibers of a bird’s feather, was discovered as early as in 1673 by James Gregory – who has also invented the reflecting (“Gregorian”) telescope.
produced by multi-frequency waves do not overlap even if the frequencies of their adjacent components are very close.

Two unavoidable features of practical diffraction gratings make their properties different from this simple, ideal picture. First, the finite number $N$ of slits, which may be described by limiting the sum (125) to the interval $n = [-N/2, +N/2]$, results in a non-zero spread, $\delta \theta \sim 1/N$, of each diffraction peak, and hence in the reduction of the grating’s spectral resolution. (Unintentional variations of the inter-slit distance $d$ have a similar effect, so that before the advent of high-resolution photolithography, special high-precision mechanical tools had been used for grating fabrication.)

Second, a finite slit width $w$ leads to the diffraction peak pattern modulation by a $\text{sinc}^2(kw\theta/2)$ envelope, similar to the pattern shown in Fig. 15. Actually, for spectroscopic purposes, such modulation is sometimes a plus, because only one diffraction peak (say, with $m = \pm 1$) is practically used, and if the frequency spectrum of the analyzed wave is very broad (covers more than one octave), the higher peaks produce undesirable hindrance. Because of this reason, $w$ is frequently selected to be equal exactly to $d/2$, thus suppressing each other diffraction maximum. Moreover, sometimes semi-transparent films are used to make the transparency function $T(r')$ continuous and close to a sinusoidal one:

$$T(r') \approx T_0 + T_1 \cos \frac{2\pi x'}{d} = T_0 + \frac{T_1}{2} \left( \exp \left\{ i \frac{2\pi x'}{d} \right\} + \exp \left\{ -i \frac{2\pi x'}{d} \right\} \right).$$

Plugging the last expression into Eq. (116) and integrating, we see that the output wave consists of just 3 components: the direct-passing wave (proportional to $T_0$) and two diffracted waves (proportional to $T_1$) propagating in the directions of the two lowest Bragg angles, $\theta_{\pm 1} = \pm \lambda / d$.

The same Eq. (116) may be also used to obtain one more general (and rather curious) result, called the Babinet principle.\(^{49}\) Consider two experiments with the diffraction of similar plane waves on two “complementary” screens who together would cover the whole plane, without a hole or an overlap. (Think, for example, about an opaque disk of radius $R$ and a large opaque screen with a round orifice of the same radius.) Then, according to the Babinet principle, the diffracted wave patterns produced by these two screens in all directions with $\theta \neq 0$ are identical. The proof of this principle is straightforward: since the transparency functions produced by the screens are complementary in the following sense:

$$T(r') = T_0(r') + T_1(r') = 1,$$

and (in the Fraunhofer approximation only!) the diffracted wave is a Fourier transform of $T(r')$, which is a linear operation, we get

$$f_1(\rho) + f_2(\rho) = f_0(\rho),$$

where $f_0$ is the wave “scattered” by the composite screen with $T_0(\rho') \equiv 1$, i.e. the unperturbed initial wave propagating in the initial direction ($\theta = 0$). In all other directions, $f_1 = -f_2$, i.e. the diffracted waves are indeed similar besides the difference in sign – which is equivalent to a phase shift by $\pm \pi$. However, it is important to remember that the Babinet principle notwithstanding, in real experiments, with screens at finite distances, the diffracted waves may interfere with the unperturbed plane wave $f_0(\rho)$, leading to different diffraction patterns in the cases 1 and 2 – see, e.g., Fig. 14 and its discussion.

\(^{49}\) Named after Jacques Babinet (1784-1874) who made several important contributions to optics.
8.9. Magnetic dipole and electric quadrupole radiation

Throughout this chapter, we have seen how many important results may be obtained from Eq. (26) for the electric dipole radiation by a small-size source (Fig. 1). Only in rare cases when this radiation is absent, for example if the dipole moment $p$ of the source equals zero (or does not change in time – either at all or at the frequency of our interest), higher-order effects may be important. I will discuss the main two of them, the quadrupole electric radiation and the dipole magnetic radiation.

In Sec. 2 above, the electric dipole radiation was calculated by plugging the expansion (19) into the exact formula (17b) for the retarded vector potential $A(r, t)$. Let us make a more exact calculation, by keeping the second term of that expansion as well:

$$j\left( r', t - \frac{R}{v} \right) \approx j\left( r', t - \frac{r'}{v} + \frac{r' \cdot n}{v} \right) \equiv j\left( r', t' + \frac{r' \cdot n}{v} \right), \quad \text{where} \quad t' \equiv t - \frac{r}{v}. \quad (8.130)$$

Since the expansion is only valid if the last term in the time argument of $j$ is relatively small, in the Taylor expansion of $j$ with respect to that argument we may keep just two leading terms:

$$j\left( r', t' + \frac{r' \cdot n}{v} \right) \approx j(r', t') + \frac{\partial j(r', t')}{\partial t'} \left( r' \cdot n \right), \quad (8.131)$$

so that Eq. (17b) yields $A = A_e + A'$, where $A_e$ is the electric dipole contribution as given by Eq. (23), and $A'$ is the new term of the next order in the small parameter $r' << r$:

$$A'(r, t) = \frac{\mu}{4\pi rv} \frac{\partial}{\partial t} \int j(r', t')(r' \cdot n) d^3 r'. \quad (8.132)$$

Just as it was done in Sec. 2, let us evaluate this term for a system of non-relativistic particles with electric charges $q_k$ and radius-vectors $r_k(t)$:

$$A'(r, t) = \frac{\mu}{4\pi rv} \left[ \frac{d}{dt} \sum_k q_k \dot{r}_k (r_k \cdot n) \right]_{t=t'}. \quad (8.133)$$

Using the “bac minus cab” identity of the vector algebra again,\(^{50}\) the vector operand of Eq. (133) may be rewritten as

$$\dot{r}_k (r_k \cdot n) = \frac{1}{2} \dot{r}_k (r_k \cdot n) + \frac{1}{2} \ddot{r}_k (n \cdot r_k) = \frac{1}{2}(r_k \times \ddot{r}_k) \times n + \frac{1}{2}r_k (n \cdot \ddot{r}_k) + \frac{1}{2}r_k (n \cdot r_k)$$

$$\equiv \frac{1}{2}(r_k \times \ddot{r}_k) \times n + \frac{1}{2} \frac{d}{dt} [r_k (n \cdot r_k)], \quad (8.134)$$

so that the right-hand side of Eq. (133) may be represented as a sum of two terms, $A' = A_m + A_q$, where

$$A_m(r, t) = \frac{\mu}{4\pi rv} \hat{m}(t') \times n \equiv \frac{\mu}{4\pi rv} \hat{m}\left( t - \frac{r}{v} \right) \times n, \quad \text{with} \quad \hat{m}(t) \equiv \frac{1}{2} \sum_k r_k(t) \times q_k \ddot{r}_k(t); \quad (8.135)$$

$$A_q(r, t) = \frac{\mu}{8\pi rv} \left[ \frac{d^2}{dt^2} \sum_k q_k r_k (n \cdot r_k) \right]_{t=t'}. \quad (8.136)$$

\(^{50}\) If you need, see, e.g., MA Eq. (7.5).
Comparing the second of Eqs. (135) with Eq. (5.91), we see that \( m \) is just the total magnetic moment of the source. On the other hand, the first of Eqs. (135) is absolutely similar in structure to Eq. (23), with \( p \) replaced with \( (m \times n)/v \), so that for the corresponding component of the magnetic field it gives (in the same approximation \( r \gg \lambda \)) a result similar to Eq. (24):

\[
B_m(\mathbf{r}, t) = \frac{\mu}{4\pi rv} \nabla \times \left[ \mathbf{m} \left( t - \frac{r}{v} \right) \times \mathbf{n} \right] = -\frac{\mu}{4\pi rv^2} \mathbf{n} \times \left[ \dot{\mathbf{m}} \left( t - \frac{r}{v} \right) \times \mathbf{n} \right]. \tag{8.137}
\]

According to this expression, just as at the electric dipole radiation, the vector \( \mathbf{B} \) is perpendicular to the vector \( \mathbf{n} \), and its magnitude is also proportional to \( \sin \Theta \), where \( \Theta \) is now the angle between the direction toward the observation point and the second time derivative of the vector \( \mathbf{m} \) – rather than \( \mathbf{p} \):

\[
B_m = -\frac{\mu}{4\pi rv^2} \mathbf{n} \times \left[ \dot{\mathbf{m}} \left( t - \frac{r}{v} \right) \right] \sin \Theta. \tag{8.138}
\]

As the result, the intensity of this magnetic dipole radiation has a similar angular distribution:

\[
S_r = ZH^2 = \frac{Z}{(4\pi v^2 r)^2} \left[ \dot{\mathbf{m}} \left( t - \frac{r}{v} \right) \right]^2 \sin^2 \Theta. \tag{8.139}
\]

- cf. Eq. (26), besides the (generally) different meaning of the angle \( \Theta \).

Note, however, that this radiation is usually much weaker than its electric-dipole counterpart. For example, for a non-relativistic particle with electric charge \( q \), moving on a trajectory of linear size \( \sim a \), the electric dipole moment is of the order of \( qa \), while its magnetic moment scales as \( qa^2 \omega \), where \( \omega \) is the motion frequency. As a result, the ratio of the magnetic and electric dipole radiation intensities is of the order of \( (a \omega/v)^2 \), i.e. the squared ratio of the particle’s speed to the speed of emitted waves – that has to be much smaller than 1 for our non-relativistic calculation to be valid.

The angular distribution of the electric quadrupole radiation, described by Eq. (136), is more complicated. To show this, we may add to \( \mathbf{A}_q \) a vector parallel to \( \mathbf{n} \) (i.e. along the wave’s propagation), getting

\[
\mathbf{A}_q(\mathbf{r}, t) \rightarrow \frac{\mu}{24\pi rv} \dot{\mathbf{Q}} \left( t - \frac{r}{v} \right), \quad \text{where} \quad \dot{\mathbf{Q}} = \sum_k q_k \left\{ 3\mathbf{r}_k (\mathbf{n} \cdot \mathbf{r}_k) - \mathbf{n} r_k^2 \right\}, \tag{8.140}
\]

because this addition does not give any contribution to the transverse component of the electric and magnetic fields, i.e. to the radiated wave. According to the above definition of the vector \( \dot{\mathbf{Q}} \), its Cartesian components may be represented as

\[
\mathcal{E}_j = \sum_{j'=1}^{3} \mathcal{E}_{jj'} n_{j'}, \tag{8.141}
\]

where \( \mathcal{E}_{jj'} \) are the elements of the electric quadrupole tensor of the system – see the last of Eqs. (3.4):

\[
\mathcal{E}_{jj'} = \sum_k q_k \left( 3 r_j r_{j'} - r^2 \delta_{jj'} \right)_k. \tag{8.142}
\]

(Let me hope that the reader has already acquired some experience in the calculation of this tensor’s components – e.g., for the simple systems listed in Problems 3.2 and 3.3.) Now taking the curl of the first of Eqs. (140) at \( r \gg \lambda \), we get
This expression is similar to Eqs. (24) and (137), but according to Eqs. (140) and (142), components of the vector \( \vec{n} \) do depend on the direction of the vector \( \vec{r} \), leading to a different angular dependence of \( S_r \).

As the simplest example, let us consider a system of two equal point electric charges moving symmetrically, at equal distances \( d(t) \ll \lambda \) from a stationary center – see Fig. 16.

![Fig. 8.16. The simplest system emitting electric quadrupole radiation.](image)

Due to the symmetry of the system, its dipole moments \( \vec{p} \) and \( \vec{m} \) (and hence its electric and magnetic dipole radiation) vanish, but the quadrupole tensor (142) still has non-zero components. With the coordinate choice shown in Fig. 16, these components are diagonal:

\[
\mathcal{C}_{xx} = \mathcal{C}_{yy} = -2qd^2, \quad \mathcal{C}_{zz} = 4qd^2. \tag{8.144}
\]

With the \( x \)-axis selected within the common plane of the \( z \)-axis and the direction \( \vec{n} \) toward the source (Fig. 16), so that \( n_x = \sin \Theta, \; n_y = 0, \; n_z = \cos \Theta \), Eq. (141) yields

\[
\mathcal{C}_x = -2qd^2 \sin \Theta, \quad \mathcal{C}_y = 0, \quad \mathcal{C}_z = 4qd^2 \cos \Theta, \tag{8.145}
\]

and the vector product in Eq. (143) has only one non-vanishing Cartesian component:

\[
\left( \vec{n} \times \vec{\mathcal{C}} \right)_z = n_x \mathcal{C}_{zz} - n_z \mathcal{C}_{xx} = -6q \sin \Theta \cos \Theta \frac{d^3}{dt^3} \left[ d^2(t) \right]. \tag{8.146}
\]

As a result, the quadrupole radiation intensity, \( S \propto B_q^2 \), is proportional to \( \sin^2 \Theta \cos^2 \Theta \), i.e. vanishes not only along the symmetry axis of the system (as the electric-dipole and the magnetic-dipole radiations would do), but also in all directions perpendicular to this axis, reaching its maxima at \( \Theta = \pm \pi/4 \).

For more complex systems, the angular distribution of the electric quadrupole radiation may be different, but it may be shown that its total (instant) power always obey the simple formula

\[
\mathcal{R}_q = \frac{Z}{1440 \pi^4} \sum_{j,j'=1}^3 \left( \mathcal{C}_{jj'} \right)^2. \tag{8.147}
\]

Let me finish this section by giving, also without proof, one more fact important for some applications: due to their different spatial structure, the magnetic-dipole and electric-quadrupole radiation fields do not interfere, i.e. the total power of radiation (neglecting the electric-dipole and higher multipole terms) may be found as the sum of these components, calculated independently. On the contrary, if the electric-dipole and magnetic-dipole radiations of the same system are comparable, they typically interfere coherently, so that their radiation fields (rather than powers) should be summed up.
8.10. **Exercise problems**

8.1. In the electric-dipole approximation, calculate the angular distribution and the total power of electromagnetic radiation by the hydrogen atom within the following classical model: an electron rotating, at a constant distance $R$, about a much heavier proton. Use the latter result to evaluate the classical lifetime of the atom, borrowing the initial value of $R$ from quantum mechanics: $R(0) = r_B \approx 0.53 \times 10^{-10}$ m.

8.2. A non-relativistic particle of mass $m$, with electric charge $q$, is placed into a uniform magnetic field $B$. Derive the law of decrease of the particle’s kinetic energy due to its electromagnetic radiation at the cyclotron frequency $\omega_c = qB/m$. Evaluate the rate of such radiation cooling of electrons in a magnetic field of 1 T, and estimate the energy interval in which this result is qualitatively correct.

*Hint:* The cyclotron motion will be discussed in detail (for arbitrary particle velocities $v \sim c$) in Sec. 9.6 below, but I hope that the reader knows that in the non-relativistic case ($v \ll c$) the above formula for $\omega_c$ may be readily obtained by combining the 2nd Newton law $mv_{\perp}^2/R = qv_{\perp}B$ for the circular motion of the particle under the effect of the magnetic component of the Lorentz force (5.10), and the geometric relation $v_{\perp} = R\omega_c$. (Here $v_{\perp}$ is particle’s velocity in the plane normal to the vector $B$.)

8.3. Solve the dipole antenna radiation problem discussed in Sec. 2 (see Fig. 3) for the optimal length $l = \lambda/2$, assuming that the current distribution in each of its arms is sinusoidal: $I(z, t) = I_0 \cos(\pi z/l) \cos \omega t$.

8.4. Use the Lorentz oscillator model of a bound charge, given by Eq. (7.30), to explore the transition between the two scattering limits discussed in Sec. 3, in particular, the resonant scattering taking place at $\omega \approx \omega_0$. In this context, discuss the contribution of scattering into the oscillator’s damping.

8.5. A sphere of radius $R$, made of a material with a uniform permanent electric polarization $P_0$ and a constant mass density $\rho$, is free to rotate about its center. Calculate the average total cross-section of scattering, by the sphere, of a linearly polarized electromagnetic wave of frequency $\omega \ll R/c$, propagating in free space, in the limit of small wave amplitude, assuming that the initial orientation of the polarization vector $P_0$ is random.

8.6. Use Eq. (56) to analyze the interference/diffraction pattern produced by a plane wave’s scattering on a set of $N$ similar, equidistant points on a straight line normal to the direction of the incident wave’s propagation – see the figure on the right. Discuss the trend(s) of the pattern in the limit $N \to \infty$.

8.7. Use the Born approximation to calculate the differential cross-section of the plane wave scattering by a nonmagnetic, uniform dielectric sphere of an arbitrary radius $R$. In the limits $kR \ll 1$ and $1 \ll kR$ (where $k$ is the wave number), analyze the angular dependence of the differential cross-section, and calculate the total cross-section of scattering.

---

51 As was emphasized in Sec. 2, this is a reasonable guess rather than a controllable approximation. The exact (rather involved!) theory shows that this assumption gives errors $\sim 5\%$. 

---
8.8. A sphere of radius $R$ is made of a uniform, nonmagnetic, linear dielectric material, with an arbitrary dielectric constant. Derive an exact expression for its total cross-section of scattering of a low-frequency monochromatic wave, with $k << 1/R$, and compare the result with the solution of the previous problem.

8.9. Use the Born approximation to calculate the differential cross-section of the plane wave scattering on a right, circular cylinder of length $l$ and radius $R$, for an arbitrary angle of incidence.

8.10. Formulate the quantitative condition of the Born approximation’s validity for a uniform dielectric scatterer, with all linear dimensions of the order of the same scale $a$.

8.11. If a scatterer absorbs some part of the incident wave’s power, it may be characterized by an absorption cross-section $\sigma_a$ defined similarly to Eq. (39) for the scattering cross-section:

$$\sigma_a \equiv \frac{\overline{P_a}}{|E_0|^2 / 2Z_0},$$

where the numerator is the time-averaged power absorbed is the scatterer. Calculate $\sigma_a$ for a very small sphere of radius $R << k^{-1}$, $\delta$, made of a nonmagnetic material with Ohmic conductivity $\sigma$, and with high-frequency permittivity $\varepsilon_{opt} = \varepsilon_0$. Can $\sigma_a$ of such a sphere be larger than its geometric cross-section $\pi R^2$?

8.12. Use the Huygens principle to calculate wave’s intensity on the symmetry plane of the slit diffraction experiment (i.e. at $x = 0$ in Fig. 12), for arbitrary ratio $z/ka^2$.

8.13. A plane wave with wavelength $\lambda$ is normally incident on an opaque, plane screen, with a round orifice of radius $R >> \lambda$. Use the Huygens principle to calculate the passed wave’s intensity distribution along the system’s symmetry axis, at distances $z >> R$ from the screen (see the figure on the right), and analyze the result.

8.14. A plane monochromatic wave is now normally incident on an opaque circular disk of radius $R >> \lambda$. Use the Huygens principle to calculate the wave’s intensity at distance $z >> R$ behind the disk’s center (see the figure on the right). Discuss the result.

8.15. Use the Huygens principle to analyze the Fraunhofer diffraction of a plane wave normally incident on a square-shaped hole, of size $a \times a$, in an opaque screen. Sketch the diffraction pattern you would observe at a sufficiently large distance, and quantify expression “sufficiently large” for this case.

8.16. Use the Huygens principle to analyze the propagation of a monochromatic Gaussian beam, described by Eq. (7.181), with the initial characteristic width $a_0 >> \lambda$, in a uniform, isotropic medium.
Use the result for a semi-quantitative derivation of the so-called *Abbe limit*\(^\text{52}\) for the spatial resolution of an optical system: \( w_{\text{min}} = \frac{\lambda}{2\sin\theta} \), where \( \theta \) is the half-angle of the wave cone propagating from the object, and captured by the system.

8.17. Within the Fraunhofer approximation, analyze the pattern produced by a 1D diffraction grating with the periodic transparency profile shown in the figure on the right, for the normal incidence of a plane, monochromatic wave.

8.18. \( N \) equal point charges are attached, at equal intervals, to a circle rotating with a constant angular velocity about its center – see the figure on the right. For what values of \( N \) does the system emit:

(i) the electric dipole radiation?
(ii) the magnetic dipole radiation?
(iii) the electric quadrupole radiation?

8.19. What general statements can you make about:

(i) the electric dipole radiation, and
(ii) the magnetic dipole radiation,
due to a collision of an arbitrary number of similar classical, non-relativistic particles?

8.20. Calculate the angular distribution and the total power radiated by a small round loop antenna with radius \( R \), fed by ac current \( I(t) \) with frequency \( \omega \) and amplitude \( I_0 \), into the free space.

8.21. The orientation of a magnetic dipole \( \mathbf{m} \), of a fixed magnitude, is rotating about a certain axis with angular velocity \( \omega \), with the angle \( \alpha \) between them staying constant. Calculate the angular distribution and the average power of its radiation (into the free space).

8.22. Solve Problem 8.8 (also in the low-frequency limit \( kR \ll 1 \)), for the case when the sphere’s material has a frequency-independent Ohmic conductivity \( \sigma \), and \( \varepsilon_{\text{opt}} = \varepsilon_0 \), in two limits:

(i) of a very large skin depth (\( \delta_s \gg R \)), and
(ii) of a very small skin depth (\( \delta_s \ll R \)).

8.23. Complete the solution of the problem started in Sec. 9, by calculating the full power of radiation of the system of two charges oscillating in antiphase along the same straight line – see Fig. 16. Also, calculate the average radiation power for the case of harmonic oscillations, \( d(t) = a \cos \omega t \), compare it with the case of a single charge performing similar oscillations, and interpret the difference.

\(^{52}\) Reportedly, due to not only Ernst Abbe (1873), but also to Hermann von Helmholtz (1874).
Chapter 9. Special Relativity

This chapter starts with a review of the special relativity’s basics, including the very convenient 4-vector formalism. This background is then used for the analysis of the relation between the electromagnetic field’s values measured in different reference frames moving relative to each other. The results of this discussion enable the analysis of the relativistic particle dynamics in the electric and magnetic fields, and of the analytical mechanics of the particles and the electromagnetic field as such.

9.1. Einstein postulates and the Lorentz transform

As was emphasized at the derivation of expressions for the dipole and quadrupole radiations in the last chapter, they are only valid for systems of non-relativistic particles. Thus, these results cannot be used for the description of such important phenomena as the Cherenkov radiation or the synchrotron radiation, in which relativistic effects are essential. Moreover, an analysis of the motion of charged relativistic particles in electric and magnetic fields is also a natural part of electrodynamics. This is why I will follow the tradition of using this course for a (by necessity, brief) introduction to the special relativity theory. This theory is based on the fundamental idea that measurements of physical variables (including the spatial and even temporal intervals between two events) may give different results in different reference frames, in particular in two inertial frames moving relative to each other translationally (i.e. without rotation), with a certain constant velocity \( v \) (Fig. 1).

In the non-relativistic (Newtonian) mechanics the problem of transfer between such reference frames has a simple solution at least in the limit \( v \ll c \), because the basic equation of particle dynamics (the 2nd Newton law) \(^1\)

\[
m_k \ddot{r}_k = -\nabla_k \sum_{k'} U(r_k - r_{k'}) ,
\]

where \( U \) is the potential energy of inter-particle interactions, is invariant with respect to the so-called Galilean transformation (or just “transform” for short). \(^2\) Choosing the coordinate axes of both frames so that the axes \( x \) and \( x' \) are parallel to the vector \( v \) (as in Fig. 1), the transform \(^3\) may be represented as

---

\(^1\) Let me hope that the reader does not need a reminder that for Eq. (1) to be valid, the reference frames 0 and 0’ have to be inertial – see, e.g., CM Sec. 1.2.

\(^2\) It had been first formulated by Galileo Galilei, if only rather informally, as early as in 1638 – four years before Isaac Newton was born!

\(^3\) Note the very unfortunate term “boost”, used sometimes to describe the transfer between reference frames. (It is especially unnatural in the special relativity, not describing any accelerations.) In these notes, this term is avoided.
and plugging Eq. (2a) into Eq. (1), we get an absolutely similarly looking equation of motion in the “moving” reference frame $0'$. Since the reciprocal transform,

$$x' = x - vt, \quad y = y', \quad z' = z, \quad t' = t,$$

(9.2b)

is similar to the direct one, with the replacement of $(+v)$ with $(-v)$, we may say that the Galilean invariance means that there is no any “master” (absolute) spatial reference frame in classical mechanics, although the spatial and temporal intervals between different instant events are absolute, i.e. reference-frame invariant: $\Delta x = \Delta x', \ldots, \Delta t = \Delta t'$.

However, it is straightforward to use Eq. (2) to check that the form of the wave equation

$$\left( \frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} + \frac{\partial^2}{\partial z^2} - \frac{1}{c^2} \frac{\partial^2}{\partial t^2} \right) f = 0,$$

(9.3)

describing in particular the electromagnetic wave propagation in free space, is not Galilean-invariant. For the “usual” (say, elastic) waves, which obey a similar equation albeit with a different speed, this lack of Galilean invariance is natural and is compatible with the invariance of Eq. (1), from which the wave equation originates. This is because the elastic waves are essentially the oscillations of interacting particles of a certain medium (e.g., an elastic solid), which makes the reference frame connected to this medium, special. So, if the electromagnetic waves were oscillations of a certain special medium (which was first called the “luminiferous aether” and later the aether – or just the “ether”), similar arguments might be applicable to reconcile Eqs. (2) and (3).

The detection of such a medium was the goal of the measurements carried out between 1881 and 1887 (with better and better precision) by Albert Abraham Michelson and Edward Williams Morley, which are sometimes called “the most famous failed experiments in physics”. Figure 2 shows a crude scheme of these experiments.

---

4 The discussions in this chapter and most of the next chapter will be restricted to the free-space (and hence dispersion-free) case; some media effects on the radiation by relativistic particles will be discussed in Sec. 10.4.

5 It is interesting that the usual Schrödinger equation, whose fundamental solution for a free particle is a similar monochromatic wave (albeit with a different dispersion law), is Galilean-invariant, with a certain addition to the wavefunction’s phase – see, e.g., QM Chapter 1. This is natural, because this equation is non-relativistic.

6 See, e.g., CM Secs. 6.5 and 7.7.

7 In ancient Greek mythology, aether is the clean air breathed by the gods residing on Mount Olympus.
A nearly-monochromatic wave from a light source is split into two parts (nominally, of equal intensity), using a semi-transparent mirror tilted by 45° to the incident wave direction. These two partial waves are reflected back by two full-reflection mirrors, and arrive at the same semi-transparent mirror again. Here a half of each wave is returned to the light source area (where they vanish without affecting the source), but another half passes toward the detector, forming, with its counterpart, an interference pattern similar to that in the Young experiment. Thus each of the interfering waves has traveled twice (back and forth) each of two mutually perpendicular “arms” of the interferometer. Assuming that the aether, in which light propagates with speed \( c \), moves with speed \( v < c \) along one of the arms, of length \( l_l \), it is straightforward (and hence left for reader’s exercise :-)) to get the following expression for the difference between the light roundtrip times:

\[
\Delta t = \frac{2}{c} \left[ \frac{l_l}{(1 - v^2/c^2)^{1/2}} - \frac{l_t}{1 - v^2/c^2} \right] \approx \frac{l_t}{c} \left( \frac{v}{c} \right)^2, \tag{9.4}
\]

where \( l_t \) is the length of the second, “transverse” arm of the interferometer (perpendicular to \( v \)), and the last, approximate expression is valid at \( l_t \approx l_l \equiv l \) and \( v << c \).

Since the Earth moves around the Sun with a speed \( v_E \approx 30 \text{ km/s} \approx 10^{-4} c \), the arm positions relative to this motion alternate, due to the Earth’s rotation about its axis, every 6 hours – see the right panel of Fig. 2. Hence if we assume that the aether rests in the Sun’s reference frame, \( \Delta t \) (and the corresponding shift of the interference fringes), has to change its sign with this half-period as well. The same alternation may be achieved, at a smaller time scale, by a deliberate rotation of the instrument by \( \pi/2 \). In the most precise version of the Michelson-Morley experiment (1887), this shift was expected to be close to 0.4 of the fringe pattern period. The results of the search for such a shift were negative, with the error bar about 0.01 of the fringe period.\(^8\)

The most prominent immediate explanation of this zero result\(^9\) was suggested in 1889 by George Francis FitzGerald and (independently and more qualitatively) by H. Lorentz in 1892: as evident from Eq. (4), if the longitudinal arm of the interferometer itself experiences the so-called length contraction,

\[
l_l(v) = l_l(0) \left( 1 - \frac{v^2}{c^2} \right)^{1/2}, \tag{9.5}
\]

while the transverse arm’s length is not affected by its motion through the aether, this kills the shift \( \Delta t \).

This, extremely radical, idea received strong support from the proof, in 1887-1905, that the Maxwell equations, and hence the wave equation (3), are form-invariant under the so-called Lorentz transform.\(^10\)

For the choice of coordinates shown in Fig. 1, the transform reads

---

8 Through the 20th century, the Michelson-Morley-type experiments were repeated using more and more refined experimental techniques, always with the zero results for the apparent aether motion speed. For example, recent experiments, using cryogenically cooled optical resonators, have reduced the upper limit for such speed to just 3x10^-15 c – see H. Müller et al., Phys. Rev. Lett. 91, 020401 (2003).

9 The zero result of a slightly later experiment, namely precise measurements of the torque which should be exerted by the moving aether on a charged capacitor, carried out in 1903 by F. Trouton and H. Noble (following G. FitzGerald’s suggestion), seconded the Michelson and Morley’s conclusions.

10 The theoretical work toward this goal (which I unfortunately do not have time to review in detail) included important contributions by Woldemart Voigt (in 1887), Hendrik Lorentz (in 1892-1904), Joseph Larmor (in 1897 and 1900), and Henri Poincaré (in 1900 and 1905).
It is elementary to solve these equations for the primed coordinates to get the reciprocal transform

\[ x' = \frac{x - vt}{\left(1 - v^2 / c^2\right)^{1/2}}, \quad y' = y, \quad z' = z, \quad t' = \frac{t - (v / c^2)x'}{\left(1 - v^2 / c^2\right)^{1/2}}. \]  

(I will soon represent Eqs. (6) in a more elegant form.)

The Lorentz transform relations (6) are evidently reduced to the Galilean transform formulas (2) at \( v^2 \ll c^2 \). As will be proved in the next section, Eqs. (6) also yield the FitzGerald-Lorentz length contraction (5). However, all attempts to give a reasonable interpretation of these equalities while keeping the notion of the aether have failed, in particular because of the restrictions imposed by results of earlier experiments carried out in 1851 and 1853 by Hippolyte Fizeau — that were repeated with higher accuracy by the same Michelson and Morley in 1886. These experiments have shown that if one sticks to the aether concept, this hypothetical medium has to be partially “dragged” by any moving dielectric material with a speed proportional to \((\kappa - 1)\). Such local drag is irreconcilable with the assumed continuity of the aether.

In his famous 1905 paper, Albert Einstein has suggested a bold resolution of this contradiction, essentially removing the concept of the aether altogether.\(^{11}\) Moreover, he argued that the Lorentz transform is the general property of time and space, rather than of the electromagnetic field alone. He has started with two postulates, the first one essentially repeating the principle of relativity, formulated earlier (1904) by H. Poincaré in the following form:

“…the laws of physical phenomena should be the same, whether for an observer fixed, or for an observer carried along in a uniform movement of translation; so that we have not and could not have any means of discerning whether or not we are carried along in such a motion.”\(^{12}\)

The second Einstein’s postulate was that the speed of light \(c\), in free space, should be constant in all reference frames. (This is essentially a denial of the aether’s existence.)

Then, Einstein showed how naturally do the Lorenz transform relations (6) follow from his postulates, with a few (very natural) additional assumptions. Let a point source emit a short flash of light, at the moment \( t = t' = 0 \) when the origins of the reference frames shown in Fig. 1 coincide. Then, according to the second of the Einstein’s postulates, in each of the frames, the spherical wave propagates with the same speed \(c\), i.e. the coordinates of points of its front, measured in the two frames, have to obey the following equalities:

\(^{11}\) In hindsight, this was much relief, because the aether had been a very awkward construct to start with. In particular, according to the basic theory of elasticity (see, e.g., CM Ch. 7), in order to carry such transverse waves as the electromagnetic ones, this medium would need to have a non-vanishing shear modulus, i.e. behave as an elastic solid — rather than as a rarified gas hypothesized initially by C. Huygens.

\(^{12}\) Note that though the relativity principle excludes the notion of the special (“absolute”) spatial reference frame, its verbal formulation still leaves the possibility of the Galilean “absolute time” \( t = t' \) open. The quantitative relativity theory kills this option — see Eqs. (6) and their discussion below.
What may be the general relation between the combinations in the left-hand side of these equations – not for this particular wave’s front, but in general? A very natural (essentially, the only justifiable) choice is

\[
\left[(ct)^2 - (x^2 + y^2 + z^2)\right] = f(v^2) \left[(ct')^2 - (x'^2 + y'^2 + z'^2)\right].
\]  

(9.8)

Now, according to the first postulate, the same relation should be valid if we swap the reference frames \((x \leftrightarrow x', \text{ etc.) and replace } v \text{ with } (-v). This is only possible if } f^2 = 1, \text{ so that excluding the option } f = -1 \text{ (which is incompatible with the Galilean transform in the limit } v/c \to 0), \text{ we get}

\[
(ct)^2 - (x^2 + y^2 + z^2) = (ct')^2 - (x'^2 + y'^2 + z'^2).
\]  

(9.9)

For the line with \(y = y' = 0, z = z' = 0, \) Eq. (9) is reduced to

\[
(ct)^2 - x^2 = (ct')^2 - x'^2.
\]  

(9.10)

It is very illuminating to interpret this relation as the one resulting from a mutual rotation of the reference frames (that now have to include clocks to measure time) on the plane of the coordinate \(x\) and the so-called Euclidian time \(\tau \equiv i ct – \text{ see Fig. 3.}\)

Indeed, rewriting Eq. (10) as

\[
\tau^2 + x^2 = \tau'^2 + x'^2,
\]  

(9.11)

we may consider it as the invariance of the squared radius at the rotation that is shown in Fig. 3 and described by the evident geometric relations

\[
x = x' \cos \psi - \tau' \sin \psi,
\]

(9.12a)

\[
\tau = x' \sin \psi + \tau' \cos \psi,
\]

with the reciprocal relations

\[
x' = x \cos \psi + \tau \sin \psi,
\]

(9.12b)

\[
\tau' = -x \sin \psi + \tau \cos \psi.
\]

So far, the angle \(\psi\) has been arbitrary. In the spirit of Eq. (8), a natural choice is \(\psi = \psi(v), \) with the requirement \(\psi(0) = 0. \) To find this function, let us write the definition of the velocity \(v\) of the frame \(0', \) as measured in the frame 0 (which was implied above): for \(x' = 0, x = vt. \) In the variables \(x\) and \(\tau, \) this means

\[
\frac{x}{\tau} \bigg|_{x' = 0} \equiv \frac{x}{ict} \bigg|_{x' = 0} = \frac{v}{ic}.
\]  

(9.13)
On the other hand, for the same point \( x' = 0 \), Eqs. (12a) yield

\[
\frac{x}{\tau} \bigg|_{x'=0} = -\tan \psi .
\]  
(9.14)

These two expressions are compatible only if

\[
\tan \psi = \frac{iv}{c} ,
\]  
(9.15)

so that

\[
\sin \psi \equiv \frac{\tan \psi}{(1 + \tan^2 \psi)^{1/2}} = \frac{iv/c}{(1 - v^2/c^2)^{1/2}} \equiv i\beta \gamma , \quad \cos \psi \equiv \frac{1}{(1 + \tan^2 \psi)^{1/2}} = \frac{1}{(1 - v^2/c^2)^{1/2}} \equiv \gamma ,
\]  
(9.16)

where \( \beta \) and \( \gamma \) are two very convenient and commonly used dimensionless parameters defined as

\[
\beta \equiv \frac{v}{c} , \quad \gamma \equiv \frac{1}{(1 - v^2/c^2)^{1/2}} \equiv \frac{1}{(1 - \beta^2)^{1/2}} .
\]  
(9.17)

(The vector \( \mathbf{\beta} \) is called the normalized velocity, while the scalar \( \gamma \), the Lorentz factor.)\(^{13}\)

Using the relations for \( \psi \), Eqs. (12) become

\[
x = \gamma (x' - i\beta \tau') , \quad \tau = \gamma (i\beta x' + \tau') ,
\]  
(9.18a)

\[
x' = \gamma (x + i\beta \tau) , \quad \tau' = \gamma (-i\beta x + \tau) .
\]  
(9.18b)

Now returning to the real variables \([x, ct]\), we get the Lorentz transform relations (6), in a more compact form:

\[
x = \gamma (x' + \beta ct') , \quad y = y' , \quad z = z' , \quad ct = \gamma (ct' + \beta x') ,
\]  
(9.19a)

\[
x' = \gamma (x - \beta ct) , \quad y' = y , \quad z' = z , \quad ct' = \gamma (ct - \beta x) .
\]  
(9.19b)

An immediate corollary of Eqs. (19) is that for \( \gamma \) to stay real, we need \( v^2 \leq c^2 \), i.e. that the speed of any physical body (to which we could connect a meaningful reference frame) cannot exceed the speed of light, as measured in any other meaningful reference frame.\(^{14}\)

**9.2. Relativistic kinematic effects**

Before proceeding to other corollaries of Eqs. (19), we need to spend a few minutes to discuss what do these relations actually mean. Evidently, they are trying to tell us that the spatial and temporal intervals are not absolute (as they are in the Newtonian space), but do depend on the reference frame they are measured in. So, we have to understand very clearly what exactly may be measured – and thus may be discussed in a meaningful physics theory. Recognizing this necessity, A. Einstein has introduced the notion of numerous imaginary observers that may be distributed all over each reference frame. Each

---

\(^{13}\) Note the following identities: \( \gamma^2 \equiv 1/(1-\beta^2) \) and \( (\gamma^2 - 1) \equiv \beta^2/(1-\beta^2) \equiv \gamma \beta^2 \), which are frequently handy for the relativity-related algebra. One more function of \( \beta \), the rapidity \( \phi \equiv \tanh^{-1} \beta \) (so that \( \psi = i\phi \)), is also useful for some calculations.

\(^{14}\) All attempts to rationally conjecture particles moving with \( v > c \), called tachyons, have failed – so far, at least. Possibly the strongest objection against their existence is the fact that the tachyons could be used to communicate back in time, thus violating the causality principle – see, e.g., G. Benford et al., Phys. Rev. D 2, 263 (1970).
observer has a clock and may use it to measure the instants of *local* events. He also conjectured, very reasonably, that:

(i) all observers within the same reference frame may agree on a common length measure (“a scale”), i.e. on their relative positions in that frame, and synchronize their clocks,\(^{15}\) and

(ii) the observers belonging to different reference frames may agree on the nomenclature of *world events* (e.g., short flashes of light) to which their respective measurements refer.

Actually, these additional postulates have been already implied in our “derivation” of the Lorentz transform in Sec. 1. For example, by the set \(\{x, y, z, t\}\) we mean the results of space and time measurements of a certain world event, about that all observers belonging to the frame 0 agree. Similarly, all observers of frame 0’ have to agree about the results \(\{x’, y’, z’, t’\}\). Finally, when the origin of frame 0’ passes by some sequential points \(x_k\) of frame 0, observers in that frame may measure its passage times \(t_k\) without a fundamental error, and know that all these times belong to \(x’ = 0\).

Now we can analyze the major corollaries of the Lorentz transform, which are rather striking from the point of view of our everyday (rather non-relativistic :-) experience.

(i) **Length contraction.** Let us consider a rigid rod, stretched along axis \(x\), with its length \(l \equiv x_2 - x_1\), where \(x_{1,2}\) are the coordinates of rod’s ends, as measured in its rest frame 0, at any instant \(t\) (Fig. 4). What would be the rod’s length \(l’\) measured by the Einstein observers in the moving frame 0’?

![Fig. 9.4. The relativistic length contraction.](image)

At a time instant \(t’\) agreed upon in advance, the observers who find themselves exactly at the rod’s ends, may register that fact, and then subtract their coordinates \(x’_{1,2}\) to calculate the apparent rod length \(l’ \equiv x_2’ - x_1’\) in the moving frame. According to Eq. (19a), \(l\) may be expressed via this \(l’\) as

\[
l \equiv x_2 - x_1 = \gamma(x_2' + \beta t') - \gamma(x_1' + \beta t') = \gamma(x_2' - x_1') \equiv \gamma l'.
\]

Hence, the rod’s length, as measured in the *moving* reference frame is

\[
l' = \frac{l}{\gamma} = l \left(1 - \frac{v^2}{c^2}\right)^{-1/2} \leq l,
\]

in accordance with the FitzGerald-Lorentz hypothesis (5). This is the *relativistic length contraction* effect: an object is always the longest (has the so-called *proper length* \(l\)) if measured in its *rest frame.*

---

\(^{15}\) A posteriori, the Lorenz transform may be used to show that consensus-creating procedures (such as clock synchronization) are indeed possible. The basic idea of the proof is that at \(v \ll c\), the relativistic corrections to space and time intervals are of the order of \((v/c)^2\), they have negligible effects on clocks being brought together into the same point for synchronization slowly, with a speed \(u \ll c\). The reader interested in a detailed discussion of this and other fine points of special relativity may be referred to, e.g., either H. Arzeliès, *Relativistic Kinematics*, Pergamon, 1966, or W. Rindler, *Introduction to Special Relativity*, 2nd ed., Oxford U. Press, 1991.
Note that according to Eqs. (19), the length contraction takes place only in the direction of the relative motion of two reference frames. As has been noted in Sec. 1, this result immediately explains the zero result of the Michelson-Morley-type experiments, so that they give very convincing evidence (if not an irrefutable proof) of Eqs. (18)-(19).

(ii) Time dilation. Now let us use Eqs. (19a) to find the time interval $\Delta t$, as measured in some reference frame 0, between two world events – say, two ticks of a clock moving with another frame 0' (Fig. 5), i.e. having constant values of $x'$, $y'$, and $z'$.

Let the time interval between these two events, measured in the clock’s rest frame 0’, be $\Delta t' \equiv t_2' - t_1'$. At these two moments, the clock would fly by certain two Einstein’s observers at rest in the frame 0, so that they can record the corresponding moments $t_{1,2}$ shown by their clocks, and then calculate $\Delta t$ as their difference. According to the last of Eqs. (19a),

$$c\Delta t \equiv ct_2 - ct_1 = \gamma [ct_2' + \beta x'] - (ct_1' + \beta x')] \equiv \gamma c\Delta t',$$

so that, finally,

$$\Delta t = \gamma \Delta t' \equiv \frac{\Delta t'}{(1 - v^2/c^2)^{1/2}} \geq \Delta t'.$$  \hfill (9.21a)

This is the famous relativistic time dilation (or “dilatation”) effect: a time interval is longer if measured in a frame (in our case, frame 0) moving relative to the clock, while that in the rest frame is the shortest possible – the so-called proper time interval.

This counter-intuitive effect is the everyday reality at experiments with high-energy elementary particles. For example, in a typical (and by no means record-breaking) experiment carried out in Fermilab, a beam of charged 200 GeV pions with $\gamma \approx 1,400$ traveled a distance $l = 300$ m with the measured loss of only 3% of the initial beam intensity due to the pion decay (mostly, into muon-neutrino pairs) with the proper lifetime $t_0 \approx 2.56 \times 10^{-8}$ s. Without the time dilation, only an $\exp\{-l/c\gamma t_0\} \approx 10^{-17}$ fraction of the initial pions would survive, while the relativity-corrected number $\exp\{-l/c\gamma t_0\} \approx 0.97$ was in full accordance with experimental measurements.

As another example, the global positioning systems (say, the GPS) are designed with the account of the time dilation due to the velocity of their satellites (and also some gravity-induced, i.e. general-relativity corrections, which I would not have time to discuss) and would give large errors without such corrections. So, there is no doubt that time dilation (21) is a reality, though the precision of its experimental tests I am aware of\(^{16}\) has been limited by a few percent, because of almost unavoidable involvement of less controllable gravity effects.

\[^{16}\text{See, e.g., J. Hafele and R. Keating, Science 177, 166 (1972).}\]
Before the first reliable observation of the time dilation (by B. Rossi and D. Hall in 1940), there had been serious doubts in the reality of this effect, the most famous being the twin paradox first posed (together with an immediate suggestion of its resolution) by P. Langevin in 1911. Let us send one of two twins on a long star journey with a speed \( v \) approaching \( c \). Upon his return to Earth, who of the twins would be older? The naïve approach is to say that due to the relativity principle, not one can be (and hence there is no time dilation), because each twin could claim that his counterpart, rather than himself, was moving, with the same speed, just in the opposite direction. The resolution of the paradox in the general theory of relativity (which can handle not only the gravity, but also the acceleration effects) is that one of the twins had to be accelerated to be brought back, and hence the reference frames have to be dissimilar: only one of them may stay inertial all the time. Because of that, the twin who had been accelerated (“actually traveling”) would be younger than their sibling, when they finally come together.

(iii) Velocity transformation. Now let us calculate the velocity \( u \) of a particle, as observed in the reference frame 0, provided that its velocity, as measured in the frame \( 0' \), is \( u' \) (Fig. 6).

![Fig. 9.6. The relativistic velocity addition.](image)

Keeping the usual definition of velocity, but with the due attention to the relativity of not only spatial but also temporal intervals, we may write

\[
\frac{\mathbf{u}}{dt} \equiv \frac{dr}{dt}, \quad \frac{\mathbf{u'}}{dt'} \equiv \frac{dr'}{dt'}.
\]  

(9.22)

Plugging in the differentials of the Lorentz transform relations (6a) into these definitions, we get

\[
u_x \equiv \frac{dx}{dt} = \frac{dx' + vdt'}{dt' + vdx'/c^2} = \frac{u'_x + v}{1 + u'_x v/c^2}, \quad u_y \equiv \frac{dy}{dt} = \frac{1}{\gamma} \frac{dy'}{dt' + vdx'/c^2} = \frac{1}{\gamma} \frac{u'_y}{1 + u'_x v/c^2}, \quad (9.23)
\]

and a similar formula for \( u_z \). In the classical limit \( v/c \to 0 \), these relations are reduced to

\[
u_x = u'_x + v, \quad u_y = u'_y, \quad u_z = u'_z,\]  

(9.24a)

and may be merged into the familiar Galilean form

\[
u = \mathbf{u'} + \mathbf{v}, \quad \text{for} \quad v << c.\]  

(9.24b)

In order to see how unusual the full relativistic rules (23) are at \( u \sim c \), let us first consider a purely longitudinal motion, \( u_y = u_z = 0 \); then\(^\text{17}\)

\[\text{with an account of the well-known trigonometric identity} \tan(a + b) = (\tan a + \tan b)/(1 - \tan a \tan b) \text{ and Eq. (15), Eq. (25) shows that the rapidities} \psi \text{ add up exactly as the longitudinal velocities at non-relativistic motion, making that notion very convenient for the analysis of transfer between several frames.}\]
where \( u \equiv u_x \) and \( u' \equiv u'_x \). Figure 7 shows \( u \) as the function of \( u' \), given by this formula, for several values of the reference frames' relative velocity \( v \).

The first sanity check is that if \( v = 0 \), i.e. the reference frames are at rest relative to each other, then \( u = u' \), as it should be – see the diagonal straight line. Next, if magnitudes of \( u' \) and \( v \) are both below \( c \), so is the magnitude of \( u \). (Also good, because otherwise ordinary particles in one frame would be tachyons in the other one, and the theory would be in a big trouble.) Now strange things begin: even as \( u' \) and \( v \) are both approaching \( c \), then \( u \) is also close to \( c \), but does not exceed it. As an example, if we fired forward a bullet with the relative speed 0.9\( c \), from a spaceship moving from the Earth also at 0.9\( c \), Eq. (25) predicts the speed of the bullet relative to Earth to be just \( [(0.9 + 0.9)/(1 + 0.9\times0.9)]c \approx 0.994 c < c \), rather than \( (0.9 + 0.9)c = 1.8 \ c > c \) as in the Galilean kinematics. Actually, we could expect this strangeness, because it is necessary to fulfill the 2\(^{\text{nd}}\) Einstein’s postulate: the independence of the speed of light in any reference frame. Indeed, for \( u' = \pm c \), Eq. (25) yields \( u = \pm c \), regardless of \( v \).

In the opposite case of a purely transverse motion, when a particle moves across the relative motion of the frames (for example, at our choice of coordinates, \( u'_x = u'_z = 0 \)), Eqs. (23) yield a much less spectacular result

\[
u_y = \frac{u'_y}{\gamma} \leq u'_y.
\]

This effect comes purely from the time dilation, because the transverse coordinates are Lorentz-invariant.

In the case when both \( u'_x \) and \( u'_y \) are substantial (but \( u'_z \) is still zero), we may divide Eqs. (23) by each other to relate the angles \( \theta \) of particle’s propagation, as observed in the two reference frames:

\[
\tan \theta \equiv \frac{u_y}{u_x} = \frac{u'_y}{\gamma(u'_x + v)} = \frac{\sin \theta'}{\gamma(\cos \theta' + v/u')}.
\]
This expression describes, in particular, the so-called *stellar aberration* effect, the dependence of the observed direction $\theta$ toward a star on the speed $v$ of the telescope’s motion relative to the star – see Fig. 8. (The effect is readily observable experimentally as the *annual aberration* due to the periodic change of speed $v$ by $2v_E \approx 60$ km/s because of the Earth’s rotation about the Sun. Since the aberration’s main part is of the first order in $v_E/c \sim 10^{-4}$, the effect is very significant and has been known since the early 1700s.)

For the analysis of this effect, it is sufficient to take, in Eq. (27), $u' = c$, i.e. $v/u' = \beta$, and interpret $\theta'$ as the “proper” direction to the star, that would be measured at $v = 0$. At $\beta << 1$, both Eq. (27) and the Galilean result (which the reader is invited to derive directly from Fig. 8),

$$\tan \theta = \frac{\sin \theta'}{\cos \theta' + \beta}, \quad (9.28)$$

may be well approximated by the first-order term

$$\Delta \theta \equiv \theta - \theta' \approx -\beta \sin \theta'. \quad (9.29)$$

Unfortunately, it is not easy to use the difference between Eqs. (27) and (28), of the second order in $\beta$, for the special relativity confirmation, because other components of the Earth’s motion, such as its rotation, nutation, and torque-induced precession, give masking first-order contributions to the aberration.

Finally, at a completely arbitrary direction of vector $u'$, Eqs. (22) may be readily used to calculate the velocity magnitude. The most popular form of the resulting expression is for the square of the relative velocity (or rather the relative reduced velocity $\beta$) of two particles,

$$\beta^2 = \frac{(\beta_1 - \beta_2)^2 - |\beta_1 \cdot \beta_2|}{(1 - \beta_1 \cdot \beta_2)^2} \leq 1. \quad (9.30)$$

where $\beta_{1,2} \equiv v_{1,2}/c$ are their normalized velocities as measured in the same reference frame.

---

18 Strictly speaking, to reconcile the geometries shown in Fig. 1 (for which all our formulas, including Eq. (27), are valid) and Fig. 8 (giving the traditional scheme of the stellar aberration), it is necessary to invert the signs of $u$ (and hence $\sin \theta'$ and $\cos \theta'$) and $v$, but as evident from Eq. (27), all the minus signs cancel, and the formula is valid as is.

19 See, e.g., CM Secs. 4.4-4.5.
(iv) **The Doppler effect.** Let us consider a plane, monochromatic wave moving along the x-axis:

\[
f = \text{Re}[f_\omega \exp(i(kx - \omega t))] \equiv |f_\omega| \cos(kx - \omega t + \text{arg } f_\omega) \equiv |f_\omega| \cos \Psi.
\]  

(9.31)

Its total phase, \(\Psi \equiv kx - \omega t + \text{arg } f_\omega\) (in contrast to the real amplitude \(|f_\omega|\)) cannot depend on the observer’s reference frame, because all fields of a traveling wave vanish simultaneously at \(\Psi = \pi(n + \frac{1}{2})\) (for all integer \(n\)), and such “world events” should be observable in all reference frames. The only way to keep \(\Psi = \Psi'\) at all times is to have\(^{20}\)

\[
kx - \omega t = k'x' - \omega't'.
\]

(9.32)

First, let us use this general relation to consider the Doppler effect in usual non-relativistic waves, e.g., oscillations of particles of a certain medium. Using the Galilean transform (2), we may rewrite Eq. (32) as

\[
k(x' + vt) - \omega t = k'x' - \omega't'.
\]

(9.33)

Since this transform leaves all space intervals (including the wavelength \(\lambda = 2\pi/k\) intact, we can take \(k = k'\), so that Eq. (33) yields

\[
\omega' = \omega - kv.
\]

(9.34)

For a dispersion-free medium, the wave number \(k\) is the ratio of its frequency \(\omega\), as measured in the reference frame bound to the medium, and the wave velocity \(v_w\). In particular, if the wave source rests in the medium, we may bind the reference frame 0 to the medium as well, and the frame 0′ to wave’s receiver (so that \(v = v_r\)), so that

\[
k = \frac{\omega}{v_w},
\]

(9.35)

while for the frequency perceived by the receiver, Eq. (34) yields

\[
\omega' = \omega - \frac{v_w - v_r}{v_w}.
\]

(9.36)

On the other hand, if the receiver and the medium are at rest in the reference frame 0′, while the wave source is bound to the frame 0 (so that \(v = -v_s\)), Eq. (35) should be replaced with

\[
k = k' = \frac{\omega'}{v_w},
\]

(9.37)

and Eq. (34) yields a different result:

\[
\omega' = \omega - \frac{v_w}{v_w - v_s},
\]

(9.38)

Finally, if both the source and detector are moving, it is straightforward to combine these two results to get the general relation

\[
\omega' = \omega - \frac{v_w - v_r}{v_w - v_s}.
\]

(9.39)

\(^{20}\) Strictly speaking, Eq. (32) is valid to an additive constant, but for notation simplicity, it may be always made equal to zero by selecting (at it has already been done in all relations of Sec. 1) the reference frame origins and/or clock turn-on times so that at \(t = 0\) and \(x = 0\), \(t' = 0\) and \(x' = 0\) as well.
At low speeds of both the source and the receiver, this result simplifies,

$$\omega' \approx \omega(1 - \beta), \quad \text{with} \quad \beta \equiv \frac{v_r - v_s}{v_w}, \quad (9.40)$$

but at speeds comparable to $v_w$ we have to use the more general Eq. (39). Thus, the usual Doppler effect is generally affected not only by the relative speed $(v_r - v_s)$ of wave’s source and detector, but also of their speeds relative to the medium in which the waves propagate.

Somewhat counter-intuitively, for the electromagnetic waves the calculations are simpler, because for them the propagation medium (aether) does not exist, the wave velocity equals $\pm c$ in any reference frame, and there are no two separate cases: we can always take $k = \pm \phi c$ and $k' = \pm \phi' c$. Plugging these relations, together with the Lorentz transform (19a), into the phase-invariance condition (32), we get

$$\pm \frac{\omega}{c} \gamma(x' + \beta ct') - \omega \gamma \frac{ct' + \beta x'}{c} = \pm \frac{\omega'}{c} x' - \omega't'. \quad (9.41)$$

This relation has to hold for any $x'$ and $t'$, so we may require the net coefficients before these variables to vanish. These two requirements yield the same equality:

$$\omega' = \omega \gamma(1 + \beta). \quad (9.42)$$

This result is already quite simple, but may be transformed further to be even more illuminating:

$$\omega' = \omega \frac{1 \mp \beta}{(1 - \beta^2)^{1/2}} \equiv \omega \left[\frac{(1 \mp \beta)(1 \mp \beta)}{(1 + \beta)(1 - \beta)}\right]^{1/2}. \quad (9.43)$$

At any sign before $\beta$, one pair of parentheses cancel, so that

$$\omega' = \omega \left[\frac{1 \mp \beta}{1 \pm \beta}\right]^{1/2}. \quad (9.44)$$

(It may look like the reciprocal expression of $\omega$ via $\omega'$ is different, violating the relativity principle. However, in this case we have to change the sign of $\beta$, because the relative velocity of the system is opposite, so we return to Eq. (44) again.)

Thus the Doppler effect for electromagnetic waves depends only on the relative velocity $v = \beta c$ between the wave source and detector – as it should be, given the aether’s absence. At velocities much below $c$, Eq. (44) may be approximated as

$$\omega' \approx \omega \frac{1 \mp \beta}{2} \approx \omega(1 \mp \beta), \quad (9.45)$$

i.e. in the first approximation in $\beta \equiv v/c$ it coincides with the corresponding limit (40) of the usual Doppler effect. However, even at $v \ll c$ there is still a difference, of the order of $(v/c)^2$, between the Galilean and Lorentzian relations.

If the wave vector $k$ is tilted by angle $\theta$ to the vector $v$ (as measured in frame 0), then we have to repeat the calculations, with $k$ replaced by $k_x$, and components $k_y$ and $k_z$ left intact at the Lorentz transform. As a result, Eq. (42) is generalized as...
\[ \omega' = \omega \gamma (1 - \beta \cos \theta). \]  

(9.46)

For the cases \( \cos \theta = \pm 1 \), Eq. (46) reduces to our previous result (42). However, at \( \theta = \pi/2 \) (i.e. \( \cos \theta = 0 \)), the relation is rather different:

\[ \omega' = \gamma \omega = \frac{\omega}{\sqrt{1 - \beta^2}}. \]  

(9.47)

This is the \textit{transverse Doppler effect} – which is completely absent in non-relativistic physics. Its first experimental evidence was obtained using electron beams (as suggested in 1906 by J. Stark), by H. Ives and G. Stilwell in 1938 and 1941. Later, similar experiments were repeated several times, but the first unambiguous measurements were performed only in 1979 by D. Hasselkamp \textit{et al.} who confirmed Eq. (47) with a relative accuracy of about 10\%. This precision may not look too spectacular, but besides the special tests discussed above, the Lorentz transform formulas have been also confirmed, less directly, by a huge body of other experimental data, especially in high energy physics, agreeing with calculations incorporating this transform as their part. This is why, with every respect to the spirit of challenging authority, I should warn the reader: if you decide to challenge the relativity theory (called “theory” by tradition only), you would also need to explain all these data.21 Best luck with that!

### 9.3. 4-vectors, momentum, mass, and energy

Before proceeding to the relativistic dynamics, let us discuss a mathematical formalism that makes all the calculations more compact – and more beautiful. We have already seen that the 3 spatial coordinates \( \{x, y, z\} \) and the product \( ct \) are Lorentz-transformed similarly – see Eqs. (18)-(19) again. So it is natural to consider them as components of a single 4-component vector (or, for short, \textit{4-vector}),

\[ \{x_0, x_1, x_2, x_3\} \equiv \{ct, \mathbf{r}\}, \]

(9.48)

with components

\[ x_0 \equiv ct, \quad x_1 \equiv x, \quad x_2 \equiv y, \quad x_3 \equiv z. \]

(9.49)

According to Eqs. (19), its components are Lorentz-transformed as

\[ x_j = \sum_{j'=0}^{3} L_{jj'} x_{j'}, \]

(9.50)

where \( L_{jj'} \) are the elements of the following \( 4 \times 4 \) Lorentz transform matrix

\[
\begin{pmatrix}
\gamma & \beta \gamma & 0 & 0 \\
\beta \gamma & \gamma & 0 & 0 \\
0 & 0 & 1 & 0 \\
0 & 0 & 0 & 1
\end{pmatrix}.
\]

(9.51)

Since such 4-vectors are a new notion for our course, and will be used for many more purposes than just the space-time transform, we need to discuss the mathematical rules they obey. Indeed, as was

---

21 The same fact, ignored by crackpots, is also valid for other favorite points of their attacks, including the Universe expansion and quantum mechanics in physics, and the evolution theory in biology.
already mentioned in Sec. 8.9, the usual (3-component) vector is not just any ordered set (string) of three scalars \( \{A_x, A_y, A_z\} \); if we want it to represent a reference-frame-independent physical reality, the vector’s components have to obey certain rules at the transfer from one reference frame to another. In particular, the vector’s norm (its magnitude squared),

\[
A^2 = A_x^2 + A_y^2 + A_z^2 ,
\]

(9.52)

should be an invariant at the Galilean transform (2). However, a naïve extension of this formula to 4-vectors would not work, because, according to the calculations of Sec. 1, the Lorentz transform keeps intact the combinations of the type (7), with one sign negative, rather than the sum of all components squared. Hence for the 4-vectors, all the rules of the game have to be reviewed and adjusted – or rather redefined from the very beginning.

An arbitrary 4-vector is a string of 4 scalars,\(^{22}\)

\[
\{A_0, A_1, A_2, A_3\} ,
\]

(9.53)

whose components \( A_j \), as measured in the systems 0 and 0’ shown in Fig. 1, obey the Lorentz transform relations similar to Eq. (50):

\[
A_j = \sum_{j=0}^{3} L_{jj'} A_{j'} .
\]

(9.54)

As we have already seen on the example of the space-time 4-vector (48), this means in particular that

\[
A_0^2 - \sum_{j=1}^{3} A_j^2 = (A_0')^2 - \sum_{j=1}^{3} (A_j')^2 .
\]

(9.55)

This is the so-called Lorentz invariance condition of the norm of the 4-vector. (The difference between this relation and Eq. (52), pertaining to the Euclidian geometry, is the reason why the Minkowski space is called pseudo-Euclidian.) It is also straightforward to use Eqs. (51) and (54) to check that an evident generalization of the norm, the scalar product of two arbitrary 4-vectors,

\[
A_0 B_0 - \sum_{j=1}^{3} A_j B_j ,
\]

(9.56)

is also Lorentz-invariant.

Now consider the 4-vector corresponding to a small interval between two close world events:

\[
\{dx_0, dx_1, dx_2, dx_3\} = \{cdt, d\mathbf{r}\} ;
\]

(9.57)

its norm,

\[
(ds)^2 \equiv dx_0^2 - \sum_{j=1}^{3} dx_j^2 = c^2 (dt)^2 - (d\mathbf{r})^2 ,
\]

(9.58)

is of course also Lorentz-invariant. Since the speed of any particle (or signal) cannot be larger than \( c \), for any pair of world events that are in a causal relation with each other, \((d\mathbf{r})^2\) cannot be larger than \((cdt)^2\),

\(^{22}\) Such vectors are said to reside in so-called 4D Minkowski spaces – called after Hermann Minkowski who was the first one to recast (in 1907) the special relativity relations in a form in which the spatial coordinates and time (or rather \( ct \)) are treated on an equal footing.
i.e. such *time-like* interval \((ds)^2\) cannot be negative. The 4D surface separating such intervals from *space-like* intervals \((ds)^2 < 0\) is called the light cone (Fig. 9).

Now let us assume that two close world events happen with the same particle that moves with velocity \(\mathbf{u}\). Then in the frame moving with the particle \((v = u)\), the last term on the right-hand side of Eq. (58) equals zero, so that

\[
ds = cd\tau, \tag{9.59}
\]

where \(d\tau\) is the proper time interval. But according to Eq. (21), this means that we can write

\[
d\tau = \frac{dt}{\gamma}, \tag{9.60}
\]

where \(dt\) is the time interval in an *arbitrary* (besides being inertial) reference frame, while

\[
\beta \equiv \frac{u}{c} \quad \text{and} \quad \gamma \equiv \frac{1}{\sqrt{1 - \beta^2}} = \frac{1}{\sqrt{1 - u^2/c^2}} \tag{9.61}
\]

are the parameters (17) corresponding to the particle’s velocity \((\mathbf{u})\) in that frame, so that \(ds = cdt/\gamma\).\(^{23}\)

![Fig. 9.9. A 2+1 dimensional image of the light cone – which is actually 3+1 dimensional.](image)

Let us use Eq. (60) to explore whether a 4-vector may be formed using the spatial components of the particle’s velocity

\[
\mathbf{u} = \left\{ \frac{dx}{dt}, \frac{dy}{dt}, \frac{dz}{dt} \right\}. \tag{9.62}
\]

Here we have a slight problem: as Eqs. (22) show, these components do not obey the Lorentz transform. However, let us use \(d\tau = dt/\gamma\), the proper time interval of the particle, to form the following string:

\[
\left\{ \frac{dx_0}{d\tau}, \frac{dx_1}{d\tau}, \frac{dx_2}{d\tau}, \frac{dx_3}{d\tau} \right\} \equiv \gamma \left\{ \frac{c}{d\tau}, \frac{dx}{d\tau}, \frac{dy}{d\tau}, \frac{dz}{d\tau} \right\} \equiv \gamma \{ c, \mathbf{u} \}. \tag{9.63}
\]

As it follows from the comparison of the middle form of this expression with Eq. (48), since the time-space vector obeys the Lorentz transform, and \(\tau\) is Lorentz-invariant, the string (63) is a legitimate 4-vector; it is called the *4-velocity* of the particle.

---

\(^{23}\) I have opted against using special indices (e.g., \(\beta, \gamma\)) to distinguish Eqs. (17) and (61) here and below, in a hope that the suitable velocity (of either a reference frame or a particle) will be always clear from the context.
Now we are well equipped to proceed to the relativistic dynamics. Let us start with such basic notions as the momentum $\mathbf{p}$ and the energy $\mathcal{E}$—so far, for a free particle.\(^\text{24}\) Perhaps the most elegant way to “derive” (or rather guess\(^\text{25}\)) the expressions for $\mathbf{p}$ and $\mathcal{E}$ as functions of the particle’s velocity $\mathbf{u}$, is based on analytical mechanics. Due to the conservation of $\mathbf{v}$, the trajectory of a free particle in the 4D Minkowski space $\{ct, \mathbf{r}\}$ is always a straight line. Hence, from the Hamilton principle,\(^\text{26}\) we may expect its action $\mathcal{S}$, between points 1 and 2, to be a linear function of the space-time interval (59):

$$
\mathcal{S} = \alpha \int_{t_1}^{t_2} ds \equiv \alpha c \int_{t_1}^{t_2} d\tau \equiv \alpha c \int_{t_1}^{t_2} \frac{dt}{\gamma},
$$

where $\alpha$ is some constant. On the other hand, in analytical mechanics, the action is defined as

$$
\mathcal{S} = \int_{t_1}^{t_2} \mathcal{L} dt,
$$

where $\mathcal{L}$ is particle’s Lagrangian function.\(^\text{27}\) Comparing these two expressions, we get

$$
\mathcal{S} = \frac{\alpha c}{\gamma} \equiv \alpha c \left( 1 - \frac{u^2}{c^2} \right)^{1/2}.
$$

In the non-relativistic limit ($u << c$), this function tends to

$$
\mathcal{S} \approx \alpha c \left( 1 - \frac{u^2}{2c^2} \right) = \alpha c - \frac{\alpha u^2}{2c}.
$$

To correspond to the Newtonian mechanics,\(^\text{28}\) the last (velocity-dependent) term should equal $\mu u^2/2$. From here we find $\alpha = -mc$, so that, finally,

$$
\mathcal{S} = -mc^2 \left( 1 - \frac{u^2}{c^2} \right)^{1/2} \equiv mc^2 - \frac{mc^2}{\gamma}.
$$

Now we can find the Cartesian components $p_j$ of the particle’s momentum as the generalized momenta corresponding to the components $r_j (j = 1, 2, 3)$ of the 3D radius-vector $\mathbf{r}$:\(^\text{29}\)

$$
p_j = \frac{\partial \mathcal{S}}{\partial \dot{r}_j} = \frac{\partial \mathcal{S}}{\partial \dot{u}_j} = -mc^2 \frac{\partial}{\partial u_j} \left( 1 - \frac{u_1^2 + u_2^2 + u_3^2}{c^2} \right)^{1/2} = \frac{\mu u_j}{\left( 1 - u^2/c^2 \right)^{1/2}} = m\gamma u_j.
$$

\(^{24}\) I am sorry for using, just as in Sec. 6.3, the same traditional notation ($\mathbf{p}$) for the particle’s momentum as had been used earlier for the electric dipole moment. However, since the latter notion will be virtually unused in the balance of this course, this may hardly lead to confusion.

\(^{25}\) Indeed, such a derivation uses additional assumptions, however natural (such as the Lorentz-invariance of $\mathcal{S}$), i.e. it can hardly be considered as a real proof of the final results, so that they require experimental confirmation. Fortunately, such confirmations have been numerous—see below.

\(^{26}\) See, e.g., CM Sec. 10.3.

\(^{27}\) See, e.g., CM Sec. 2.1.

\(^{28}\) See, e.g., CM Eq. (2.19b).

\(^{29}\) See, e.g., CM Sec. 2.3, in particular Eq. (2.31).
Thus for the 3D vector of momentum, we can write the result in the same form as in non-relativistic mechanics,

\[ \mathbf{p} = m \gamma \mathbf{u} \equiv M \mathbf{u}, \]  

(9.70)

where the reference-frame-dependent scalar \( M \) (called the \textit{relativistic mass}) is defined as

\[ M \equiv m \gamma = \frac{m}{\sqrt{1 - u^2 / c^2}} \geq m, \]  

(9.71)

\( m \) being the non-relativistic mass of the particle. (More often, \( m \) is called the \textit{rest mass}, because in the reference frame in that the particle rests, Eq. (71) yields \( M = m \).)

Next, let us return to analytical mechanics to calculate the particle’s energy \( \mathcal{E} \) (which for a free particle coincides with the Hamiltonian function \( \mathcal{H} \)):

\[ \mathcal{E} = \mathcal{H} = \sum_{j=1}^{3} p_j u_j - \mathcal{L} = \mathbf{p} \cdot \mathbf{u} - \mathcal{L} = \frac{m u^2}{\sqrt{1 - u^2 / c^2}} + m c^2 \left( \frac{1 - u^2 / c^2}{\sqrt{1 - u^2 / c^2}} \right) \equiv \frac{m c^2}{\sqrt{1 - u^2 / c^2}}. \]  

(9.72)

Thus, we have arrived at the most famous of Einstein’s formulas – and probably the most famous formula of physics as a whole:

\[ \mathcal{E} = m \gamma c^2 \equiv M c^2, \]  

(9.73)

\[ \mathcal{E} = M c^2 \]

which expresses the relation between the free particle’s mass and its energy.\(^{31}\) In the non-relativistic limit, it reduces to

\[ \mathcal{E} = \frac{m c^2}{\sqrt{1 - u^2 / c^2}} \approx m c^2 \left( 1 + \frac{u^2}{2 c^2} \right) = mc^2 + \frac{m u^2}{2}, \]  

(9.74)

the first term \( mc^2 \) being called the \textit{rest energy} of a particle.

Now let us consider the following string of 4 scalars:

\[ \left\{ \frac{\mathcal{E}}{c}, p_1, p_2, p_3 \right\} \equiv \left\{ \frac{\mathcal{E}}{c}, \mathbf{p} \right\}. \]  

(9.75)

Using Eqs. (70) and (73) to represent this expression as

\[ \left\{ \frac{\mathcal{E}}{c}, \mathbf{p} \right\} = m \gamma \left\{ c, \mathbf{u} \right\}, \]  

(9.76)

and comparing the result with Eq. (63), we immediately see that, since \( m \) is a Lorentz-invariant constant, this string is a legitimate 4-vector of \textit{energy-momentum}. As a result, its norm,

\(^{30}\) See, e.g., CM Eq. (2.32).

\(^{31}\) Let me hope that the reader understands that all the layman talk about the “mass to energy conversion” is only valid in a very limited sense of the word. While the Einstein relation (73) does allow the conversion of “massive” particles (with \( m \neq 0 \)) into particles with \( m = 0 \), such as photons, each of the latter particles also has a non-zero relativistic mass \( M \), and \textit{simultaneously} the energy \( \mathcal{E} \) related to this \( M \) by Eq. (73).
\[
\left( \frac{\mathcal{E}}{c} \right)^2 - p^2 = \left( \frac{m c^2}{c} \right)^2 = (mc)^2, \quad (9.77a)
\]
is Lorentz-invariant, and in particular, has to be equal to the norm in the particle-bound frame. But in
that frame, \( p = 0 \), and, according to Eq. (73), \( \mathcal{E} = mc^2 \), and so that the norm is just
\[
\left( \frac{\mathcal{E}}{c} \right)^2 = \left( \frac{mc^2}{c} \right)^2 = (mc)^2, \quad (9.77b)
\]
so that in an arbitrary frame
\[
\left( \frac{\mathcal{E}}{c} \right)^2 - p^2 = (mc)^2. \quad (9.78a)
\]
This very important relation\(^{32}\) between the relativistic energy and momentum (valid for free particles
only!) is usually represented in the form\(^{33}\)
\[
\mathcal{E}^2 = (mc^2)^2 + (pc)^2. \quad (9.78b)
\]
According to Eq. (70), in the ultra-relativistic limit \( u \to c \), \( p \) tends to infinity, while \( mc^2 \) stays
constant, so that \( pc >> mc^2 \). As follows from Eq. (78), in this limit \( \mathcal{E} \approx pc \). Though the above discussion
was for particles with finite \( m \), the 4-vector formalism allows us to consider particles with zero rest mass
as ultra-relativistic particles for which the above energy-to-moment relation,
\[
\mathcal{E} = pc, \quad \text{for } m = 0, \quad (9.79)
\]
is exact. Quantum electrodynamics\(^{34}\) tells us that under certain conditions, the electromagnetic field
quanta (photons) may be also considered as such massless particles, with momentum \( \mathbf{p} = h \mathbf{k} \). Plugging
(the modulus of) the last relation into Eq. (78), for the photon’s energy we get \( \mathcal{E} = pc = hkc = h \omega \). Please
note again that according to Eq. (73), the relativistic mass of a photon is not equal to zero: \( M = \mathcal{E}/c^2 = h \omega/c^2 \),
so that the term “massless particle” has a limited meaning: \( m = 0 \). For example, the relativistic
mass of an optical phonon is of the order of \( 10^{-36} \) kg. This is not too much, but still a noticeable
(approximately one-millionth) part of the rest mass \( m_e \) of an electron.

The fundamental relations (70) and (73) have been repeatedly verified in numerous particle
collision experiments, in which the total energy and momentum of a system of particles are conserved –
at the same conditions as in non-relativistic dynamics. (For the momentum, this is the absence of
external forces, and for the energy, the elasticity of particle interactions – in other words, the absence
of alternative channels of energy escape.) Of course, generally only the total energy of the system is
conserved, including the potential energy of particle interactions. However, at typical high-energy
particle collisions, the potential energy vanishes so rapidly with the distance between them that we can
use the momentum and energy conservation laws using Eq. (73).

\(^{32}\) Please note one more simple and useful relation following from Eqs. (70) and (73): \( \mathbf{p} = (\mathcal{E}/c^2) \mathbf{u} \).

\(^{33}\) It may be tempting to interpret this relation as the perpendicular-vector-like addition of the rest energy \( mc^2 \) and
the “kinetic energy” \( pc \), but from the point of view of the total energy conservation (see below), a better definition
of the kinetic energy is \( T(u) = \mathcal{E}(u) - \mathcal{E}(0) \).

\(^{34}\) It is briefly reviewed in QM Chapter 9.
As an example, let us calculate the minimum energy $\epsilon_{\text{min}}$ of a proton ($p_a$), necessary for the well-known high-energy reaction that generates a new proton-antiproton pair, $p_a + p_b \rightarrow p + p + p + \bar{p}$, provided that before the collision, the proton $p_b$ has been at rest in the lab frame. This minimum corresponds to the vanishing relative velocity of the reaction products, i.e. their motion with virtually the same velocity ($u_{\text{fin}}$), as seen from the lab frame – see Fig. 10.

![Fig. 9.10. A high-energy proton reaction at $\mathcal{E} \approx \epsilon_{\text{min}}$ – schematically.](image)

Due to the momentum conservation, this velocity should have the same direction as the initial velocity ($u_{\text{min}}$) of proton $p_a$. This is why two scalar equations: for energy conservation,

$$\frac{mc^2}{\left(1-\frac{u_{\text{min}}^2}{c^2}\right)^{1/2}} + mc^2 = \frac{4mc^2}{\left(1-\frac{u_{\text{fin}}^2}{c^2}\right)^{1/2}}, \quad (9.80a)$$

and for momentum conservation,

$$\frac{mu}{\left(1-\frac{u_{\text{min}}^2}{c^2}\right)^{1/2}} + 0 = \frac{4mu_{\text{fin}}}{\left(1-\frac{u_{\text{fin}}^2}{c^2}\right)^{1/2}}, \quad (9.80b)$$

are sufficient to find both $u_{\text{min}}$ and $u_{\text{fin}}$. After a conceptually simple but technically somewhat tedious solution of this system of two nonlinear equations, we get

$$u_{\text{min}} = \frac{4\sqrt{3}}{7} c, \quad u_{\text{fin}} = \frac{\sqrt{3}}{2} c. \quad (9.81)$$

Finally, we can use Eq. (73) to calculate the required energy; the result is $\epsilon_{\text{min}} = 7 mc^2$. (Note that of the kinetic energy of the initial moving particle, $6mc^2$, only $2mc^2$ go into the “useful” proton-antiproton pair production.) The proton’s rest mass, $m_p \approx 1.67 \times 10^{-27}$ kg, corresponds to $m_p c^2 \approx 1.502 \times 10^{-10}$ J $\approx 0.938$ GeV, so that $\epsilon_{\text{min}} \approx 6.57$ GeV.

The second, more intelligent way to solve the same problem is to use the center-of-mass (c.o.m.) reference frame that, in relativity, is defined as the frame in which the total momentum of the system vanishes.\(^{35}\) In this frame, at $\mathcal{E} = \epsilon_{\text{min}}$, the velocity and momenta of all reaction products are vanishing, while the velocities of protons $p_b$ and $p_b$ before the collision are equal and opposite, with some magnitude $u'$. Hence the energy conservation law becomes

$$\frac{2mc^2}{\left(1-u'^2 / c^2\right)^{1/2}} = 4mc^2, \quad (9.82)$$

\(^{35}\) Note that according to this definition, the c.o.m.’s radius-vector is $\mathbf{R} = \sum_b M_b \mathbf{r}_b / \sum_b M_b = \sum_k \gamma_k m_k \mathbf{r}_k / \sum_k \gamma_k m_k$, i.e. is generally different from the well-known non-relativistic expression $\mathbf{R} = \sum m_k \mathbf{r}_k / \sum m_k$. 

---

35 Note that according to this definition, the c.o.m.‘s radius-vector is $\mathbf{R} = \sum_b M_b \mathbf{r}_b / \sum_b M_b = \sum_k \gamma_k m_k \mathbf{r}_k / \sum_k \gamma_k m_k$, i.e. is generally different from the well-known non-relativistic expression $\mathbf{R} = \sum m_k \mathbf{r}_k / \sum m_k$. 

---
readily giving \( u' = (\sqrt{3/2}) c \). (This is of course the same result as Eq. (81) gives for \( u_{\text{fin}} \).) Now we can use the fact that the velocity of the proton \( p_b \) in the c.o.m. frame is \((-u')\), and hence the velocity of the proton \( p_a \) is \((+u')\). Hence we may find the lab-frame speed of the proton \( p_a \) using the velocity transform (25):

\[
    u_{\text{min}} = \frac{2u'}{1 + u'^2 / c^2}.
\]  

With the above result for \( u' \), this relation gives the same result as the first method, \( u_{\text{min}} = (4\sqrt{3/7})c \), but in a much simpler way.

### 9.4. More on 4-vectors and 4-tensors

This is a good moment to describe a formalism that will allow us, in particular, to solve the same proton collision problem in one more (and arguably, the most elegant) way. Much more importantly, this formalism will be virtually necessary for the description of the Lorentz transform of the electromagnetic field, and its interaction with relativistic particles – otherwise the formulas would be too cumbersome. Let us call the 4-vectors we have used before,

\[
    A^\alpha \equiv \{A^0, A\},
\]  

_contravariant_, and denote them with the top index, and introduce also _covariant_ vectors,

\[
    A_{\alpha} \equiv \{A_0, -A\},
\]  

_marked by the lower index. Now if we form a scalar product of these vectors using the _standard_ (3D-like) rule, just as a sum of the products of the corresponding components, we immediately get

\[
    A_\alpha A^\alpha \equiv A_\alpha A^\alpha = A^2_0 - A^2.
\]  

Here and below the sign of the sum of four components of the product has been dropped.\(^{36}\) The scalar product (86) is just the norm of the 4-vector in our former definition, and as we already know, is Lorentz-invariant. Moreover, the scalar product of two different vectors (also a Lorentz invariant), may be rewritten in any of two similar forms:\(^{37}\)

\[
    A_\alpha B_\beta - A_\beta B_\alpha \equiv A_\alpha B^\alpha = A^\alpha B_\alpha; \tag{9.87}
\]

again, the only caveat is to take one vector in the covariant, and the other one in the contravariant form.

Now let us return to our sample problem (Fig. 10). Since all the components \((\mathbf{E}/c\) and \(\mathbf{p}\)) of the total 4-momentum of our system are conserved at the collision, its norm is conserved as well:

\[
    \left( p_a + p_b \right)_\alpha \left( p_a + p_b \right)^\alpha = (4p)_\alpha (4p)^\alpha. \tag{9.88}
\]

\(^{36}\) This compact notation may take some time to be accustomed to, but is very convenient (compact) and can hardly lead to any confusion, due to the following rule: the summation is implied when, and only when an index is repeated twice, once on the top and another at the bottom. In these notes, this shorthand notation will be used only for 4-vectors, but not for the usual (spatial) vectors.

\(^{37}\) Note also that, by definition, for any two 4-vectors, \( A_\alpha B^\alpha = B^\alpha A_\alpha \).
Since now the vector product is the usual math construct, we know that the parentheses on the left-hand side of this equation may be multiplied as usual. We may also swap the operands and move constant factors around as convenient. As a result, we get

\[ (p_a)_a (p_a)^a + (p_b)_a (p_b)^a + 2(p_a)_a (p_b)^a = 16 p_a p^a. \] (9.89)

Thanks to the Lorentz-invariance of each of the terms, we may calculate it in the reference frame we like. For the first two terms on the left-hand side, as well as for the right-hand side term, it is beneficial to use the frames in which that particular proton is at rest; as a result, according to Eq. (77b), each of the left-hand side terms equals \((mc)^2\), while the right-hand side equals \(16(mc)^2\). On the contrary, the last term on the left-hand side is more easily evaluated in the lab frame, because in that frame the three spatial components of the 4-momentum \(p_b\) vanish, and the scalar product is the just the product of the scalars \(E/c\) for protons \(a\) and \(b\). For the latter proton, this ratio is just \(mc\), so that we get a simple equation,

\[ (mc)^2 + (mc)^2 + 2\frac{\varepsilon_{\min}}{c}mc = 16(mc)^2, \] (9.90)

immediately giving the final result: \(\varepsilon_{\min} = 7 mc^2\) we had already obtained in two more complex ways.

Let me hope that this example was a convincing demonstration of the convenience of representing 4-vectors in the contravariant (84) and covariant (85) forms, with Lorentz-invariant norms (86). To be useful for more complex tasks, the formalism should be developed a little bit further. In particular, it is crucial to know how do the 4-vectors change under the Lorentz transform. For contravariant vectors, we already know the answer (54); let us rewrite it in our new notation:

\[ A^\alpha = L^\alpha_\beta A'^\beta. \] (9.91)

where \(L^\alpha_\beta\) is the matrix (51), generally called the mixed Lorentz tensor.\(^{39}\)

Note that though the position of the indices \(\alpha\) and \(\beta\) in the Lorentz tensor notation is not crucial, because it is symmetric, it is convenient to place them using the general index balance rule: the difference of the numbers of the upper and lower indices should be the same in both parts of any 4-vector/tensor equality. (Check yourself that all the formulas above do satisfy this rule.)

---

\(^{38}\) These forms are 4-vector extensions of the notions of contravariance and covariance, introduced in the 1850s by J. Sylvester (who in particular introduced the term “matrix”) for the description of the change of the usual geometric (3-component) vectors at the transfer between different reference frames – e.g., resulting from the frame rotation. In this case, the contravariance or covariance of a vector is uniquely determined by its nature: if the Cartesian coordinates of a vector (such as the non-relativistic velocity \(v = dr/dt\)) are transformed similarly to the radius-vector \(r\), it is called contravariant, while the vectors (such as \(\nabla f\)) that require the reciprocal transform, are called covariant. In the Minkowski space, both forms may be used for any 4-vector.

\(^{39}\) Just as the 4-vectors, 4-tensors with two top indices are called contravariant, and those with two bottom indices, covariant. The tensors with one top and one bottom index are called mixed.
In order to rewrite Eq. (91) in a more general form that would not depend on the particular orientation of the coordinate axes (Fig. 1), let us use the contravariant and covariant forms of the 4-vector of the time-space interval (57),

\[ dx^\alpha = \{cdt,dr\}, \quad dx_\alpha = \{cdt,-dr\}; \quad (9.93) \]

then its norm (58) may be represented as

\[ (ds)^2 \equiv (cdt)^2 - (dr)^2 = dx^\alpha dx_\alpha = dx_\alpha dx^\alpha. \quad (9.94) \]

Applying Eq. (91) to the contravariant form of the first of 4-vectors (93), we get

\[ dx^\alpha = L^\alpha_\beta dx^\beta. \quad (9.95) \]

But, with our new shorthand notation, we can also write the usual rule of differentiation of each component \( x^\alpha \), considering it as a (in our case, linear) function of 4 arguments \( x^\beta \), as follows:

\[ dx^\alpha = \frac{\partial x^\alpha}{\partial x^\beta} dx^\beta. \quad (9.96) \]

Comparing Eqs. (95) and (96), we can rewrite the general Lorentz transform rule (92) in the new form,

\[ A^\alpha = \frac{\partial x^\alpha}{\partial x^\beta} A^\beta. \quad (9.97a) \]

which evidently does not depend on the coordinate axes’ orientation.

It is straightforward to verify that the reciprocal transform may be represented as

\[ A'^\alpha = \frac{\partial x'^\alpha}{\partial x^\beta} A^\beta. \quad (9.97b) \]

However, the reciprocal transform has to differ from the direct one only by the sign of the relative velocity of the frames, so that for the coordinate choice shown in Fig. 1, the matrix is

\[ g^{\alpha\beta} \equiv g_{\alpha\beta} \equiv \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & -1 & 0 & 0 \\ 0 & 0 & -1 & 0 \\ 0 & 0 & 0 & -1 \end{pmatrix}, \]

which may be used, in particular, to a transfer a covariant vector into the corresponding contravariant one and back: \( A'^\alpha = g^{\alpha\beta} A_\beta \), \( A_\alpha = g_{\alpha\beta} A^\beta \). The metric tensor plays a key role in the general relativity, in which it is affected by gravity – “curved” by particles’ masses.

40 Another way to write this relation is \((ds)^2 = g_{\alpha\beta} dx^\alpha dx^\beta = g^{\alpha\beta} dx_\alpha dx_\beta\), where double summation over indices \( \alpha \) and \( \beta \) is implied, and \( g \) is the so-called metric tensor,

41 Note that in the index balance rule, the top index in the denominator of a fraction is counted as a bottom index in the numerator, and vice versa.
\[
\frac{\partial x'{}^\alpha}{\partial x{}^\beta} = \begin{pmatrix}
\gamma & -\beta\gamma & 0 & 0 \\
-\beta\gamma & \gamma & 0 & 0 \\
0 & 0 & 1 & 0 \\
0 & 0 & 0 & 1
\end{pmatrix},
\]
(9.98)

Since according to Eqs. (84)-(85), covariant 4-vectors differ from the contravariant ones by the sign of the spatial components, their direct transform is given by the matrix (98). Hence their direct and reciprocal transforms may be represented, respectively, as

\[
A{}_{\alpha} = \frac{\partial x'{}^\beta}{\partial x{}^\alpha} A'{}^\beta, \quad A'{}_{\alpha} = \frac{\partial x{}^\beta}{\partial x'{}^\alpha} A'{}^\beta,
\]
(9.99)
evidently satisfying the index balance rule. (Note that primed quantities are now multiplied, rather than divided as in the contravariant case.) As a sanity check, let us apply this formalism to the scalar product \(A_{\alpha}A{}^{\alpha}\). As Eq. (96) shows, the implicit summation notation allows us to multiply and divide any equality by the same partial differential of a coordinate, so that we can write:

\[
A_{\alpha}A{}^{\alpha} = \frac{\partial x'{}^\beta}{\partial x{}^\alpha} \frac{\partial x{}^\alpha}{\partial x'{}^\gamma} A'{}^\beta A'{}^\gamma = \frac{\partial x'{}^\beta}{\partial x{}^\alpha} \frac{\partial x{}^\beta}{\partial x'{}^\gamma} A'{}^\beta A'{}^\gamma = \delta_{\beta\gamma} A'{}^\beta A'{}^\gamma = A'{}_{\gamma} A'{}^{\gamma},
\]
(9.100)
i.e. the scalar product \(A_{\alpha}A{}^{\alpha}\) (as well as \(A{}^{\alpha}A_{\alpha}\)) is Lorentz-invariant, as it should be.

Now, let us consider the 4-vectors of derivatives. Here we should be very careful. Consider, for example, the following vector operator

\[
\frac{\partial}{\partial x{}^\alpha} \equiv \left\{ \frac{\partial}{\partial (ct)}, \mathbf{\nabla} \right\},
\]
(9.101)
As was discussed above, the operator is not changed by its multiplication and division by another differential, e.g., \(\partial x'{}^\beta\) (with the corresponding implied summation over \(\beta\)), so that

\[
\frac{\partial}{\partial x{}^\alpha} = \frac{\partial x'{}^\beta}{\partial x{}^\alpha} \frac{\partial}{\partial x'{}^\beta}.
\]
(9.102)
But, according to the first of Eqs. (99), this is exactly how the covariant vectors are Lorentz-transformed! Hence, we have to consider the derivative over a contravariant space-time interval as a covariant 4-vector, and vice versa.\(^{42}\) (This result might be also expected from the index balance rule.) In particular, this means that the scalar product

\[
\frac{\partial}{\partial x{}^\alpha} A{}^{\alpha} \equiv \frac{\partial A{}_{0}}{\partial (ct)} + \mathbf{\nabla} \cdot \mathbf{A}
\]
(9.103)
should be Lorentz-invariant for any legitimate 4-vector. A convenient shorthand for the covariant derivative, which complies with the index balance rule, is

\[
\frac{\partial}{\partial x{}^\alpha} \equiv \partial{}_{\alpha},
\]
(9.104)

\(^{42}\) As was mentioned above, this is also a property of the reference-frame transform of the “usual” 3D vectors.
so that the invariant scalar product may be written just as $\partial AAPA$. A similar definition of the contravariant derivative,

$$
\partial^A = \frac{\partial}{\partial x_A} = \left\{ \frac{\partial}{\partial (ct)}, \nabla \right\}, \quad (9.105)
$$

allows us to write the Lorentz-invariant scalar product (103) in any of two forms:

$$
\frac{\partial A_\alpha}{\partial (ct)} + \nabla \cdot A = \partial^A A_\alpha = \partialAAPA. \quad (9.106)
$$

Finally, let us see how does the general Lorentz transform change 4-tensors. A second-rank 4×4 matrix is a legitimate 4-tensor if the 4-vectors it relates obey the Lorentz transform. For example, if two legitimate 4-vectors are related as

$$
A^\alpha = T^{\alpha\beta} B_\beta, \quad (9.107)
$$

we should require that

$$
A'^\alpha = T'^{\alpha\beta} B'_\beta, \quad (9.108)
$$

where $A^\alpha$ and $A'^\alpha$ are related by Eqs. (97), while $B_\beta$ and $B'_\beta$ by Eqs. (99). This requirement immediately yields

$$
T^{\alpha\beta} = \frac{\partial x^\alpha}{\partial x'^\gamma} \frac{\partial x^\beta}{\partial x'^\delta} T'^{\gamma\delta}, \quad T'^{\alpha\beta} = \frac{\partial x'^\alpha}{\partial x^\gamma} \frac{\partial x'^\beta}{\partial x^\delta} T^{\gamma\delta}, \quad (9.109)
$$

with the implied summation over two indices, $\gamma$ and $\delta$. The rules for the covariant and mixed tensors are similar.43

9.5. Maxwell equations in the 4-form

This 4-vector formalism background is already sufficient to analyze the Lorentz transform of the electromagnetic field. Just to warm up, let us consider the continuity equation (4.5),

$$
\frac{\partial \rho}{\partial t} + \nabla \cdot j = 0, \quad (9.110)
$$

which expresses the electric charge conservation, and, as we already know, is compatible with the Maxwell equations. If we now define the contravariant and covariant 4-vectors of electric current as

$$
j^\alpha \equiv \{ \rho c, j \}, \quad j_\alpha \equiv \{ \rho c, -j \}, \quad (9.111)
$$

then Eq. (110) may be represented in the form

$$
\partial^A j_\alpha = \partialAAPA = 0, \quad (9.112)
$$

showing that the continuity equation is form-invariant with respect to the Lorentz transform.

---

43 It is straightforward to check that transfer between the contravariant and covariant forms of the same tensor may be readily achieved using the metric tensor $g$: $T_{\alpha\beta} = g_{\alpha\gamma} T^{\gamma\delta} g_{\delta\beta}, \quad T'^{\alpha\beta} = g^{\alpha\gamma} T_{\gamma\delta} g^{\delta\beta}$. 
Of course, such form’s invariance of a relation does not mean that all component values of the 4-vectors participating in it are the same in both frames. For example, let us have some static charge density \( \rho \) in frame 0; then Eq. (97b), applied to the contravariant form of the 4-vector (111), reads

\[
\frac{\partial}{\partial x^\beta} j^\beta = \rho c, \quad \text{with} \quad j^\beta = \{\rho c, 0, 0, 0\}. \tag{9.113}
\]

Using the particular form (98) of the reciprocal Lorentz matrix for the coordinate choice shown in Fig. 1, we see that this relation yields

\[
\rho' = \gamma \rho, \quad j'_x = -\gamma \beta \rho c = -\gamma \nu \rho, \quad j'_y = j'_z = 0. \tag{9.114}
\]

Since the charge velocity, as observed from frame 0’, is \( -\nu \), the non-relativistic results would be \( \rho' = \rho, \quad j' = -\nu \rho \). The additional \( \gamma \) factor in the relativistic results is caused by the length contraction: \( dx' = dx/\gamma \), so that to keep the total charge \( dQ = \rho d^3r = \rho dx dy dz \) inside the elementary volume \( d^3r = dx dy dz \) intact, \( \rho \) (and hence \( j \)) should increase proportionally.

Next, at the end of Chapter 6 we have seen that Maxwell equations for the electromagnetic potentials \( \phi \) and \( A \) may be represented in similar forms (6.118), under the Lorenz (again, not “Lorentz” please!) gauge condition (6.117). For the free space, this condition takes the form

\[
\nabla \cdot A + \frac{1}{c^2} \frac{\partial \phi}{\partial t} = 0. \tag{9.115}
\]

This expression gives us a hint of how to form the 4-vector of the potentials:45

\[
A^\alpha \equiv \left\{ \frac{\phi}{c}, A \right\}, \quad A_\alpha \equiv \left\{ \frac{\phi}{c}, -A \right\}; \tag{9.116}
\]

indeed, this vector satisfies Eq. (115) in its 4-form:

\[
\nabla^\alpha A_\alpha = \nabla_\alpha A^\alpha = 0. \tag{9.117}
\]

Since this scalar product is Lorentz-invariant, and the derivatives (104)-(105) are legitimate 4-vectors, this implies that the 4-vector (116) is also legitimate, i.e. obeys the Lorentz transform formulas (97), (99). A more convincing evidence of this fact may be obtained from the Maxwell equations (6.118) for the potentials. In the free space, they may be rewritten as

\[
\left[ \frac{\partial^2}{\partial (ct)^2} - \nabla^2 \right] \frac{\phi}{c} = \frac{(\rho c)}{\varepsilon_0 c^2} \equiv \mu_0 (\rho c), \quad \left[ \frac{\partial^2}{\partial (ct)^2} - \nabla^2 \right] A = \mu_0 \vec{j}. \tag{9.118}
\]

Using the definition (116), these equations may be merged to one:46

\[
\square A^\alpha = \mu_0 j^\alpha, \tag{9.119}
\]

44 In some texts, the equations preserving their form at a transform are called “covariant”, creating a possibility for confusion with the covariant vectors and tensors. On the other hand, calling such equations “invariant” would not distinguish them properly from invariant quantities, such as the scalar products of 4-vectors.

45 In the Gaussian units, the scalar potential should not be divided by \( c \) in this relation.

46 In the Gaussian units, the coefficient \( \mu_0 \) in Eq. (119) should be replaced, as usual, with \( 4\pi/c \).
where \( \Box \) is the d'Alembert operator,\(^{47} \) which may be represented as either of two scalar products,

\[
\Box \equiv \frac{\partial^2}{\partial (ct)^2} - \nabla^2 = \partial^\beta \partial_\beta = \partial_\beta \partial^\beta .
\]  

(9.120)

and hence is Lorentz-invariant. Because of that, and the fact that the Lorentz transform changes both 4-vectors \( A^\alpha \) and \( j^\alpha \) in a similar way, Eq. (119) does not depend on the reference frame choice. Thus we have arrived at a key point of this chapter: we see that the Maxwell equations are indeed form-invariant with respect to the Lorentz transform. As a by-product, the 4-vector form (119) of these equations (for potentials) is extremely simple – and beautiful.

However, as we have seen in Chapter 7, for many applications the Maxwell equations for the field vectors are more convenient; so let us represent them in the 4-form as well. For that, we may express all Cartesian components of the usual (3D) field vectors

\[
E = -\nabla \phi - \frac{\partial A}{\partial t}, \quad B = \nabla \times A,
\]  

(9.121)

via those of the potential 4-vector \( A^\alpha \). For example,

\[
E_x = -\frac{\partial \phi}{\partial x} - \frac{\partial A_x}{\partial t} = -c \left( \frac{\partial \phi}{\partial x} + \frac{\partial A_x}{\partial (ct)} \right) \equiv -c (\phi^0 A^1 - \phi^1 A^0),
\]  

(9.122)

\[
B_x = \frac{\partial A_y}{\partial y} - \frac{\partial A_z}{\partial z} = -c (\phi^2 A^3 - \phi^3 A^2).
\]  

(9.123)

Completing similar calculations for other field components (or just generating them by the appropriate index shifts), we find that the following asymmetric, contravariant field-strength tensor,

\[
F^{\alpha \beta} \equiv \partial^\alpha A^\beta - \partial^\beta A^\alpha,
\]  

(9.124)

may be expressed via the field components as follows:\(^{48} \)

\[
F^{\alpha \beta} = \begin{pmatrix}
0 & -E_x/c & -E_y/c & -E_z/c \\
E_x/c & 0 & B_y & -B_z \\
E_y/c & -B_y & 0 & B_x \\
E_z/c & B_z & -B_x & 0
\end{pmatrix},
\]  

(9.125a)

so that the covariant form of the tensor is

\[
F_{\alpha \beta} \equiv g_{\alpha \gamma} F^{\gamma \delta} g_{\delta \beta} = \begin{pmatrix}
0 & E_x/c & E_y/c & E_z/c \\
-\frac{E_x}{c} & 0 & B_z & B_y \\
-\frac{E_y}{c} & -B_z & 0 & B_x \\
-\frac{E_z}{c} & B_y & -B_x & 0
\end{pmatrix}.
\]  

(9.125b)

---

\(^{47}\) Named after Jean-Baptiste le Rond d’Alembert (1717-1783), who made several pioneering contributions to the general theory of waves — see, e.g., CM Chapter 6. (Some older textbooks use notation \( \Box^2 \) for this operator.)

\(^{48}\) In Gaussian units, this formula, as well as Eq. (131) for \( G^{\alpha \beta} \), does not have the factors \( c \) in all the denominators.
If this expression looks a bit too bulky, please note that as a reward, the pair of inhomogeneous Maxwell equations, i.e. the two equations of the system (6.99), which in free space ($\mathbf{D} = \varepsilon_0 \mathbf{E}$, $\mathbf{B} = \mu_0 \mathbf{H}$) may be rewritten as

$$\nabla \cdot \frac{\mathbf{E}}{c} = \mu_0 c \rho, \quad \nabla \times \mathbf{B} - \frac{\partial}{\partial (ct)} \frac{\mathbf{E}}{c} = \mu_0 \mathbf{j},$$

(9.126)

may be now represented in a very simple (and manifestly form-invariant) way,

$$\partial_\alpha F^{\alpha \beta} = \mu_0 j^\beta,$$

(9.127)

which is comparable with Eq. (119) in its beauty and simplicity. Somewhat counter-intuitively, the pair of homogeneous Maxwell equations of the system (6.99),

$$\nabla \times \mathbf{E} + \frac{\partial \mathbf{B}}{\partial t} = 0, \quad \nabla \cdot \mathbf{B} = 0,$$

(9.128)

look, in the 4-vector notation, a bit more complicated:

$$\partial_\alpha F^{\alpha \beta} + \partial_\beta F_{\gamma \alpha} + \partial_\gamma F^{\alpha \beta} = 0.$$

(9.129)

Note, however, that Eqs. (128) may be also represented in a much simpler form,

$$\partial_\alpha G^{\alpha \beta} = 0,$$

(9.130)

using the so-called dual tensor

$$G^{\alpha \beta} = \begin{pmatrix} 0 & B_x & B_y & B_z \\ -B_x & 0 & -E_z/c & E_y/c \\ -B_y & E_z/c & 0 & -E_x/c \\ -B_z & -E_y/c & E_x/c & 0 \end{pmatrix},$$

(9.131)

which may be obtained from $F^{\alpha \beta}$, given by Eq. (125a), by the following replacements:

$$\frac{\mathbf{E}}{c} \rightarrow -\mathbf{B}, \quad \mathbf{B} \rightarrow \frac{\mathbf{E}}{c}.$$

(9.132)

Besides the proof of the form-invariance of the Maxwell equations with respect to the Lorentz transform, the 4-vector formalism allows us to achieve our initial goal: find out how do the electric and magnetic field components change at the transfer between (inertial!) reference frames. For that, let us apply to the tensor $F^{\alpha \beta}$ the reciprocal Lorentz transform described by the second of Eqs. (109). Generally, it gives, for each field component, a sum of 16 terms, but since (for our choice of coordinates, shown in Fig. 1) there are many zeros in the Lorentz transform matrix, and the diagonal components of $F^{\gamma \delta}$ equal zero as well, the calculations are rather doable. Let us calculate, for example, $E'_x \equiv -cF^{01}$. The only non-vanishing terms on the right-hand side are

$$E'_x = -cF^{01} = -c \left( \frac{\partial x'^0}{\partial x^0} \frac{\partial x'^1}{\partial x^0} F^{10} + \frac{\partial x'^0}{\partial x^0} \frac{\partial x'^1}{\partial x^1} F^{01} \right) \equiv c \gamma^2 (\beta^2 - 1) \frac{E_x}{c} \equiv E'_x.$$

(9.133)

---

49 To be fair, note that just as Eq. (127), Eq. (129) this is also a set of four scalar equations – in the latter case with indices $\alpha, \beta, \gamma$ taking any three different values of the set \{0, 1, 2, 3\}.  

---
Repeating the calculation for the other five components of the fields, we get very important relations

\[
\begin{align*}
E'_x &= E_x, & B'_x &= B_x, \\
E'_y &= \gamma(E_y - vB_x), & B'_y &= \gamma(B_y + vE_z / c^2), \\
E'_z &= \gamma(E_z + vB_y), & B'_z &= \gamma(B_z - vE_y / c^2),
\end{align*}
\]  
\tag{9.134}

whose more compact “semi-vector” form is

\[
\begin{align*}
\mathbf{E}'_{\parallel} &= \mathbf{E}_\parallel, & \mathbf{B}'_{\parallel} &= \mathbf{B}_\parallel, \\
\mathbf{E}'_{\perp} &= \gamma(\mathbf{E} + \mathbf{v} \times \mathbf{B})_{\perp}, & \mathbf{B}'_{\perp} &= \gamma(\mathbf{B} - \mathbf{v} \times \mathbf{E} / c^2)_{\perp},
\end{align*}
\]  
\tag{9.135}

where the indices \(\parallel\) and \(\perp\) stand, respectively, for the field components parallel and perpendicular to the relative velocity \(\mathbf{v}\) of the two reference frames. In the non-relativistic limit, the Lorentz factor \(\gamma\) tends to 1, and Eqs. (135) acquire an even simpler form

\[
\mathbf{E}' \to \mathbf{E} + \mathbf{v} \times \mathbf{B}, \quad \mathbf{B}' \to \mathbf{B} - \frac{1}{c^2} \mathbf{v} \times \mathbf{E}.
\]  
\tag{9.136}

Thus we see that the electric and magnetic fields are transformed to each other even in the first order of the \(v/c\) ratio. For example, if we fly across the field lines of a uniform, static, purely electric field \(\mathbf{E}\) (e.g., the one in a plane capacitor) we will see not only the electric field’s renormalization (in the second order of the \(v/c\) ratio), but also a non-vanishing dc magnetic field \(\mathbf{B}'\) perpendicular to both the vector \(\mathbf{E}\) and the vector \(\mathbf{v}\), i.e. to the direction of our motion. This is of course what might be expected from the relativity principle: from the point of view of the moving observer (which is as legitimate as that of a stationary observer), the surface charges of the capacitor’s plates, which create the field \(\mathbf{E}\), move back creating the dc currents (114), which induce the magnetic field \(\mathbf{B}'\). Similarly, motion across a magnetic field creates, from the point of view of the moving observer, an electric field.

This fact is very important philosophically. One can say there is no such thing in Mother Nature as an electric field (or a magnetic field) all by itself. Not only can the electric field induce the magnetic field (and vice versa) in dynamics, but even in an apparently static configuration, what exactly we measure depends on our speed relative to the field sources – hence the very appropriate term for the whole field we are studying: the electromagnetism.

Another simple but very important application of Eqs. (134)-(135) is the calculation of the fields created by a charged particle moving in free space by inertia, i.e. along a straight line with constant velocity \(\mathbf{u}\), at the impact parameter\(^{50}\) (the closest distance) \(b\) from the observer. Selecting the reference frame 0’ to move with the particle in its origin, and the frame 0 to reside in the “lab” (in that the fields \(\mathbf{E}\) and \(\mathbf{B}\) are measured), we can use the above formulas with \(\mathbf{v} = \mathbf{u}\). In this case the fields \(\mathbf{E}'\) and \(\mathbf{B}'\) may be calculated from, respectively, electro- and magnetostatics:

\[
\begin{align*}
\mathbf{E}' &= \frac{q}{4\pi\varepsilon_0} \frac{r'}{rr'^3}, & \mathbf{B}' &= 0,
\end{align*}
\]  
\tag{9.137}

\(^{50}\) This term is very popular in the theory of particle scattering – see, e.g., CM Sec. 3.7.
because in the frame $0'$ the particle does not move. Selecting the coordinate axes so that at the
measurement point $x = 0, y = b, z = 0$ (Fig. 11a), for this point we may write $x' = -ut', y' = b, z' = 0$, so
that $r' = (u^2 t'^2 + b^2)^{1/2}$, and the Cartesian components of the fields (137) are:

$$E'_x = -\frac{q}{4\pi \varepsilon_0} \left(\frac{ut'}{u^2 t'^2 + b^2}\right)^{3/2}, \quad E'_y = \frac{q}{4\pi \varepsilon_0} \left(\frac{b}{u^2 t'^2 + b^2}\right)^{3/2}, \quad E'_z = 0, \quad (9.138)$$

$$B'_x = B'_y = B'_z = 0.$$

Now using the last of Eqs. (19b), with $x = 0$, for the time transform, and the relations reciprocal
to Eqs. (134) for the field transform (it is evident that they are similar to the direct transform, with $v$
replaced with $-v = -u$), in the lab frame we get

$$E_x = E'_x = -\frac{q}{4\pi \varepsilon_0} \left(\frac{u \gamma t}{u^2 \gamma^2 t^2 + b^2}\right)^{3/2}, \quad E_y = \gamma E'_y = \frac{q}{4\pi \varepsilon_0} \left(\frac{\gamma b}{u^2 \gamma^2 t^2 + b^2}\right)^{3/2}, \quad E_z = 0, \quad (9.139)$$

$$B_x = 0, \quad B_y = 0, \quad B_z = \frac{\gamma q}{c^2} E'_y = \frac{u}{c^2} \frac{q}{4\pi \varepsilon_0} \left(\frac{\gamma b}{u^2 \gamma^2 t^2 + b^2}\right)^{3/2} \equiv \frac{u}{c^2} E_y. \quad (9.140)$$

These results, 51 plotted in Fig. 11b in units of $\gamma q^2/4\pi \varepsilon_0 b^2$, reveal two major effects. First, the
charge passage by the observer generates not only an electric field pulse, but also a magnetic field pulse.
This is natural, because, as was repeatedly discussed in Chapter 5, any charge motion is essentially an
electric current. 52 Second, Eqs. (139)-(140) show that the pulse duration scale is

$$\Delta t = \frac{b}{\gamma u} = \frac{b}{u} \left(1 - \frac{u^2}{c^2}\right)^{1/2}, \quad (9.141)$$

i.e. shrinks to virtually zero as the charge’s velocity $u$ approaches the speed of light. This is of course a
direct corollary of the relativistic length contraction: in the frame $0'$ moving with the charge, the
longitudinal spread of its electric field at distance $b$ from the motion line is of the order of $\Delta x' = b$.

51 In the next chapter, we will re-derive them in a different way.
52 It is straightforward to use Eq. (140) and the linear superposition principle to calculate, for example, the
magnetic field of a string of charges moving along the same line, and separated by equal distances $\Delta x = a$ (so that
the average current, as measured in frame 0, is $q u/a$), and to show that the time-average of the magnetic field is
given by the familiar Eq. (5.20) of magnetostatics, with $b$ instead of $\rho$. 
When observed from the lab frame 0, this interval, in accordance with Eq. (20), shrinks to \( \Delta x = \Delta x' / \gamma = b / \gamma \), and hence so does the pulse duration scale \( \Delta t = \Delta x / u = b / \gamma u \).

9.6. Relativistic particles in electric and magnetic fields

Now let us analyze the dynamics of charged particles in electric and magnetic fields. Inspired by “our” success in forming the 4-vector (75) of the energy-momentum, with the contravariant form

\[
p^\alpha = \left\{ \frac{E}{c}, \mathbf{p} \right\} = \gamma (mc, \mathbf{p}) = m \frac{dx^\alpha}{d\tau} \equiv mu^\alpha,
\]

where \( u^\alpha \) is the contravariant form of the 4-velocity (63) of the particle,

\[
u^\alpha \equiv \frac{dx^\alpha}{d\tau}, \quad u^\alpha \equiv \frac{dx^\alpha}{d\tau},
\]

we may notice that the non-relativistic equation of motion, resulting from the Lorentz-force formula (5.10) for the three spatial components of \( p^\alpha \), at charged particle’s motion in an electromagnetic field,

\[
\frac{dp}{dt} = q(E + u \times B),
\]

is fully consistent with the following 4-vector equality (which is evidently form-invariant with respect to the Lorentz transform):

\[
\frac{dp^\alpha}{d\tau} = qF_{\alpha \beta}u^\beta.
\]

For example, according to Eq. (125), the \( \alpha = 1 \) component of this equation reads

\[
\frac{dp^1}{d\tau} = qF_{1 \beta}u^\beta = q \left[ \frac{E_x}{c} \gamma c + 0 \cdot (-\gamma u_x) + (-B_z)(-\gamma u_y) + B_y(-\gamma u_z) \right] = q \gamma[E + u \times B],
\]

and similarly for two other spatial components (\( \alpha = 2 \) and \( \alpha = 3 \)). It may look that these expressions differ from the 2\(^{nd}\) Newton law (144) by the extra factor \( \gamma \). However, plugging into Eq. (146) the definition of the proper time interval, \( d\tau = dt / \gamma \), and canceling \( \gamma \) in both parts, we recover Eq. (144) exactly – for any velocity of the particle! The only caveat is that if \( u \) is comparable with \( c \), the vector \( p \) in Eq. (144) has to be understood as the relativistic momentum (70) proportional to the velocity-dependent mass \( M = \gamma m \geq m \) rather than to the rest mass \( m \).

The only remaining general task is to examine the meaning of the 0\(^{th}\) component of Eq. (145). Let us spell it out:

\[
\frac{dp^0}{d\tau} = qF_{0 \beta}u^\beta = q \left[ 0 \cdot \gamma c + \left( -\frac{E_x}{c} \right)(-\gamma u_x) + \left( -\frac{E_y}{c} \right)(-\gamma u_y) + \left( -\frac{E_z}{c} \right)(-\gamma u_z) \right] = q \gamma E \cdot \mathbf{u}.
\]
Recalling that \( p^0 = E/c, \) and using the basic relation \( d\tau = dt/\gamma \) again, we see that Eq. (147) looks exactly as the non-relativistic relation for the kinetic energy change (what is sometimes called the *work-energy principle*, in our case for the Lorentz force only\(^{53}\)):

\[
\frac{d\mathcal{E}}{dt} = qE \cdot u,
\]  

(9.148)

besides that in the relativistic case the energy has to be taken in the general form (73).

No question, the 4-component equation (145) of the relativistic dynamics is absolutely beautiful in its simplicity. However, for the solution of particular problems, Eqs. (144) and (148) are frequently more convenient. As an illustration of this point, let us now use these equations to explore the relativistic effects at charged particle motion in uniform, time-independent electric and magnetic fields. In doing that, we will, for the time being, neglect the contributions into the field by the particle itself.\(^{54}\)

(i) Uniform magnetic field. Let the magnetic field be constant and uniform in the “lab” reference frame 0. Then in this frame, Eqs. (144) and (148) yield

\[
\frac{dp}{dt} = qu \times B, \quad \frac{d\mathcal{E}}{dt} = 0.
\]  

(9.149)

From the second equation, \( \mathcal{E} = \text{const} \), we get \( u = \text{const} \), \( \beta = u/c = \text{const} \), \( \gamma = (1 - \beta^2)^{-1/2} = \text{const} \), and \( M = \gamma m = \text{const} \), so that the first of Eqs. (149) may be rewritten as

\[
\frac{du}{dt} = u \times \omega_c,
\]  

(9.150)

where \( \omega_c \) is the vector directed along the magnetic field \( B \), with the magnitude equal to the *cyclotron frequency* (sometimes called “gyrofrequency”)

\[
\omega_c \equiv \frac{qB}{M} = \frac{qB}{\gamma m} = \frac{qc^2B}{\mathcal{E}}.
\]  

(9.151)

If the particle’s initial velocity \( u_0 \) is perpendicular to the magnetic field, Eq. (150) describes its circular motion, with a constant speed \( u = u_0 \), in a plane perpendicular to \( B \), with the angular velocity (151). In the non-relativistic limit \( u << c \), when \( \gamma \to 1 \), i.e. \( M \to m \), the cyclotron frequency \( \omega_c \) equals \( qB/m \), i.e. is independent of the speed. However, as the kinetic energy is increased to become comparable with the rest energy \( mc^2 \) of the particle, the frequency decreases, and in the ultra-relativistic limit:

\[
\omega_c \approx \frac{qcB}{p} << \frac{qB}{m}, \quad \text{at} \ u \approx c.
\]  

(9.152)

The cyclotron motion’s radius may be calculated as \( R = u/\omega_c \); in the non-relativistic limit it is proportional to the particle’s speed, i.e. to the square root of its kinetic energy. However, as Eq. (151)

---

\(^{53}\) See, e.g., CM Eq. (1.20) divided by \( dt \), and with \( dp/dt = F = qE \). (As a reminder, the magnetic field cannot affect the particle’s energy, because the magnetic component of the Lorentz force is perpendicular to its velocity.)

\(^{54}\) As was emphasized earlier in this course, in statics this contribution has to be ignored. In dynamics, this is generally not true; these *self-action effects* (in most cases, negligible) will be discussed in Sec. 10.6.
shows, in the general case the radius is proportional to the particle’s relativistic momentum rather than its speed:

\[
R = \frac{u}{\omega_c} = \frac{Mu}{qB} = \frac{m\gamma u}{qB} = \frac{1}{\gamma q} B p,
\]

so that in the ultra-relativistic limit, when \( p \approx \gamma q/c \), \( R \) is proportional to the kinetic energy.

This dependence of \( \omega_c \) and \( R \) on energy are the major factors in the design of circular accelerators of charged particles. In the simplest of these machines (the \textit{cyclotron}, invented in 1929 by Ernest Orlando Lawrence), the frequency \( \omega \) of the accelerating ac electric field is constant, so that even it is tuned to the \( \omega_c \) of the initially injected particles, the drop of the cyclotron frequency with energy eventually violates this tuning. Due to this reason, the largest achievable particle’s speed is limited to just \( \sim 0.1 \) \( c \) (for protons, corresponding to the kinetic energy of just \( \sim 15 \) MeV). This problem may be addressed in several ways. In particular, in \textit{synchrotrons} (such as Fermilab’s Tevatron and the CERN’s Large Hadron Collider, LHC\textsuperscript{55}) the magnetic field is gradually increased in time to compensate for the momentum increase \((B \propto p)\), so that both \( R \) (148) and \( \omega_c \) (147) stay constant, enabling the proton acceleration to energies as high as \( \sim 7 \) TeV, i.e. \( \sim 2,000 \) \( mc^2 \).\textsuperscript{56}

Returning to our initial problem, if the particle’s initial velocity has a component \( u_\parallel \) along the magnetic field, then it is conserved in time, so that the trajectory is a spiral around the magnetic field lines. As Eqs. (149) show, in this case Eq. (150) remains valid, but in Eqs. (151) and (153) the full speed and momentum have to be replaced with magnitudes of their (also time-conserved) components, \( u_\perp \) and \( p_\perp \), normal to \( B \), while the Lorentz factor \( \gamma \) in those formulas still includes the full speed of the particle.

Finally, in the special case when particle’s initial velocity is directed \textit{exactly} along the magnetic field’s direction, it continues to move by straight line along the vector \( B \). In this case, the cyclotron frequency still has its non-zero value (151), but does not correspond to any real motion, because \( R = 0 \).

\textbf{(ii) Uniform electric field.} This problem is (technically) more complex than the previous one, because in the electric field, the particle’s energy may change. Directing the \( z \)-axis along the field \( E \), from Eq. (144) we get

\[
\frac{dp_z}{dt} = qE, \quad \frac{dp_\perp}{dt} = 0 .
\]

If the field does not change in time, the first integration of these equations is elementary,

\[
p_z(t) = p_z(0) + qEt, \quad p_\perp(t) = \text{const} = p_\perp(0),
\]

but the further integration requires care, because the effective mass \( M = \gamma m \) of the particle depends on its full speed \( u \), with

\[
u^2 = u_z^2 + u_\perp^2,
\]

making the two motions, along and across the field, mutually dependent.

\textsuperscript{55} See \url{https://home.cern/topics/large-hadron-collider}.
\textsuperscript{56} For more on this topic, I have to refer the interested reader to special literature, for example, either S. Lee, \textit{Accelerator Physics}, 2\textsuperscript{nd} ed., World Scientific, 2004, or E. Wilson, \textit{An Introduction to Particle Accelerators}, Oxford U. Press, 2001.
If the initial velocity is perpendicular to the field \( E \), i.e. if \( p_z(0) = 0 \), \( p_{\perp}(0) = p(0) \equiv p_0 \), the easiest way to proceed is to calculate the kinetic energy first:

\[
\mathcal{E}^2 = (mc^2)^2 + c^2 p^2(t) = \mathcal{E}_0^2 + c^2 (qEt)^2, \quad \text{where} \quad \mathcal{E}_0 \equiv \left[(mc^2)^2 + c^2 p_0^2\right]^{1/2}.
\]  

(9.157)

On the other hand, we can calculate the same energy by integrating Eq. (148),

\[
\frac{d\mathcal{E}}{dt} = q\mathbf{E} \cdot \mathbf{u} \equiv qE \frac{dz}{dt},
\]

(9.158)

over time, with a simple result:

\[
\mathcal{E} = \mathcal{E}_0 + qEZ(t),
\]

(9.159)

where (just for the notation simplicity) I took \( z(0) = 0 \). Requiring Eq. (159) to give the same \( \mathcal{E}^2 \) as Eq. (157), we get a quadratic equation for the function \( z(t) \),

\[
\mathcal{E}_0^2 + c^2 (qEt)^2 = \left[\mathcal{E}_0 + qEZ(t)\right]^2,
\]

(9.160)

whose solution (with the sign before the square root corresponding to \( E > 0 \), i.e. \( z \geq 0 \)) is

\[
z(t) = \frac{\mathcal{E}_0}{qE} \left[1 + \left(\frac{cqEt}{\mathcal{E}_0}\right)^2\right]^{1/2} - 1.
\]

(9.161)

Now let us find the particle’s trajectory. Selecting the \( x \)-axis so that the initial velocity vector (and hence the velocity vector at any further instant) is within the \([x, z]\) plane, i.e. that \( y(t) = 0 \) identically, we may use Eqs. (155) to calculate the trajectory’s slope, at its arbitrary point, as

\[
\frac{dz}{dx} \equiv \frac{dz}{dt} / \frac{dx}{dt} \equiv \frac{Mu_z}{Mu} \equiv \frac{p_z}{p} = \frac{qEt}{p_0}.
\]

(9.162)

Now let us use Eq. (160) to express the numerator of this fraction, \( qEt \), as a function of \( z \):

\[
qEt = \frac{1}{c} \left[\mathcal{E}_0^2 + qEZ^2 - \mathcal{E}_0^2\right]^{1/2}.
\]

(9.163)

Plugging this expression into Eq. (161), we get

\[
\frac{dz}{dx} = \frac{1}{cp_0} \left[\mathcal{E}_0 + qEZ^2 - \mathcal{E}_0^2\right]^{1/2}.
\]

(9.164)

This differential equation may be readily integrated, separating the variables \( z \) and \( x \), and using the following substitution: \( \xi = \cosh^{-1}(qEZ/\mathcal{E}_0 + 1) \). Selecting the origin of axis \( x \) at the initial point, so that \( x(0) = 0 \), we finally get the trajectory:

\[
z = \frac{\mathcal{E}_0}{qE} \left(\cosh \frac{qEx}{cp_0} - 1\right).
\]

(9.165)

This curve is usually called the \textit{catenary}, but sometimes the “chainette”, because it (with the proper constant replacement) describes the stationary shape of a heavy, uniform chain in a uniform gravity field, directed along the \( z \)-axis. At the initial part of the trajectory, where \( qEx << cp_0(0) \), this
expression may be approximated by the first non-zero term of its Taylor expansion in small \( x \), giving a parabola:

\[
z = \frac{\varepsilon_0 q E}{2} \left( \frac{x}{\epsilon p_0} \right)^2,
\]

so that if the initial velocity of the particle is much less than \( c \) (i.e. \( p_0 \approx m u_0, \varepsilon_0 \approx m c^2 \)), we get the familiar non-relativistic formula:

\[
z = \frac{q E}{2 m u_0^2} x^2 = \frac{a}{2} t^2, \quad \text{where} \quad a = \frac{F}{m} = \frac{q E}{m}.
\]

The straightforward generalization of this solution to the case of an arbitrary direction of the particle’s initial velocity is left for the reader’s exercise.

(iii) Crossed uniform magnetic and electric fields (\( E \perp B \)). In the view of the somewhat bulky solution of the previous problem (i.e. the particular case of the current problem for \( B = 0 \)), one might think that this problem, with \( B \neq 0 \), should be forbiddingly complex for an analytical solution. Counter-intuitively, it is not the case, due to the help from the field transform relations (135). Let us consider two possible cases.

**Case 1**: \( E/c < B \). Let us consider an inertial reference frame moving (relatively the “lab” reference frame \( 0 \) in which fields \( E \) and \( B \) are defined) with the following velocity:

\[
v = \frac{E \times B}{B^2},
\]

and hence the magnitude \( v = c \times (E/c)/B < c \). Selecting the coordinate axes as shown in Fig. 12, so that

\[
E_x = 0, \quad E_y = E, \quad E_z = 0; \quad B_x = 0, \quad B_y = 0, \quad B_z = 0,
\]

we see that the Cartesian components of this velocity are \( v_x = v, \ v_y = v_z = 0 \).

![Fig. 9.12. Particle’s trajectory in crossed electric and magnetic fields (at \( E/c < B \)).](image)

Since this choice of the coordinates complies with the one used to derive Eqs. (134), we can readily use that simple form of the Lorentz transform to calculate the field components in the moving reference frame:

\[
E'_x = 0, \quad E'_y = \gamma (E - vB) = \gamma \left( E - \frac{E}{B} B \right) = 0, \quad E'_z = 0,
\]

\[
B'_x = 0, \quad B'_y = 0, \quad B'_z = \gamma \left( B - \frac{vE}{c^2} \right) = \gamma B \left( 1 - \frac{v^2}{c^2} \right) = \gamma B \left( 1 - \frac{v^2}{c^2} \right) = \frac{B}{\gamma} \leq B,
\]
where the Lorentz parameter \( \gamma \equiv (1 - v^2/c^2)^{-1/2} \) corresponds to the velocity (168) rather than that of the particle. These relations show that in this special reference frame the particle only “sees” the renormalized uniform magnetic field \( B' \leq B \), parallel to the initial field, i.e. perpendicular to the velocity (168). Using the result of the above case (i), we see that in this frame the particle moves along either a circle or a spiral winding about the direction of the magnetic field, the with the angular speed (151),

\[
\omega' = \frac{qB'}{\varepsilon'c^2},
\]

and the radius (153):

\[
R' = \frac{p'}{qB'}.
\]

Hence in the lab frame, the particle performs this orbital/spiral motion plus a “drift” with the constant velocity \( v \) (Fig. 12). As the result, the lab-frame trajectory of the particle (or rather its projection onto the plane perpendicular to the magnetic field) is a \textit{trochoid}-like curve\(^{57}\) that, depending on the initial velocity, may be either \textit{prolate} (self-crossing), as in Fig. 12, or \textit{curtate} (drift-stretched so much that it is not self-crossing).

Such looped motion of electrons (in practice, with \( v \ll c \)) is used, in particular, in \textit{magnetrons} – very popular generators of microwave radiation. In such a device (Fig. 13), the magnetic field, usually created by specially-shaped permanent magnets, is nearly uniform (in the region of electron motion) and directed along the magnetron’s axis (in Fig. 13, normal to the plane of the drawing), while the electric field of magnitude \( E \ll cB \), created by the dc voltage applied between the anode and cathode, is virtually radial.

As a result, the above simple theory is only approximately valid, and the electron trajectories are close to \textit{epicycloids} rather than trochoids. The applied electric field is adjusted so that these looped trajectories pass close to the anode’s surface, and hence to the gap openings of the cylindrical microwave cavities drilled in the anode’s bulk. The fundamental mode of such a cavity is quasi-lumped,

\(^{57}\) As a reminder, a trochoid may be described as the trajectory of a point on a rigid disk rolled along a straight line. It’s canonical parametric representation is \( x = \Theta + acos \Theta, y = asin \Theta \). (For \( a > 1 \), the trochoid is \textit{prolate}, if \( a < 1 \), it is \textit{curtate}, and if \( a = 1 \), it is called the \textit{cycloid}.) Note, however, that for our problem, the trajectory in the lab frame is exactly trochoidal only in the non-relativistic limit \( v \ll c \) (i.e. \( E/c \ll B \)).
with the cylindrical walls working mostly as inductances, and the gap openings as capacitances, with the microwave electric field concentrated in these openings. This is why the mode is strongly coupled to the electrons passing nearby, and their interaction creates large positive feedback (equivalent to negative damping), which results in intensive microwave self-oscillations at the cavities’ own frequency. The oscillation energy, of course, is taken from the dc-field-accelerated electrons; due to the energy loss, the looped trajectory of each electron gradually moves closer to the anode and finally lands on its surface. The wide use of such generators (in particular, in microwave ovens, which operate in a narrow frequency band around 2.45 GHz, allocated for these devices to avoid their interference with wireless communication systems) is due to their simplicity and high (up to 65%) efficiency.

Case 2: \( E/c > B \). In this case, the speed given by Eq. (168) would be above the speed of light, so let us introduce a reference frame moving with a different velocity,

\[
v = \frac{\mathbf{E} \times \mathbf{B}}{(E/c)^2},
\]

whose direction is the same as before (Fig. 12), and magnitude \( v = c \times B/(E/c) \) is again below \( c \). A calculation absolutely similar to the one performed above for Case 1, yields

\[
\begin{align*}
E'_x &= 0, & E'_y &= \gamma(E - vB) = \gamma E \left(1 - \frac{vB}{E}\right) = \frac{E}{\gamma} \leq E, & E'_z &= 0, \\
B'_x &= 0, & B'_y &= 0, & B'_z &= \gamma \left(B - \frac{vE}{c^2}\right) = \gamma \left(B - \frac{EB}{E}\right) = 0.
\end{align*}
\]

so that in the moving frame the particle “sees” only the electric field \( E' \leq E \). According to the solution of our previous problem (ii), the trajectory of the particle in the moving frame is the catenary (165), so that in the lab frame it has an “open”, hyperbolic character as well.

To conclude this section, let me note that if the electric and magnetic fields are non-uniform, the particle motion may be much more complex, and in most cases, the integration of equations (144), (148) may be carried out only numerically. However, if the field’s nonuniformity is small, approximate analytical methods may be very effective. For example, if \( E = 0 \), and the magnetic field has a small transverse gradient \( \nabla B \) in a direction perpendicular to the vector \( B \) itself, such that

\[
\eta \equiv \frac{\|\nabla B\|}{B} \ll \frac{1}{R},
\]

where \( R \) is the cyclotron radius (153), then it is straightforward to use Eq. (150) to show that the cyclotron orbit drifts perpendicular to both \( B \) and \( \nabla B \), with the drift speed

\[
v_d \approx \frac{\eta}{\omega_c} \left(\frac{1}{2} u^2_\perp + u^2_\parallel\right) \ll u.
\]

The physics of this drift is rather simple: according to Eq. (153), the instant curvature of the cyclotron orbit is proportional to the local value of the field. Hence if the field is nonuniform, the

---

58 See, e.g., CM Sec. 5.4.
trajectory bends slightly more on its parts passing through a stronger field, thus acquiring a shape close to a curate trochoid.

For experimental physics and engineering practice, the effects of longitudinal gradients of magnetic field on the charged particle motion are much more important, but it is more convenient for me to postpone their discussion until we have developed a little bit more analytical tools in the next section.

9.7. Analytical mechanics of charged particles

The general equation (145) gives a full description of relativistic particle dynamics in electric and magnetic fields, just as the 2nd Newton law (1) does it in the non-relativistic limit. However, we know that in the latter case, the Lagrange formalism of analytical mechanics allows an easier solution of many problems. We can expect that to be true in relativistic mechanics as well, so let us expand the analysis of Sec. 3 (valid only for free particles) to particles in the field.

Let recall that for a free particle, our main result was Eq. (68), which may be rewritten as

$$\gamma L = -mc^2,$$  \hspace{1cm} (9.179)

with $\gamma \equiv (1 - u^2/c^2)^{-1/2}$, showing that the product on the left-hand side is Lorentz-invariant. How can the electromagnetic field affect this relation? In non-relativistic electrostatics, we could write

$$\phi q = -L.$$  \hspace{1cm} (9.180)

However, in relativity, the scalar potential $\phi$ is just one component of the potential 4-vector (116). The only way to get from this full 4-vector a Lorentz-invariant contribution to $\gamma L$, that would be also proportional to the Lorentz force, i.e. to the first power of the particle’s velocity (to account for the magnetic component of the Lorentz force), is evidently

$$\gamma L = -mc^2 + \text{const} \times u^\alpha A_\alpha,$$  \hspace{1cm} (9.181)

where $u^\alpha$ is the 4-velocity (63). To comply with Eq. (180) in electrostatics, the constant factor should be equal to $(-qc)$, so that Eq. (181) becomes

$$\gamma L = -mc^2 - q u^\alpha A_\alpha,$$  \hspace{1cm} (9.182)

and, finally, we get an extremely important equality:

$$L = -\frac{mc^2}{\gamma} - q \phi + q u \cdot A,$$  \hspace{1cm} (9.183)

whose Cartesian form is

$$L = -mc^2 \left(1 - \frac{u_x^2 + u_y^2 + u_z^2}{c^2}\right)^{1/2} - q \phi + q(u_x A_x + u_y A_y + u_z A_z).$$  \hspace{1cm} (9.184)

Let us see whether this relation (which admittedly was obtained by an educated guess rather than by a strict derivation) passes a natural sanity check. For the case of an unconstrained motion of a particle, we can select its three Cartesian coordinates $r_j$ ($j = 1, 2, 3$) as the generalized coordinates, and

---

60 See, e.g., CM Sec. 2.2 and on.
its linear velocity components \( u_j \) as the corresponding generalized velocities. In this case, the Lagrange equations of motion are

\[
\frac{d}{dt} \frac{\partial \mathcal{L}}{\partial u_j} - \frac{\partial \mathcal{L}}{\partial r_j} = 0.
\]  
(9.185)

For example, for \( r_1 = x \), Eq. (184) yields

\[
\frac{\partial \mathcal{L}}{\partial u_x} = \frac{m u_x}{\left(1 - u^2/c^2\right)^{3/2}} + q A_x \equiv p_x + q A_x, \quad \frac{\partial \mathcal{L}}{\partial x} = -q \frac{\partial \phi}{\partial x} + q u \cdot \frac{\partial A}{\partial x},
\]  
(9.186)

so that Eq. (185) takes the form

\[
\frac{dp_x}{dt} = -q \frac{\partial \phi}{\partial x} + q u \cdot \frac{\partial A}{\partial x} - q \frac{dA_x}{dt}.
\]  
(9.187)

In the equations of motion, the field values have to be taken at the instant position of the particle, so that the last (full) derivative has components due to both the actual field’s change (at a fixed point of space) and the particle’s motion. Such addition is described by the so-called \textit{convective derivative} \(^{61}\)

\[
\frac{d}{dt} = \frac{\partial}{\partial t} + u \cdot \nabla.
\]  
(9.188)

Spelling out both scalar products, we may group the terms remaining after cancellations as follows:

\[
\frac{dp_x}{dt} = q \left[ \left( -\frac{\partial \phi}{\partial x} - \frac{\partial A_x}{\partial t} \right) + u_x \left( \frac{\partial A_x}{\partial x} - \frac{\partial A_x}{\partial y} \right) - u_x \left( \frac{\partial A_x}{\partial z} - \frac{\partial A_x}{\partial x} \right) \right].
\]  
(9.189)

But taking into account the relations (121) between the electric and magnetic fields and potentials, this expression is nothing more than

\[
\frac{dp_x}{dt} = q \left( E_x + u_x B_z - u_z B_y \right) = q \left( \mathbf{E} + \mathbf{u} \times \mathbf{B} \right)_x,
\]  
(9.190)

i.e. the \( x \)-component of Eq. (144). Since other Cartesian coordinates participate in Eq. (184) in a similar way, it is evident that the Lagrangian equations of motion along other coordinates yield other components of the same vector equation of motion.

So, Eq. (183) does indeed give the correct Lagrangian function, and we can use it for further analysis, in particular to discuss the first of Eqs. (186). This relation shows that in the electromagnetic field, the generalized momentum corresponding to particle’s coordinate \( x \) is \textit{not} \( p_x = m \gamma u_x \), but \(^{62}\)

\[
P_x = \frac{\partial \mathcal{L}}{\partial u_x} = p_x + q A_x.
\]  
(9.191)

Thus, as was already discussed (at that point, without a proof) in Sec. 6.4, the particle’s motion in a magnetic field may be is described by two different momentum vectors: the \textit{kinetic momentum} \( \mathbf{p} \), defined by Eq. (70), and the \textit{canonical} (or “conjugate”) \textit{momentum} \(^{63}\)

---

\(^{61}\) Alternatively called the “Lagrangian derivative”; for its (rather simple) derivation see, e.g., CM Sec. 8.3.

\(^{62}\) With regrets, I have to use for the generalized momentum the same (very common) notation as was used earlier in the course for the electric polarization – which is not discussed below.
In order to facilitate discussion of this notion, let us generalize expression (72) for the Hamiltonian function $\mathcal{H}$ of a free particle to the case of a particle in the field:

$$\mathcal{H} \equiv P \cdot u - L = (p + qA) \cdot u - \left( -\frac{mc^2}{\gamma} + qu \cdot A - q\phi \right) = p \cdot u + \frac{mc^2}{\gamma} + q\phi. \quad (9.193)$$

Merging the first two terms exactly as it was done in Eq. (72), we get an extremely simple result,

$$\mathcal{H} = \gamma mc^2 + q\phi, \quad (9.194)$$

which may leave us wondering: where is the vector potential $A$ here – and the magnetic field effects is has to describe? The resolution of this puzzle is easy: as we know from analytical mechanics, for most practical uses, for example for the alternative derivation of the equations of motion, $\mathcal{H}$ has to be represented as a function of particle’s generalized coordinates (in the case of unconstrained motion, these may be the Cartesian components of the vector $r$ that serves as an argument for potentials $A$ and $\phi$), and the generalized momenta, i.e. the components of the vector $P$ – generally, plus time. Hence, the velocity $u$ and the factor $\gamma$ should be eliminated from Eq. (194). This may be done using the relation (192), $\gamma mu = P - qA$. For the elimination, it is sufficient to notice that according to Eq. (193), the difference ($\mathcal{H} - q\phi$) is equal to the right-hand side of Eq. (72), so that the generalization of Eq. (78) is

$$(\mathcal{H} - q\phi)^2 = (mc^2)^2 + c^2(P - qA)^2, \quad \text{giving } \mathcal{H} = mc^2 \left[ 1 + \left( \frac{P}{mc} \right)^2 \right]^{1/2} + q\phi, \quad (9.195)$$

It is straightforward to verify that the Hamilton equations of motion for three Cartesian coordinates of the particle, obtained in the regular way from this $\mathcal{H}$, may be merged into the same vector equation (144). In the non-relativistic limit, performing the expansion of the latter of Eqs. (195) into the Taylor series in $p^2$, and limiting it to two leading terms, we get the following generalization of Eq. (74):

$$\mathcal{H} \approx mc^2 + \frac{p^2}{2m} + q\phi, \quad \text{i.e. } \mathcal{H} - mc^2 \approx \frac{1}{2m} (P - qA)^2 + U, \quad \text{with } U = q\phi. \quad (9.196)$$

These expressions for $\mathcal{H}$, and Eq. (183) for $L$, give a clear view of the electromagnetic field effect account in analytical mechanics. The electric part of the total Lorentz force $q(E + u \times B)$ can perform work on the particle, i.e. change its kinetic energy – see Eq. (148) and its discussion. As a result, the scalar potential $\phi$, whose gradient gives a contribution to $E$, may be directly associated with the potential energy $U = q\phi$ of the particle. On the contrary, the magnetic component $qu \times B$ of the Lorentz force is always perpendicular to particle’s velocity $u$, and cannot perform a non-zero work on it, and as a result, cannot be described by a contribution to $U$. However, if $A$ did not participate in the functions $L$ and/or $\mathcal{H}$ at all, the analytical mechanics would be unable to describe effects of the magnetic field $B = \nabla \times A$ on the particle’s motion. The relations (183) and (195)-(196) show the

---

63 In Gaussian units, Eq. (192) has the form $P = p + qA/c$.
64 See, e.g., CM Sec. 10.1.
65 Alternatively, this relation may be obtained from the expression for the Lorentz-invariant norm, $p^\alpha p_\alpha = (mc)^2$, of the 4-momentum (75), $p^\alpha = \{E/c, p\} = \{(\mathcal{H} - q\phi)/c, P - qA\}$. 
wonderful way in which physics (with some help from Mother Nature herself :-) solves this problem: the vector potential gives such contributions to the functions $\mathcal{L}$ and $\mathcal{H}$ (if the latter is considered, as it should be, a function of $\mathbf{P}$ rather than $\mathbf{p}$) that cannot be uniquely attributed to either kinetic or potential energy, but ensure the correct equation of motion (144) in both the Lagrange and Hamilton formalisms.

I believe I still owe the reader some discussion of the physical sense of the canonical momentum $\mathbf{P}$. For that, let us consider a charged particle moving near a region of localized magnetic field $\mathbf{B}(\mathbf{r}, t)$, but not entering this region (see Fig. 14), so that on its trajectory $\mathbf{B} \equiv \nabla \times \mathbf{A} = 0$.

![Fig. 9.14. Particle’s motion around a localized magnetic field with a time-dependent flux.](image)

If there is no electrostatic field (i.e. no other electric charges nearby), we may select such a local gauge that $\phi(\mathbf{r}, t) = 0$ and $\mathbf{A} = \mathbf{A}(t)$, so that Eq. (144) is reduced to

$$\frac{d\mathbf{p}}{dt} = q\mathbf{E} = -q \frac{d\mathbf{A}}{dt}, \quad (9.197)$$

and Eq. (192) immediately gives

$$\frac{d\mathbf{P}}{dt} \equiv \frac{d\mathbf{p}}{dt} + q \frac{d\mathbf{A}}{dt} = 0. \quad (9.198)$$

Hence, even if the magnetic field is changed in time, so that the induced electric field does accelerate the particle, its canonical momentum does not change. Hence $\mathbf{P}$ is a variable more stable to magnetic field changes than its kinetic counterpart $\mathbf{p}$. This conclusion may be criticized because it relies on a specific gauge, and generally $\mathbf{P} \equiv \mathbf{p} + q\mathbf{A}$ is not gauge–invariant, because the vector potential $\mathbf{A}$ is not. However, as was already discussed in Sec. 5.3, the integral $\int \mathbf{A} \cdot d\mathbf{r}$ over a closed contour does not depend on the chosen gauge and equals to the magnetic flux $\Phi$ through the area limited by the contour – see Eq. (5.65). So, integrating Eq. (197) over a closed trajectory of a particle (Fig. 14), and over the time of one orbit, we get

$$\Delta \oint_c \mathbf{p} \cdot d\mathbf{r} = -q\Delta \Phi, \quad \text{so that} \quad \Delta \oint_c \mathbf{P} \cdot d\mathbf{r} = 0, \quad (9.199)$$

where $\Delta \Phi$ is the change of flux during that time. This gauge-invariant result confirms the above conclusion about the stability of the canonical momentum to magnetic field variations.

Generally, Eq. (199) is invalid if a particle moves inside a magnetic field and/or changes its trajectory at the field variation. However, if the field is almost uniform, i.e. its gradient is small in the sense of Eq. (177), this result is (approximately) applicable. Indeed, analytical mechanics tells us that for any canonical coordinate-momentum pair $\{q_j, p_j\}$, the corresponding action variable,

---

66 The kinetic momentum $\mathbf{p} = M\mathbf{u}$ is just the usual $m\mathbf{u}$ product modified for relativistic effects, so that this variable is evidently gauge- (though not Lorentz-) invariant.

67 See, e.g., CM Sec. 10.2.
remains virtually constant at slow variations of motion conditions. According to Eq. (191), for a particle in a magnetic field, the generalized momentum, corresponding to the Cartesian coordinate \( r_j \), is \( P_j \) rather than \( p_j \). Thus forming the net action variable \( J \equiv J_x + J_y + J_z \), we may write

\[
2\pi J = \oint \mathbf{P} \cdot d\mathbf{r} = \oint \mathbf{P} \cdot d\mathbf{r} + q\Phi = \text{const}.
\] (9.201)

Let us apply this relation to the motion of a non-relativistic particle in an almost uniform magnetic field, with a small longitudinal velocity, \( \cdot u_\parallel / u_\perp \to 0 \) – see Fig. 15.

In this case, \( \Phi \) in Eq. (201) is the flux encircled by a cyclotron orbit, equal to \(-\pi R^2 B\), where \( R \) is its radius given by Eq. (153), and the negative sign accounts for the fact that the “correct” direction of the normal vector \( \mathbf{n} \) in the definition of flux, \( \Phi = \int \mathbf{B} \cdot \mathbf{n} d^2 r \), is antiparallel to the vector \( \mathbf{B} \). At \( u \ll c \), the kinetic momentum is just \( p_\perp = mu_\perp \), while Eq. (153) yields

\[
mu_\perp = qBR.
\] (9.202)

Plugging these relations into Eq. (201), we get

\[
2\pi J = mu_\perp 2\pi R - q\pi R^2 B = m\frac{qRB}{m} 2\pi R - q\pi R^2 B \equiv (2-1)q\pi R^2 B = -q\Phi.
\] (9.203)

This means that even if the circular orbit slowly moves in the magnetic field, the flux encircled by the cyclotron orbit should remain virtually constant. One manifestation of this effect is the result already mentioned in the end of Sec. 6: if a small gradient of the magnetic field is perpendicular to the field itself, then the particle orbit’s drift direction is perpendicular to \( \nabla B \), so that \( \Phi \) stays constant.

Now let us analyze the case of a small longitudinal gradient, \( \nabla B \parallel B \) (Fig. 15). If the small initial longitudinal velocity \( u_\parallel \) is directed toward the higher field region, the cyclotron orbit has to gradually shrink to keep \( \Phi \) constant. Rewriting Eq. (202) as

\[
mu_\perp = q \frac{\pi R^2 B}{\pi R} = q \left| \frac{\Phi}{\pi R} \right|,
\] (9.204)

we see that this reduction of \( R \) (at constant \( \Phi \)) should increase the orbiting speed \( u_\perp \). But since the magnetic field cannot perform any work on the particle, its kinetic energy,

\[
\mathcal{E} = \frac{m}{2} \left( u_\parallel^2 + u_\perp^2 \right),
\] (9.205)
should stay constant, so that the longitudinal velocity $u_\parallel$ has to decrease. Hence eventually the orbit’s drift has to stop, and then the orbit has to start moving back toward the region of lower fields, being essentially repulsed from the high-field region. This effect is very important, in particular, for plasma confinement systems. In the simplest of such systems, two coaxial magnetic coils, inducing magnetic fields of the same direction (Fig. 16), naturally form a “magnetic bottle”, which traps charged particles injected, with sufficiently low longitudinal velocities, into the region between the coils. More complex systems of this type, but working on the same basic principle, are the most essential components of the persisting large-scale efforts to achieve the controllable nuclear fusion.\footnote{For further reading on this technology, the reader may be referred, for example, to the simple monograph by F. Chen, \textit{Introduction to Plasma Physics and Controllable Fusion}, vol. 1, 2\textsuperscript{nd} ed., Springer, 1984, and/or the graduate-level theoretical treatment by R. Hazeltine and J. Meiss, \textit{Plasma Confinement}, Dover, 2003.}

![Fig. 9.16. A simple magnetic bottle (schematically).](image)

Returning to the constancy of the magnetic flux encircled by free particles, it reminds us of the Meissner-Ochsenfeld effect, which was discussed in Sec. 6.4, and gives a motivation for a brief revisit of the electrodynamics of superconductivity. As was emphasized in that section, superconductivity is a substantially quantum phenomenon; nevertheless the classical notion of the conjugate momentum $\mathbf{P}$ helps to understand its theoretical description. Indeed, the general rule of quantization of physical systems\footnote{See, e.g., CM Sec. 10.1.} is that each canonical pair \{q\_j, p\_j\} of a generalized coordinate $q\_j$ and the corresponding generalized momentum $p\_j$ is described by quantum-mechanical operators that obey the following commutation relation:

$$\left[ \hat{q}\_j, \hat{p}\_j \right] = i\hbar \delta\_jj'. \quad (9.206)$$

According to Eq. (191), for the Cartesian coordinates $r\_j$ of a particle in the magnetic field, the corresponding generalized momenta are $P\_j$, so that their operators should obey the following commutation relations:

$$\left[ \hat{r}\_j, \hat{P}\_j \right] = i\hbar \delta\_jj'. \quad (9.207)$$

In the coordinate representation of quantum mechanics, the canonical operators of the Cartesian components of the linear momentum are described by the corresponding components of the vector operator $-i\hbar \mathbf{\nabla}$. As a result, ignoring the rest energy $mc^2$ (which gives an inconsequential phase factor $\exp\{-imc^2t/\hbar\}$ in the wave function), we can use Eq. (196) to rewrite the usual non-relativistic Schrödinger equation,

$$i\hbar \frac{\partial \psi}{\partial t} = \hat{H} \psi, \quad (9.208)$$

as follows:

$$i\hbar \frac{\partial \psi}{\partial t} = \left( \frac{\hat{p}^2}{2m} + U \right) \psi \equiv \left[ \frac{1}{2m} (-i\hbar \mathbf{\nabla} - q\mathbf{A})^2 + q\phi \right] \psi. \quad (9.209)$$
Thus, I believe I have finally delivered on my promise to justify the replacement (6.50), which had been used in Secs. 6.4 and 6.5 to discuss the electrodynamics of superconductors, including the Meissner-Ochsenfeld effect.\footnote{Eq. (209) is also the basis for discussion of numerous other magnetic field phenomena, including the AB and quantum Hall effects – see, e.g., QM Secs. 3.1-3.2.}

9.8. Analytical mechanics of the electromagnetic field

We have just seen that the analytical mechanics of a particle in an electromagnetic field may be used to get some important results. The same is true for the analytical mechanics of the field as such, and the field-particle system as a whole. For such a space-distributed system as the field, governed by local dynamics laws (Maxwell equations), we need to apply analytical mechanics to the local densities $l$ and $h$ of the Lagrangian and Hamiltonian functions, defined by relations

$$
\mathcal{L} = \int \mathcal{L} d^3r, \quad \mathcal{H} = \int \mathcal{H} d^3r.
$$

Let us start, as usual, from the Lagrange formalism. Some clues on the possible structure of the Lagrangian function density $\mathcal{L}$ may be obtained from that of the particle-field interaction in this formalism, discussed in the last section. As we have seen, for the case of a single particle, the interaction is described by the last two terms of Eq. (183):

$$
\mathcal{L}_{\text{int}} = -q\phi - q\mathbf{u} \cdot \mathbf{A}.
$$

It is virtually obvious that if the charge $q$ is continuously distributed over some volume, we may represent this $\mathcal{L}_{\text{int}}$ as a volume integral of the following Lagrangian function density:

$$
\mathcal{L}_{\text{int}} = -\rho \phi + \mathbf{j} \cdot \mathbf{A} \equiv -j_\alpha A^\alpha.
$$

Notice that this density (in contrast to $\mathcal{L}_{\text{int}}$ itself!) is Lorentz-invariant. (This is due to the contraction of the longitudinal coordinate, and hence volume, at the Lorentz transform.) Hence we may expect the density of the field's Lagrangian to be Lorentz-invariant as well. Moreover, in the view of the simple, local structure of the Maxwell equations (containing only the first spatial and temporal derivatives of the fields), $\mathcal{L}_{\text{field}}$ should be a simple function of the potential’s 4-vector and its 4-derivative:

$$
\mathcal{L}_{\text{field}} = \mathcal{L}_{\text{field}}(A^\alpha, \partial_\alpha A^\beta).
$$

Also, the density should be selected in such a way that the 4-vector analog of the Lagrangian equation of motion,

$$
\partial_\alpha \frac{\partial \mathcal{L}_{\text{field}}}{\partial (\partial_\alpha A^\beta)} - \partial_\beta \frac{\partial \mathcal{L}_{\text{field}}}{\partial A^\beta} = 0,
$$

gave us the correct inhomogeneous Maxwell equations (127).\footnote{Eq. (209) is also the basis for discussion of numerous other magnetic field phenomena, including the AB and quantum Hall effects – see, e.g., QM Secs. 3.1-3.2.} It is clear that the field part $\mathcal{L}_{\text{field}}$ of the total Lagrangian density $\mathcal{L}$ should be a scalar, and a quadratic form of the field strength, i.e. of $F^{\alpha\beta}$, so that the natural choice is
\[ \mathcal{L}_{\text{field}} = \text{const} \times F_{\alpha\beta} F^{\alpha\beta}. \]  

(9.215)

with the usual implied summation over both indices. Indeed, adding to this expression the interaction Lagrangian (212),

\[ \mathcal{L} = \mathcal{L}_{\text{field}} + \mathcal{L}_{\text{int}} = \text{const} \times F_{\alpha\beta} F^{\alpha\beta} - j_{\alpha} A^{\alpha}, \]  

(9.216)

and performing the differentiation (214), we see that the relations (214)-(215) indeed yield Eqs. (127), provided that the constant factor equals \((-1/4\mu_0)\).\(^72\) So, the field’s Lagrangian density is

\[ \mathcal{L}_{\text{field}} = -\frac{1}{4\mu_0} F_{\alpha\beta} F^{\alpha\beta} = \frac{1}{2\mu_0} \left( \frac{E^2}{c^2} - B^2 \right) \equiv \frac{\varepsilon_0}{2} E^2 - \frac{B^2}{2\mu_0} = u_e - u_m, \]  

(9.217)

where \(u_e\) is the electric field energy density (1.65), and \(u_m\) is the magnetic field energy density (5.57). Let me hope the reader agrees that Eq. (217) is a wonderful result, because the Lagrangian function has the structure absolutely similar to the well-known expression \(\mathcal{L} = T - U\) of the classical mechanics. So, for the field alone, the “potential” and “kinetic” energies are separable again.\(^73\)

Now let us explore whether we can calculate the 4-form of the field’s Hamiltonian function \(\mathcal{H}\). In the generic analytical mechanics,

\[ \mathcal{H} = \sum_j \vec{\partial} \mathcal{L} \hat{q}_j - \mathcal{L}. \]  

(9.218)

However, just as for the Lagrangian function, for a field we should find the spatial density \(\mathcal{h}\) of the Hamiltonian, defined by the second of Eqs. (210), for which a natural 4-form of Eq. (218) is

\[ \mathcal{h}^{\alpha\beta} = \frac{\partial \mathcal{L}}{\partial (\partial_\alpha A_\beta)} \partial_\gamma A^{\gamma} - g^{\alpha\beta} \mathcal{L}. \]  

(9.219)

Calculated for the field alone, i.e. using Eq. (217) for \(\mathcal{L}_{\text{field}}\), this definition yields

\[ \mathcal{h}^{\alpha\beta}_{\text{field}} = \Theta^{\alpha\beta} - \tau_D^{\alpha\beta}, \]  

(9.220)

where the tensor

\[ \Theta^{\alpha\beta} \equiv \frac{1}{\mu_0} \left( g^{\alpha\gamma} F_{\beta\gamma} F^{\beta\gamma} + \frac{1}{4} g^{\alpha\beta} F_{\gamma\delta} F^{\gamma\delta} \right), \]  

(9.221)

is gauge-invariant, while the remaining term,

\[^{71}\) Here the implicit summation over the index \(\alpha\) plays the role similar to the convective derivative (188) in replacing the full derivative over time, in a way that reflects the symmetry of time and space in special relativity. I do not want to spend more time justifying Eq. (214), because of the reasons that will be clear imminently.

\[^{72}\) In the Gaussian units, this coefficient is \((-1/16\pi)\).

\[^{73}\) Since the Lagrange equations of motion are homogeneous, the simultaneous change of the signs of \(T\) and \(U\) does not change them. Thus, it is not important which of the two energy densities, \(u_e\) or \(u_m\), we count as the potential, and which as the kinetic energy. (Actually, such duality of the two field energy components is typical for all analytical mechanics – see, e.g., the discussion in CM Sec. 2.2.)}
\[ \tau_{D}^{\alpha\beta} \equiv \frac{1}{\mu_0} g^{\alpha\gamma} F_{\gamma\delta} \delta^\delta A^\beta, \quad (9.222) \]
is not, so that it cannot correspond to any measurable variables. Fortunately, it is straightforward to verify that the last tensor may be represented in the form

\[ \tau_{D}^{\alpha\beta} = \frac{1}{\mu_0} \partial_{\gamma} \left( F^{\gamma\alpha} A^\beta \right), \quad (9.223) \]

and as a result, obeys the following relations:

\[ \partial_{\alpha} \tau_{D}^{\alpha\beta} = 0, \quad \int \tau_{D}^{0\beta} d^3r = 0, \quad (9.224) \]

so it does not interfere with the conservation properties of the gauge-invariant, symmetric energy-momentum tensor (also called the symmetric stress tensor) \( \theta^{\alpha\beta} \), to be discussed below.

Let us use Eqs. (125) to express the components of the latter tensor via the electric and magnetic fields. For \( \alpha = \beta = 0 \), we get

\[ \theta^{00} = \frac{\varepsilon_0}{2} E^2 + \frac{B^2}{2\mu_0} = u_e + u_m \equiv u, \quad (9.225) \]
i.e. the expression for the total energy density \( u \) – see Eq. (6.113). The other 3 components of the same row/column turn out to be just the Cartesian components of the Poynting vector (6.114), divided by \( c \):

\[ \theta^{j0} = \frac{1}{\mu_0} \left( \frac{E}{c} \times B \right)_j = \left( \frac{E}{c} \times H \right)_j \equiv S_j \frac{c}{c}, \quad \text{for } j = 1, 2, 3. \quad (9.226) \]

The remaining 9 components \( \theta^{ij} \) of the tensor, with \( j, j' = 1, 2, 3 \), are usually represented as

\[ \theta^{ij} = -\tau^{(M)}_{ij}, \quad (9.227) \]

where \( \tau^{(M)} \) is the so-called Maxwell stress tensor:

\[ \tau^{(M)}_{ij} = \varepsilon_0 \left( E_i E_j - \frac{\delta_{ij}}{2} E^2 \right) + \frac{1}{\mu_0} \left( B_i B_j - \frac{\delta_{ij}}{2} B^2 \right), \quad (9.228) \]

so that the whole symmetric energy-momentum tensor (221) may be conveniently represented in the following symbolic way:

\[ \theta^{\alpha\beta} = \begin{pmatrix} u & \leftrightarrow & S/c \rightarrow \\ S/c & \downarrow & -\tau^{(M)} \\ \end{pmatrix}. \quad (9.229) \]

The physical meaning of this tensor may be revealed in the following way. Considering Eq. (221) just as the definition of tensor \( \theta^{\alpha\beta} \), \(^{74}\) and using the 4-vector form of Maxwell equations given by

\(^{74}\) In this way, we are using Eq. (219) just as a useful guess, which has led us to the definition of \( \theta^{\alpha\beta} \), and may leave its strict justification for more deep field theory courses.

---

74 In this way, we are using Eq. (219) just as a useful guess, which has led us to the definition of \( \theta^{\alpha\beta} \), and may leave its strict justification for more deep field theory courses.
Eqs. (127) and (129), it is straightforward to verify an extremely simple result for the 4-derivative of the symmetric tensor:

$$\frac{\partial}{\partial \alpha} \theta^{\alpha \beta} = -F^{\alpha \gamma} j_{\gamma}. \quad (9.230)$$

This expression is valid in the presence of electromagnetic field sources, e.g., for any system of charged particles and the fields they have created. Of these 4 equations (for 4 values of the index $\beta$), the temporal one (with $\beta = 0$) may be simply expressed via the energy density (225) and the Poynting vector (226):

$$\frac{\partial u}{\partial t} + \nabla \cdot S = -\mathbf{j} \cdot \mathbf{E}, \quad (9.231)$$

while 3 spatial equations (with $\beta = j = 1, 2, 3$) may be represented in the form

$$\frac{\partial}{\partial t} \frac{S_j}{c^2} - \sum_{\gamma=1}^{3} \frac{\partial}{\partial r_{\gamma}} \tau^{(M)}_{\gamma j} = -\left(\rho \mathbf{E} + \mathbf{j} \times \mathbf{B}\right). \quad (9.232)$$

Integrated over a volume $V$ limited by surface $S$, with the account of the divergence theorem, Eq. (231) returns us to the Poynting theorem (6.111):

$$\int \left(\frac{\partial u}{\partial t} + \mathbf{j} \cdot \mathbf{E}\right) d^3r + \int_S n d^2r = 0, \quad (9.233)$$

while Eq. (232) yields:

$$\int \left[\frac{\partial}{\partial t} \frac{S_j}{c^2} + \mathbf{f}\right] d^3r = \sum_{\gamma=1}^{3} \int_S \tau^{(M)}_{\gamma j} dA_j, \quad \text{with } \mathbf{f} = \rho \mathbf{E} + \mathbf{j} \times \mathbf{B}, \quad (9.234)$$

where $dA_j = n_j dA = n_j d^2r$ is the $j^{th}$ component of the elementary area vector $dA = n dA = n d^2r$ that is normal to volume’s surface, and directed out of the volume – see Fig. 17.76

Since, according to Eq. (5.10), the vector $\mathbf{f}$ is nothing other than the density of volume-distributed Lorentz forces exerted by the field on the charged particles, we can use the 2$^{nd}$ Newton law, in its relativistic form (144), to rewrite Eq. (234), for a stationary volume $V$, as

---

75 Just like the Poynting theorem (233), Eq. (234) may be obtained directly from the Maxwell equations, without resorting to the 4-vector formalism – see, e.g., Sec. 8.2.2 in D. Griffiths, *Introduction to Electrodynamics*, 3$^{rd}$ ed., Prentice-Hall, 1999. However, the derivation discussed above is preferable, because it shows the wonderful unity between the laws of conservation of energy and momentum.

76 The same notions are used in the mechanical stress theory – see, e.g., CM Sec. 7.2.
\[
\frac{d}{dt} \left[ \frac{1}{c^2} \int_V d^3 r + \mathbf{p}_{\text{part}} \right] = \mathbf{F},
\]  
\tag{9.235}

where \( \mathbf{p}_{\text{part}} \) is the total mechanical (relativistic) momentum of all particles in the volume \( V \), and the vector \( \mathbf{F} \) is defined by its Cartesian components:

\[
F_j = \sum_{j'=1}^3 \int_S \varepsilon_{ji}^{(M)} dA_{j'}.
\tag{9.236}

Relations (235)-(236) are our main new results. The first of them shows that the vector

\[
g \equiv \frac{S}{c^2},
\tag{9.237}
\]

already discussed in Sec. 6.8 without derivation, may be indeed interpreted as the density of momentum of the electromagnetic field (per unit volume). This classical relation is consistent with the quantum-mechanical picture of photons ultra-relativistic particles, with the momentum’s magnitude \( \frac{E}{c} \), because then the total flux of the momentum carried by photons through a unit normal area per unit time may be represented either as \( S_\sigma/c \) or as \( g_n c \). It also allows us to revisit the Poynting vector paradox that was discussed in Sec. 6.8 – see Fig. 611 and its discussion. As has been emphasized at this discussion, the vector \( \mathbf{S} = \mathbf{E} \times \mathbf{H} \) in this case does not correspond to any measurable energy flow. However, the corresponding momentum of the field, equal to the integral of the density (237) over a volume of interest, is not only real, but may be measured by the recoil impulse\(^77\) it gives to the field sources – say, to a magnetic coil inducing the field \( \mathbf{H} \), or to the capacitor plates creating the field \( \mathbf{E} \).

Now let us turn to our second result, Eq. (236). It tells us that the 3×3-element Maxwell stress tensor complies with the general definition of the stress tensor\(^78\) characterizing the force \( \mathbf{F} \) exerted on the boundary of a volume, in this case occupied by the electromagnetic field (Fig. 17). Let us use this important result to analyze two simple examples of static fields.

(i) Electrostatic field’s effect on a perfect conductor. Since Eq. (235) has been derived for a free space region, we have to select volume \( V \) outside the conductor, but we may align one of its faces with the conductor’s surface (Fig. 18).

---

\(^77\) This impulse is sometimes called the *hidden momentum*; this term makes sense if the field sources have finite masses, so that their velocity change at the field variation is measurable.

\(^78\) See, e.g., CM Sec. 7.2.
From Chapter 2, we know that the electrostatic field has to be perpendicular to the conductor’s surface. Selecting the $z$-axis in this direction, we have $E_x = E_y = 0$, $E_z = \pm E$, so that only diagonal components of the tensor (228) are not equal to zero:

$$
\tau^{(M)}_{xx} = \tau^{(M)}_{yy} = -\frac{\varepsilon_0}{2} E^2, \quad \tau^{(M)}_{zz} = \frac{\varepsilon_0}{2} E^2,
$$

(9.238)

Since the elementary surface area vector has just one non-vanishing component, $dA_z$, according to Eq. (236), only the last component (that is positive regardless of the sign of $E$) gives a contribution to the surface force $F$. We see that the force exerted by the conductor (and eventually by external forces that hold the conductor in its equilibrium position) on the field is normal to the conductor and directed out of the field volume: $dF_z \geq 0$. Hence, by the 3rd Newton law, the force exerted by the field on the conductor’s surface is directed toward the field-filled space:

$$
dF_{\text{surface}} = -dF_z = -\frac{\varepsilon_0}{2} E^2 dA.
$$

(9.239)

This important result could be obtained by simpler means as well. (Actually, this was the task of one of the problems given in Chapter 2.) For example, one could argue, quite convincingly, that the local relation between the force and the field should not depend on the global configuration creating the field, and thus consider the simplest configuration, a planar capacitor (see, e.g. Fig. 2.3) with surfaces of both plates charged by equal and opposite charges of density $\sigma = \pm \varepsilon_0 E$. According to the Coulomb law, the charges should attract each other, pulling each plate toward the field region, so that Maxwell-tensor result gives the correct direction of the force. The force’s magnitude (239) can be verified either by the direct integration of the Coulomb law, or by the following simple reasoning. In the plane capacitor, the field $E_z = \sigma \varepsilon_0$ is equally contributed by two surface charges; hence the field created by the negative charge of the counterpart plate (not shown in Fig. 18) is $E_z = -\sigma \varepsilon_0$, and the force it exerts of the elementary surface charge $dQ = \sigma dA$ of the positively charged plate is $dF_{\text{surface}} = EdQ = -\sigma^2 dA/2 \varepsilon_0 = -\varepsilon_0 E^2 dA/2$, in accordance with Eq. (239).\(^{79}\)

Quantitatively, even for such high electric field as $E = 3$ MV/m (close to the electric breakdown in air), the “negative pressure” ($dF/dA$) given by Eq. (239) is of the order of 500 Pa (N/m\(^2\)), i.e. below one-thousandth of the ambient atmospheric pressure (1 bar $\approx 10^5$ Pa). Still, this negative pressure may be substantial (above 1 bar) in some cases, for example in good dielectrics (such as high-quality SiO\(_2\), grown at high temperature, which is broadly used in integrated circuits), which can withstand electric fields up to $\sim 10^9$ V/m.

(ii) Static magnetic field’s effect on its source\(^{80}\) – say a solenoid’s wall or a superconductor’s surface (Fig. 19). With the choice of coordinates shown in that figure, we have $B_x = \pm B, B_y = B_z = 0$, so that the Maxwell stress tensor (228) is diagonal again:

---

\(^{79}\) By the way, repeating these arguments for a plane capacitor filled with a linear dielectric, we may readily see that Eq. (239) may be generalized for this case by replacing $\varepsilon_0$ for $\varepsilon$. A similar replacement ($\mu_0 \to \mu$) is valid for Eq. (241) in a linear magnetic medium.

\(^{80}\) The causal relation is not important here. Especially in the case of a superconductor, the magnetic field may be induced by another source, with the surface supercurrent $j$ just shielding the superconductor’s bulk from its penetration – see Sec. 6.
\[
\tau^{(M)}_{xx} = \frac{1}{2\mu_0} B^2, \quad \tau^{(M)}_{yy} = \tau^{(M)}_{zz} = -\frac{1}{2\mu_0} B^2. \tag{9.240}
\]

However, since for this geometry, only \(dA_z\) differs from 0 in Eq. (236), the sign of the resulting force is opposite to that in electrostatics: \(dF_z \leq 0\), and the force exerted by the magnetic field upon the conductor’s surface,

\[
dF_{\text{surface}} = -dF_z = \frac{1}{2\mu_0} B^2 dA, \tag{9.241}
\]

corresponds to positive pressure. For good laboratory magnets (\(B \sim 10\ T\)), this pressure is of the order of \(4 \times 10^7 \text{ Pa} \approx 400\) bars, i.e. is very substantial, so the magnets require solid mechanical design.

The direction of the force (241) could be also readily predicted using elementary magnetostatics arguments. Indeed, we can imagine the magnetic field volume limited by another, parallel wall with the opposite direction of surface current. According to the starting point of magnetostatics, Eq. (5.1), such surface currents of opposite directions have to repulse each other – doing that via the magnetic field.

Another explanation of the fundamental sign difference between the electric and magnetic field pressures may be provided using the electric circuit language. As we know from Chapter 2, the potential energy of the electric field stored in a capacitor may be represented in two equivalent forms,

\[
U_e = \frac{CV^2}{2} = \frac{Q^2}{2C}. \tag{9.242}
\]

Similarly, the magnetic field energy of an inductive coil is

\[
U_m = \frac{LI^2}{2} = \frac{\Phi^2}{2L}. \tag{9.243}
\]

If we do not want to consider the work of external sources at a virtual change of the system dimensions, we should use the latter forms of these relations, i.e. consider a galvanically detached capacitor (\(Q = \text{const}\)) and an externally-shorted inductance (\(\Phi = \text{const}\)).\(^81\) Now if we let the electric field forces (239) to drag capacitor’s plates in the direction they “want”, i.e. toward each other, this would lead to a reduction of the capacitor thickness, and hence to an increase of its capacitance \(C\), and hence to a decrease of \(U_e\). Similarly, for a solenoid, allowing the positive pressure (241) to move its walls from each other would lead to an increase of the solenoid’s volume, and hence of its inductance \(L\), so that the

\(^81\) Of course, this condition may hold “forever” only for solenoids with superconducting wiring, but even in normal-metal solenoids with practicable inductances, the flux relaxation constants \(L/R\) may be rather large (practically, up to a few minutes), quite sufficient to carry out the force measurement.
potential energy $U_m$ would be also reduced – as it should be. It is remarkable (actually, beautiful) how do the local field formulas (239) and (241) “know” about these global circumstances.

Finally, let us see whether the major results (237) and (241), obtained in this section, match each other. For that, let us return to the normal incidence of a plane, monochromatic wave from the free space upon the plane surface of a perfect conductor (see, e.g., Fig. 7.8 and its discussion), and use those results to calculate the time average of the pressure $dF_{\text{surface}}/dA$ imposed by the wave on the surface. At elastic reflection from conductor’s surface, the electromagnetic field’s momentum retains its amplitude but changes its sign, so that the average momentum transferred to a unit area of the surface in a unit time (i.e. average pressure) is

$$\frac{dF_{\text{surface}}}{dA} = 2cE_{\text{incident}} = 2c \frac{S_{\text{incident}}}{c^2} = 2c \frac{EH}{c^2} = \frac{E_\omega H_\omega^*}{2},$$

(9.244)

where $E_\omega$ and $H_\omega$ are complex amplitudes of the incident wave. Using the relation (7.7) between these amplitudes (for $\varepsilon = \varepsilon_0$ and $\mu = \mu_0$ giving $E_\omega = cB_\omega$), we get

$$\frac{dF_{\text{surface}}}{dA} = \frac{1}{c} \frac{cB_\omega}{\mu_0} \frac{B_\omega^*}{\mu_0} \equiv \frac{|B_\omega|^2}{\mu_0}. \quad (9.245)$$

On the other hand, as was discussed in Sec. 7.3, at the surface of a perfect mirror the electric field vanishes while the magnetic field doubles, so that we can use Eq. (241) with $B \rightarrow B(t) = 2\text{Re}[B_\omega e^{-i\omega t}]$. Averaging the pressure given by Eq. (241) over time, we get

$$\frac{dF_{\text{surface}}}{dA} = \frac{1}{2\mu_0} \left(2\text{Re}[B_\omega e^{-i\omega t}]\right)^2 = \frac{|B_\omega|^2}{\mu_0}, \quad (9.246)$$

i.e. the same result as Eq. (245).

For the physics intuition development, it is useful to estimate the electromagnetic radiation pressure’s magnitude. Even for a relatively high wave intensity $S_\omega$ of 1 kW/m$^2$ (close to that of the direct sunlight at the Earth’s surface), the pressure $2cS_\omega = 2S_\omega/c$ is somewhat below $10^{-5}$ Pa $\sim 10^{-10}$ bar. Still, this extremely small effect was experimentally observed (by P. Lebedev) as early as in 1899, giving one more confirmation of Maxwell’s theory. Currently, there are ongoing attempts to use the pressure of the Sun’s light for propelling small spacecraft, e.g., the \textit{LightSail 2} satellite with a 32-m$^2$ sail.

### 9.9. Exercise problems

9.1. Use the non-relativistic picture of the Doppler effect, in which the light propagates, with velocity $c$, in a Sun-bound aether, to derive Eq. (4).

9.2. Show that two successive Lorentz space/time transforms in the same direction, with velocities $u'$ and $v$, are equivalent to a single transform with the velocity $u$ given by Eq. (25).

9.3. $N + 1$ reference frames, numbered by index $n$ (taking values 0, 1, …, $N$), move in the same direction as a particle. Express the particle’s velocity in the frame number 0 via its velocity $u_N$ in the frame number $N$, and the set of velocities $v_n$ of the frame number $n$ relative to the frame number ($n - 1$).
9.4. A spaceship, moving with a constant velocity $v$ directly from the Earth, sends back brief flashes of light with a period $\Delta t_s$ – as measured by the spaceship's clock. Calculate the period with which Earth's observers receive the signals – as measured by the Earth's clock.

9.5. From the point of view of observers in a “moving” reference frame $0'$, a straight thin rod, parallel to the $x'$-axis, is moving, without rotation, with a constant velocity $u'$ directed along the $y'$-axis. The reference frame $0'$ is itself moving relative to another ("lab") reference frame $0$ with a constant velocity $v$ along the $x$-axis, also without rotation – see the figure on the right. Calculate:

(i) the direction of the rod's velocity, and
(ii) the orientation of the rod on the [$x$, $y$] plane,
both as observed from the lab reference frame. Is the velocity, in this frame, perpendicular to the rod?

9.6. Starting from the rest at $t = 0$, a spaceship moves directly from the Earth, with a constant acceleration, as measured in its instantaneous rest frame. Find its displacement $x(t)$ from the Earth, as measured from Earth’s reference frame, and interpret the result.

Hint: The instantaneous rest frame of a moving particle is the inertial reference frame that, at the considered moment of time, has the same velocity as the particle.

9.7. Calculate the first relativistic correction to the frequency of a harmonic oscillator as a function of its amplitude.

9.8. An atom, with an initial rest mass $m$, has been excited to an internal state with an additional energy $\Delta E$, still being at rest. Next, it returns into its initial state, emitting a photon. Calculate the photon’s frequency, taking into account the relativistic recoil of the atom.

Hint: In this problem, and in Problems 11-13, treat photons as ultra-relativistic point particles with zero rest mass, energy $\varepsilon = h\omega$, and momentum $p = \hbar k$.

9.9. A particle of mass $m$, initially at rest, decays into two particles, with rest masses $m_1$ and $m_2$. Calculate the total energy of the first decay product, in the reference frame moving with that particle.

9.10. A relativistic particle with a rest mass $m$, moving with velocity $u$, decays into two particles with zero rest mass.

(i) Calculate the smallest possible angle between the decay product velocities (in the lab frame, in which the velocity $u$ is measured).
(ii) What is the largest possible energy of one product particle?
9.11. A relativistic particle, propagating with velocity \( \mathbf{u} \), in the absence of external fields, decays into two photons.\(^{82}\) Calculate the angular dependence of the probability of photon detection, as measured in the lab frame.

\[
\text{\lambda}'
\]

9.12. A photon with wavelength \( \lambda \) is scattered by an electron, initially at rest. Calculate the wavelength \( \lambda' \) of the scattered photon as a function of the scattering angle \( \alpha \) – see the figure on the right.\(^{83}\)

9.13. Calculate the threshold energy of a \( \gamma \)-photon for the reaction

\[
\gamma + p \rightarrow p + \pi^0,
\]

if the proton was initially at rest.

*Hint:* For protons \( m_p c^2 \approx 938 \text{ MeV} \), while for neutral pions \( m_{\pi} c^2 \approx 135 \text{ MeV} \).

9.14. A relativistic particle with energy \( E \) and rest mass \( m \) collides with a similar particle, initially at rest in the laboratory reference frame. Calculate:

(i) the final velocity of the center of mass of the system, in the lab frame,
(ii) the total energy of the system, in the center-of-mass frame, and
(iii) the final velocities of both particles (in the lab frame), if they move along the same direction.

9.15. A “primed” reference frame moves, with the reduced velocity \( \beta \equiv \mathbf{v}/c = n_x \beta \), relative to the “lab” frame. Use Eq. (109) to express the components \( T'_{00} \) and \( T'_{0j} \) (with \( j = 1, 2, 3 \)) of an arbitrary contravariant 4-tensor \( T^{\gamma\delta} \) via its components in the lab frame.

9.16. Static fields \( \mathbf{E} \) and \( \mathbf{B} \) are uniform but arbitrary (both in magnitude and in direction). What should be the velocity of an inertial reference frame to have the vectors \( \mathbf{E}' \) and \( \mathbf{B}' \), observed from that frame, parallel? Is this solution unique?

9.17. Two charged particles, moving with equal constant velocities \( \mathbf{u} \), are offset by distance \( \mathbf{R} = \{a, b\} \) (see the figure on the right), as measured in the lab frame. Calculate the forces between the particles – also in the lab frame.

9.18. Each of two thin, long, parallel particle beams of the same velocity \( \mathbf{u} \), separated by distance \( d \), carries electric charge with a constant density \( \lambda \) per unit length, as measured in the reference frame moving with the particles.

\(^{82}\) Such a decay may happen, for example, with a neutral pion.

\(^{83}\) This the famous Compton scattering effect, whose discovery in 1923 was one of the major motivations for the development of quantum mechanics – see, e.g., QM Sec. 1.1.
(i) Calculate the distribution of the electric and magnetic fields in the system (outside the beams), as measured in the lab reference frame.

(ii) Calculate the interaction force between the beams (per particle) and the resulting acceleration, both in the lab reference frame and in the frame moving with the electrons. Compare the results and give a brief discussion of the comparison.

9.19. Spell out the Lorentz transform of the scalar-potential and vector-potential components, and use the result to calculate the potentials of a point charge $q$, moving with a constant velocity $u$, as measured in the lab reference frame.

9.20. Calculate the scalar and vector potentials created by a time-independent electric dipole $p$, as measured in a reference frame that moves relative to the dipole with a constant velocity $v$, with the shortest distance (“impact parameter”) equal to $b$.

9.21. Solve the previous problem, in the limit $v \ll c$, for a time-independent magnetic dipole $m$.

9.22. Assuming that the magnetic monopole does exist and has magnetic charge $g$, calculate the change $\Delta \Phi$ of magnetic flux in a superconductor ring due to the passage of single monopole through it. Evaluate $\Delta \Phi$ for the monopole charge conjectured by P. Dirac, $g = n g_0 \equiv n \left(\frac{2 \pi \hbar}{e}\right)$, where $n$ is an integer; compare the result with the magnetic flux quantum $\Phi_0$ (6.62) with $|q| = e$, and discuss their relation.

*Hint:* For simplicity, you may consider monopole’s passage along the symmetry axis of a thin, round superconducting ring, in the otherwise free space.

9.23. Calculate the trajectory of a relativistic particle in a uniform electrostatic field $E$, for an arbitrary direction of its initial velocity $u(0)$, using two different approaches – at least one of them different from the approach used in Sec. 6 for the case $u(0) \perp E$.

9.24. A charged relativistic particle with velocity $u$ performs planar cyclotron rotation in a uniform external magnetic field $B$. How much would the velocity and the orbit’s radius change at a slow change of the field to a new magnitude $B'$?

9.25. Analyze the motion of a relativistic particle in uniform, mutually perpendicular fields $E$ and $B$, for the particular case when $E$ is exactly equal to $cB$.

9.27. Neglecting relativistic kinetic effects, calculate the smallest voltage $V$ that has to be applied between the anode and cathode of a magnetron (see Fig. 13 and its discussion) to enable electrons to reach the anode, at negligible electron-electron interactions (including the space-charge effects), and collisions with the residual gas molecules. You may:

(i) model the cathode and anode as two coaxial round cylinders, of radii $R_1$ and $R_2$, respectively;
(ii) assume that the magnetic field $B$ is uniform and directed along their common axis; and
(iii) neglect the initial velocity of the electrons emitted by the cathode.
(After the solution, estimate the validity of the last assumption, and of the non-relativistic
approximation, for reasonable values of parameters.)

9.28. A charged relativistic particle has been injected into a uniform electric field whose
magnitude oscillates in time with frequency \( \omega \). Calculate the time dependence of the particle’s velocity,
as observed from the lab reference frame.

9.29. Analyze the motion of a non-relativistic particle in a region where the electric and
magnetic fields are both uniform and constant in time, but not necessarily parallel or perpendicular to
each other.

9.30. A static distribution of electric charge in otherwise free space has created a time-
dependent distribution \( \mathbf{E}(\mathbf{r}) \) of the electric field. Use two different approaches to express the field
energy density \( u' \) and the Poynting vector \( \mathbf{S}' \), as observed from a reference frame moving with constant
velocity \( \mathbf{v} \), via the components of the vector \( \mathbf{E} \). In particular, is \( \mathbf{S}' \) equal to \((-\mathbf{v}u')\)?

9.31. A plane wave, of frequency \( \omega \) and intensity \( S \), is normally incident on a perfect mirror,
moving with velocity \( \mathbf{v} \) in the same direction as the wave.

(i) Calculate the reflected wave’s frequency, and
(ii) use the Lorentz transform of the fields to calculate the reflected wave’s intensity
- both as observed from the lab reference frame.

9.32. Carry out the second task of the previous problem by using general relations between
wave’s energy, power, and momentum.

Hint: As a byproduct, this approach should also give you the pressure exerted by the wave on the
moving mirror.

9.33. Consider the simple model of plane capacitor charging by a
lumped current source, shown in the figure on the right, and prove that the
momentum given by the constant, uniform external magnetic field \( \mathbf{B} \) to the
current-carrying conductor is equal and opposite to the momentum of the
electromagnetic field that the current \( I(t) \) builds up in the capacitor. (You may
assume that the capacitor is plane and very broad, and neglect the fringe field
effects.)

9.34. Consider an electromagnetic plane wave packet propagating in free space, with the electric
field represented as the Fourier integral

\[
\mathbf{E}(\mathbf{r}, t) = \text{Re} \int_{-\infty}^{+\infty} E_k e^{i\psi_k} dk, \quad \text{with} \quad \psi_k \equiv kz - \omega_k t, \quad \text{and} \quad \omega_k \equiv c|k|.
\]

Express the full linear momentum (per unit area of wave’s front) of the packet via the complex
amplitudes \( E_k \) of its Fourier components. Does the momentum depend on time? (In contrast with
Problem 7.7, in this case the wave packet is not necessarily narrow.)
9.35. Calculate the force exerted on well-conducting walls of a waveguide with a rectangular \((a \times b)\) cross-section, by a wave propagating along it in the fundamental \((H_{10})\) mode. Give an interpretation of the result.
Chapter 10. Radiation by Relativistic Charges

The discussion of the special relativity in the previous chapter enables us to revisit the analysis of the electromagnetic radiation by charged particles, now for arbitrary velocities. For a single point particle, we will be able to calculate the radiated wave fields in an explicit form, and analyze them for such important particular cases as the synchrotron radiation and “Bremsstrahlung” (brake radiation). After that, we will discuss the apparently unrelated effect of the so-called Coulomb losses of energy by a particle moving in condensed matter, because this discussion will naturally lead us to such important phenomena as the Cherenkov radiation and the transitional radiation. In the end of the chapter, I will briefly review the effects of back action of the emitted radiation on the emitting particle, whose analysis reveals some limitations of classical electrodynamics.

10.1. Liénard-Wiechert potentials

A convenient starting point for the discussion of radiation by relativistic charges is provided by Eqs. (8.17) for the retarded potentials. In the free space, these formulas, with the integration variable changed from \( r' \) to \( r'' \) for the clarity of what follows, are reduced to

\[
\phi(r, t) = \frac{1}{4\pi \varepsilon_0} \int \frac{\rho(r'', t - R/c) d^3r''}{R}, \quad
A(r, t) = \frac{\mu_0}{4\pi} \int \frac{j(r'', t - R/c) d^3r''}{R},
\]

with \( R \equiv r - r'' \). (10.1a)

As a reminder, Eqs. (1a) were derived from the Maxwell equations without any restrictions, and are very natural for situations with continuous distributions of the electric charge and/or current. However, for a single point charge, with

\[
\rho(r, t) = q \delta(r - r'), \quad j(r, t) = qu \delta(r - r'), \quad \text{with} \quad u = \dot{r}', \quad \text{(10.1b)}
\]

where \( r' \) is the instantaneous position of the charge, it is more convenient to recast Eqs. (1a) into an explicit form that would not require the integration in each particular case. Indeed, as Eqs. (1) show, the potentials at each observation point \( \{r, t\} \) are contributed by only one specific point \( \{r'(t_{ret}), t_{ret}\} \) of the particle’s 4D trajectory (called its world line), which satisfies the following condition:

\[
t_{ret} \equiv t - \frac{R_{ret}}{c}, \quad \text{(10.2)}
\]

where \( t_{ret} \) is called the retarded time, and \( R_{ret} \) is the length of the following distance vector

\[
R_{ret} = r(t) - r'(t_{ret}), \quad \text{(10.3)}
\]

- physically, the distance covered by the electromagnetic wave from its emission to observation.

The reduction of Eqs. (1) to such a simpler form, however, requires care. Indeed, their naïve integration over \( r'' \) would yield the following apparent, but wrong results:

\[
\phi(r, t) = \frac{1}{4\pi \varepsilon_0} \frac{q}{R_{ret}}, \quad \text{i.e.} \quad \frac{\phi(r, t)}{c} = \frac{\mu_0}{4\pi} \frac{qc}{R_{ret}}; \quad
A(r, t) = \frac{\mu_0}{4\pi} \frac{qu_{ret}}{R_{ret}}, \quad \text{(WRONG!)} \quad \text{(10.4)}
\]
where \( \mathbf{u}_{\text{ret}} \) is the particle’s velocity at the retarded point \( \mathbf{r}'(t_{\text{ret}}) \). Eqs. (4) is a good example of how the relativity theory (even the special one :-) cannot be taken too lightly. Indeed, the strings (9.84)-(9.85), formed from the apparent potentials (4), would not obey the Lorentz transform rule (9.91), because according to Eqs. (2)-(3), the distance \( R_{\text{ret}} \) also depends on the reference frame it is measured in.

In order to correct the error, we need, first of all, discuss the conditions (2)-(3). Combining them (eliminating \( R_{\text{ret}} \)), we get the following equation for \( t_{\text{ret}} \):

\[
 c(t - t_{\text{ret}}) = \left| \mathbf{r}(t) - \mathbf{r}'(t_{\text{ret}}) \right|. 
\]

(10.5)

Figure 1 depicts the graphical solution of this self-consistency equation as the only point of intersection of the light cone of the observation point (see Fig. 9.9 and its discussion) and the particle’s world line.

In Eq. (5), just as in Eqs. (1)-(3), all variables have to be measured in the same inertial (“lab”) reference frame, in which the observation point \( \mathbf{r} \) rests. Now let us write Eqs. (1) for a point charge in another inertial reference frame \( 0' \), whose velocity (as measured in the lab frame) coincides, at the moment \( t' = t_{\text{ret}} \), with the velocity \( \mathbf{u}_{\text{ret}} \) of the charge. In that frame, the charge rests, so that, as we know from the electro- and magnetostatics,

\[
 \phi' = \frac{q}{4\pi\varepsilon_0 R'}, \quad A' = 0. 
\]

(10.6a)

(Remember that this \( R' \) may not be equal to \( R \), because the latter distance is measured in the “lab” reference frame.) Let us use the identity \( 1/\varepsilon_0 \equiv \mu_0 c^2 \) to rewrite Eqs. (6a) in the form of components of a 4-vector similar in structure to Eq. (4):

\[
 \frac{\phi'}{c} = \frac{\mu_0}{4\pi} q \frac{c}{R'}, \quad A' = 0. 
\]

(10.6b)

Now it is easy to guess the correct answer for the whole 4-potential:

\[
 A^\alpha = \frac{\mu_0}{4\pi} q \frac{c \mathbf{u}_\alpha R^\beta}{u_\beta}, 
\]

(10.7)

\(^1\) As Fig. 1 shows, there is always another, “advanced” point \( \{ \mathbf{r}'(t_{\text{adv}}), t_{\text{adv}} \} \) of the particle’s world line, with \( t_{\text{adv}} > t \), which is also a solution of Eq. (5), but it does not fit Eqs. (1), because the observation of the field, induced at the advanced point, at the point \( \{ \mathbf{r}, t < t_{\text{adv}} \} \) would violate the causality principle.
where (just as a reminder), \( A^\alpha \equiv \{ \phi/c, A \}, \) \( u^\alpha \equiv \gamma(c, u) \), and \( R^\alpha \) is a 4-vector of the inter-event distance, formed similarly to that of a single event – cf. Eq. (9.48):

\[
R^\alpha \equiv \{ c(t-t'), R' \} \equiv \{ c(t-t'), r - r' \} .
\] (10.8)

Indeed, we needed the 4-vector \( A^\alpha \) that would:

(i) obey the Lorentz transform,
(ii) have its spatial components \( A_j \) scaling, at low velocity, as \( u_j \), and
(iii) be reduced to the correct result (6) in the reference frame moving with the charge.

Eq. (7) evidently satisfies all these requirements, because the scalar product in its denominator is just

\[
u_\beta R^\beta = \gamma \{ c, -u \} \cdot \{ c(t-t'), R \} \equiv \gamma [c^2 (t-t') - u \cdot R] \equiv \gamma c R(1 - \beta \cdot n),
\] (10.9)

where \( n \equiv R/R \) is a unit vector in the observer’s direction, \( \beta \equiv u/c \) is the normalized velocity of the particle, and \( \gamma \equiv 1/(1 - u^2/c^2)^{1/2} \). In the reference frame of the charge (in which \( \beta = 0 \) and \( \gamma = 1 \)), the expression (9) is reduced to \( cR \), so that Eq. (7) is correctly reduced to Eq. (6b). Now let us spell out the components of Eq. (7) in the lab frame (in which \( t' = t_{\text{ret}} \) and \( R = R_{\text{ret}} \)):

\[
\phi(r,t) = \frac{1}{4\pi \varepsilon_0} \frac{q}{(R - \beta \cdot R)_{\text{ret}}} = \frac{1}{4\pi \varepsilon_0} \frac{q}{R(1 - \beta \cdot n)_{\text{ret}}},
\] (10.10a)

\[
A(r,t) = \frac{\mu_0}{4\pi} q \left( \frac{u}{R - \beta \cdot R} \right)_{\text{ret}} = \frac{\mu_0}{4\pi} q c \left[ \frac{\beta}{R(1 - \beta \cdot n)} \right]_{\text{ret}} \equiv \phi(r,t) \frac{u_{\text{ret}}}{c^2}.
\] (10.10b)

These formulas are called the Liénard-Wiechert potentials.\(^2\) In the non-relativistic limit, they coincide with the naïve guess (4), but in the general case include an additional factor \( 1/(1 - \beta \cdot n)_{\text{ret}} \). Its physical origin may be illuminated by one more formal calculation – which we will need anyway. Let us differentiate the geometric relation (5), rewritten as

\[
R_{\text{ret}} = c(t-t_{\text{ret}}),
\] (10.11)

over \( t_{\text{ret}} \) and then, independently, over \( t \), assuming that \( r \) is fixed. For that, let us first differentiate, over \( t_{\text{ret}} \), both sides of the identity \( R_{\text{ret}}^2 = R_{\text{ret}} \cdot R_{\text{ret}} \):

\[
2R_{\text{ret}} \frac{\partial R_{\text{ret}}}{\partial t_{\text{ret}}} = 2R_{\text{ret}} \frac{\partial R_{\text{ret}}}{\partial t_{\text{ret}}}.
\] (10.12)

If \( r \) is fixed, then \( \partial R_{\text{ret}}/\partial t_{\text{ret}} \equiv \partial (r - r')/\partial t_{\text{ret}} = -\partial r'/\partial t_{\text{ret}} \equiv -u_{\text{ret}} \), and Eq. (12) yields

\[
\frac{\partial R_{\text{ret}}}{\partial t_{\text{ret}}} = \frac{R_{\text{ret}}}{R_{\text{ret}}} \cdot \frac{\partial R_{\text{ret}}}{\partial t_{\text{ret}}} = -(n \cdot u)_{\text{ret}}.
\] (10.13)

Now let us differentiate the same \( R_{\text{ret}} \) over \( t \). On one hand, Eq. (11) yields

\[
\frac{\partial R_{\text{ret}}}{\partial t} = c - \frac{\partial t_{\text{ret}}}{\partial t}.
\] (10.14)

\(^2\) They were derived in 1898 by Alfred-Marie Liénard and (independently) in 1900 by Emil Wiechert.
On the other hand, according to Eq. (5), at the partial differentiation over time, i.e. if \( \mathbf{r} \) is fixed, \( t_{\text{ret}} \) is a function of \( t \) alone, so that (using Eq. (13) at the second step), we may write

\[
\frac{\partial R_{\text{ret}}}{\partial t_{\text{ret}}} = \frac{\partial R_{\text{ret}}}{\partial t_{\text{ret}}} \frac{\partial t_{\text{ret}}}{\partial t} = -(\mathbf{n} \cdot \mathbf{u})_{\text{ret}} \frac{\partial t_{\text{ret}}}{\partial t}.
\]  

(10.15)

Now requiring Eqs. (14) and (15) to give the same result, we get:

\[
\frac{\partial t_{\text{ret}}}{\partial t} = \frac{c}{c - (\mathbf{n} \cdot \mathbf{u})_{\text{ret}}} = \left( \frac{1}{1 - \beta \cdot \mathbf{n}} \right)_{\text{ret}}.
\]  

(10.16)

This relation may be readily re-derived (and more clearly understood) for the simple particular case when the charge’s velocity is directed straight toward the observation point. In this case, its vector \( \mathbf{u} \) resides in the same space-time plane as the observation point’s world line \( \mathbf{r} = \text{const} – \text{say, the plane } [x, t] \), shown in Fig. 2.

Let us consider an elementary time interval \( dt_{\text{ret}} \equiv dt' \), during which the particle would travel the space interval \( dx_{\text{ret}} = u_{\text{ret}} dt_{\text{ret}} \). In Fig. 2, the corresponding segment of its world line is shown with a solid vector. The dotted vectors in this figure show the world lines of the radiation emitted by the particle in the beginning and in the end of this interval, and propagating with the speed of light \( c \). As it follows from the drawing, the time interval \( dt \) between the instants of the arrival of the radiation from these two points to any time-independent spatial point of observation is

\[
dt = dt_{\text{ret}} - \frac{dx_{\text{ret}}}{c} = dt_{\text{ret}} - \frac{u_{\text{ret}}}{c} dt_{\text{ret}}, \quad \text{so that} \quad \frac{dt_{\text{ret}}}{dt} = \frac{1}{1 - \frac{u_{\text{ret}}}{c}} \equiv \frac{1}{1 - \beta_{\text{ret}}}. \]

(10.17)

This expression coincides with Eq. (16), because in our particular case when the directions of the vectors \( \beta \equiv u/c \) and \( \mathbf{n} \equiv \mathbf{R}/R \) (both taken at time \( t_{\text{ret}} \)) coincide, and hence \( (\beta \cdot \mathbf{n})_{\text{ret}} = \beta_{\text{ret}} \). Now the general Eq. (16) may be interpreted by saying that the particle’s velocity in the transverse directions (normal to the vector \( \mathbf{n} \)) is not important for this kinematic effect – the fact almost evident from Fig. 1.

So, the additional factor in the Liénard-Wiechert potentials is just the derivative \( \partial t_{\text{ret}}/\partial t \). The reason for its appearance in Eqs. (10) is usually interpreted along the following lines. Let the charge \( q \)

---

3 This relation may be used for an alternative derivation of Eqs. (10) directly from Eqs (1) – the exercise highly recommended to the reader.

4 Note that this effect (linear in \( \beta \)) has nothing to do with the Lorentz time dilation (9.21), which is quadratic in \( \beta \). (Indeed, all our arguments above referred to the same, lab frame.) Rather, it is close in nature to the Doppler effect.
be spread along the direction of vector $\mathbf{R}_{\text{ret}}$ (in Fig. 2, along axis $x$) by an infinitesimal speed-independent interval $\delta x_{\text{ret}}$, so that the linear density $\lambda$ of its charge is proportional to $1/\delta x_{\text{ret}}$. Then the time rate of charge’s arrival at some spatial point is $\lambda u_{\text{ret}} = \lambda dx_{\text{ret}}/dt_{\text{ret}}$, i.e. scales as $1/dt_{\text{ret}}$. However, the rate of radiation’s arrival at the observation point scales as $1/dt$, so that due to the non-vanishing velocity $u_{\text{ret}}$ of the particle, this rate differs from the charge arrival rate by the factor of $dt_{\text{ret}}/dt$, given by Eq. (16). (If the particle moves toward the observation point, $(\beta \cdot \mathbf{n})_{\text{ret}} > 0$, as shown in Fig. 2, this factor is larger than 1.) This radiation compression effect leads to the field change (at $(\beta \cdot \mathbf{n})_{\text{ret}} > 0$, its enhancement) by the same factor (16) – as described by Eqs. (10).

So, the 4-vector formalism was very instrumental for the calculation of field potentials. It may be also used to calculate the fields $\mathbf{E}$ and $\mathbf{B}$ – by plugging Eq. (7) into Eq. (9.124) to calculate the field strength tensor. This calculation yields

$$F^{\alpha \beta} = \frac{\mu_0 q}{4\pi} \frac{1}{u_{\tau}R_{\tau}} \frac{du^\beta - R^\beta u^\alpha}{dt_{\text{ret}}}.$$  \hspace{1cm} (10.18)

Now using Eq. (9.125) to identify the elements of this tensor with the field components, we may bring the result to the following vector form:

$$\mathbf{E} = \frac{q}{4\pi\varepsilon_0} \left[ \frac{\mathbf{n} - \beta}{\gamma^2(1 - \beta \cdot \mathbf{n})^2 R^2} + \frac{\mathbf{n} \times (\mathbf{n} - \beta) \times \beta}{(1 - \beta \cdot \mathbf{n})^3 cR_{\text{ret}}} \right].$$  \hspace{1cm} (10.19)

$$\mathbf{B} = \frac{\mathbf{n}_{\text{ret}} \times \mathbf{E}}{c}, \quad \text{i.e.} \quad \mathbf{H} = \frac{\mathbf{n}_{\text{ret}} \times \mathbf{E}}{Z_0}.$$  \hspace{1cm} (10.20)

Thus the magnetic and electric fields of a relativistic particle are always proportional and perpendicular to each other, and related just as in a plane wave – cf. Eq. (7.6), with the difference that now the vector $\mathbf{n}_{\text{ret}}$ may be a function of time. Superficially, this result contradicts the electro- and magnetostatics, because for a particle at rest, $\mathbf{B}$ should vanish while $\mathbf{E}$ stays finite. However, note that according to the Coulomb law for a point charge, in this case $\mathbf{E} = E\mathbf{n}_{\text{ret}}$, so that $\mathbf{B} \propto \mathbf{n}_{\text{ret}} \times \mathbf{E} \propto \mathbf{n}_{\text{ret}} \times \mathbf{n}_{\text{ret}} = 0$. (Actually, in these relations, the subscript “ret” is unnecessary.)

As a sanity check, let us use Eq. (19) as an alternative way to find the electric field of a charge moving without acceleration, i.e. uniformly, along a straight line – see Fig. 9.11a reproduced, with minor changes, in Fig. 3. (This calculation will also illustrate the technical challenges of practical applications of the Liénard-Wiechert formulas for even simple cases.) In this case, the vector $\beta$ does not change in time, so that the second term in Eq. (19) vanishes, and all we need to do is to spell out the Cartesian components of the first term.

Let us select the coordinate axes and time origin in the way shown in Fig. 3, and make a clear distinction between the actual position, $\mathbf{r}'(t) = \{ut, 0, 0\}$ of the charged particle at the instant $t$ we are considering, and its position $\mathbf{r}'(t_{\text{ret}})$ at the retarded instant defined by Eq. (5), i.e. the moment when the

---

5 An alternative way of deriving these formulas (highly recommended to the reader as an exercise) is to plug Eqs. (10) into the general relations (9.121), and carry out the required temporal and spatial differentiations directly, using Eq. (16) and its spatial counterpart (which may be derived absolutely similarly):

$$\nabla t_{\text{ret}} = -\left[ \frac{\mathbf{n}}{c(1 - \beta \cdot \mathbf{n})} \right]_{\text{ret}}.$$
particle’s field has to be radiated to reach the observation point \( \mathbf{r} \) at the time \( t \), propagating with the speed of light. In these coordinates

\[
\mathbf{\beta} = \{\beta, 0, 0\}, \quad \mathbf{r} = \{0, b, 0\}, \quad \mathbf{r}'(t_{\text{ret}}) = \{ut_{\text{ret}}, 0, 0\}, \quad \mathbf{n}_{\text{ret}} = \{\cos \theta, \sin \theta, 0\},
\]

with \( \cos \theta = -ut_{\text{ret}}/R_{\text{ret}} \), so that \([n \cdot \beta]_{\text{ret}} = -ut_{\text{ret}}/R_{\text{ret}} - \beta\), and Eq. (19) yields, in particular:

\[
E_x = \frac{q}{4\pi\varepsilon_0} \frac{-ut_{\text{ret}}}{\gamma^2[(1 - \beta \cdot \mathbf{n})^3 R_{\text{ret}}^3]} \equiv \frac{q}{4\pi\varepsilon_0} \frac{-ut_{\text{ret}} - \beta R_{\text{ret}}}{\gamma^2[(1 - \beta \cdot \mathbf{n})^3 R_{\text{ret}}^3]}.
\]

But according to Eq. (5), the product \( \beta R_{\text{ret}} \) may be represented as \( \beta c(t - t_{\text{ret}}) \equiv ut(t - t_{\text{ret}}) \). Plugging this expression into Eq. (22), we may eliminate the explicit dependence of \( E_x \) on time \( t_{\text{ret}} \):

\[
E_x = \frac{q}{4\pi\varepsilon_0} \frac{-ut}{\gamma^2[(1 - \beta \cdot \mathbf{n})R_{\text{ret}}^3]}.
\]

The non-vanishing transverse component of the field also has a similar form:

\[
E_y = \frac{q}{4\pi\varepsilon_0} \frac{\sin \theta}{\gamma^2[(1 - \beta \cdot \mathbf{n})^3 R_{\text{ret}}^2]} = \frac{q}{4\pi\varepsilon_0} \frac{b}{\gamma^2[(1 - \beta \cdot \mathbf{n})R_{\text{ret}}^3]},
\]

while \( E_z = 0 \). From Fig. 3, \( \beta \cdot \mathbf{n}_{\text{ret}} = \beta \cos \theta = -\beta ut_{\text{ret}}/R_{\text{ret}} \), so that \((1 - \beta \cdot \mathbf{n})R_{\text{ret}} = R_{\text{ret}} + \beta ut_{\text{ret}}\), and we may again use Eq. (5) to get \((1 - \beta \cdot \mathbf{n})R_{\text{ret}} = c(t - t_{\text{ret}}) + \beta ut_{\text{ret}} = ct - ct_{\text{ret}}/\gamma^2\). What remains is to calculate \( t_{\text{ret}} \) from the self-consistency equation (5), whose square in our current case (Fig. 3) takes the form

\[
R_{\text{ret}}^2 = b^2 + (ut_{\text{ret}})^2 = c^2(t - t_{\text{ret}})^2.
\]

This is a simple quadratic equation for \( t_{\text{ret}} \), which (with the appropriate negative sign before the square root, to get \( t_{\text{ret}} < t \)) yields:

\[
t_{\text{ret}} = \gamma^2 t - \left[\gamma^2 t^2 - \gamma^2(t^2 - b^2/c^2)\right]^{1/2} = \gamma^2 t - \frac{\gamma}{c} \left(u^2 \gamma^2 t^2 + b^2\right)^{1/2},
\]

so that the only retarded-function combination that participates in Eqs. (23)-(24) is

\[
[(1 - \beta \cdot \mathbf{n})R]_{\text{ret}} = \frac{c}{\gamma^2} \left(u^2 \gamma^2 t^2 + b^2\right)^{1/2},
\]

and, finally, the electric field components are

\[
E_x = -\frac{q}{4\pi\varepsilon_0} \frac{\gamma ut}{\left(b^2 + \gamma^2 u^2 t^2\right)^{3/2}}, \quad E_y = \frac{q}{4\pi\varepsilon_0} \frac{\gamma b}{\left(b^2 + \gamma^2 u^2 t^2\right)^{3/2}}, \quad E_z = 0.
\]
These are exactly Eqs. (9.139), which had been obtained in Sec. 9.5 by much simpler means, without the necessity to solve the self-consistency equation (5). However, that alternative approach was essentially based on the inertial motion of the particle, and cannot be used in problems in which particle moves with acceleration. In such problems, the second term in Eq. (19), dropping with distance more slowly, as $1/R$, and hence describing the wave radiation, is essential and most important.

10.2. Radiation power

Let us calculate the angular distribution of the particle’s radiation. For that, we need to return to Eqs. (19)-(20) to find the Poynting vector $S = E \times H$, and in particular its component $S_n = S \cdot n$, at large distances $R$ from the particle. Following tradition, let us express the result as the energy radiated into unit solid angle per unit time interval $dt$ of the radiation, rather than that ($dt$) of its measurement. (We will need to return to the measurement time $t$ in the next section, to calculate the observed radiation spectrum.) Using Eq. (16), we get

$$\frac{d\varphi}{d\Omega} = -\frac{d\varepsilon}{d\Omega dt} = \left( \frac{R^2 S_n}{c} \right) \frac{\partial t}{\partial t} = (E \times H) \cdot \left[ R^2 (1 - \beta \cdot n) \right]_{\text{ret}}. \quad (10.29)$$

At sufficiently large distances from the particle, i.e. in the limit $R_{\text{ret}} \to \infty$ (in the radiation zone), the contribution of the first (essentially, the Coulomb-field) term in the square brackets of Eq. (19) vanishes as $1/R$, and the substitution of the remaining term into Eqs. (20) and then (29) yields the following formula, valid for an arbitrary law of particle motion:

$$\frac{d\varphi}{d\Omega} = \frac{Z \varepsilon}{(4\pi)^2} n \times \left[ \left( n - \beta \right) \times \beta \right]^2 / (1 - n \cdot \beta)^5. \quad (10.30)$$

Now, let us apply this important result to some simple cases. First of all, Eq. (30) says that a charge moving with a constant velocity $\beta$ does not radiate at all. This might be expected from our analysis of this case in Sec. 9.5, because in the reference frame moving with the charge it produces only the Coulomb electrostatic field, i.e. no radiation.

Next, let us consider a linear motion of a point charge with a non-vanishing acceleration – evidently directed along the straight line of motion coordinate axes directed as shown in Fig. 4a. In this case, each of the vectors involved in Eq. (30) has at most two non-vanishing Cartesian components:

$$n = \{ \sin \theta, 0, \cos \theta \}, \quad \beta = \{ 0, 0, \beta \}, \quad \beta = \{ 0, 0, \beta \}, \quad (10.31)$$

where $\theta$ is the angle between the directions of the particle’s motion and the radiation’s propagation. Plugging these expressions into Eq. (30) and performing the vector multiplications, we get

---

6 A similar calculation of magnetic field components from Eq. (20) gives the results identical to Eqs. (9.140).

7 This tradition may be reasonably justified. Indeed, we may say that the radiation field “detaches” from the particle at times close to $t$, while the observation time $t$ depends on the detector’s position, and hence is less relevant for the radiation process as such.

8 If the direction of radiation, $n$, does not change in time, this formula does not depend on the observer’s position $R$. Hence, from this point on, the index “ret” may be safely dropped for brevity, though we should always remember that $\beta$ in Eq. (30) is the reduced velocity of the particle at the instant of the radiation’s emission, not of its observation.
Figure 4b shows the angular distribution of this radiation, for three values of the particle’s speed \( u \).

If the speed is relatively low (\( u \ll c \), i.e. \( \beta \ll 1 \)), the denominator in Eq. (32) is very close to 1 for all observation angles \( \theta \), so that the angular distribution of the radiation power is close to \( \sin^2 \theta \) – just as it follows from the general non-relativistic Larmor formula (8.26), for our current case with \( \Theta = \theta \). However, as the velocity is increased, the denominator becomes less than 1 for \( \theta < \pi/2 \), i.e. for the forward-looking directions, and larger than 1 for back directions. As a result, the radiation in the direction of the particle’s motion is increased (somewhat counter-intuitively, regardless of the acceleration’s sign!), while that in the back direction is suppressed. For ultra-relativistic particles (\( \beta \to 1 \)), this trend is strongly exacerbated, and radiation to very small forward angles dominates. To describe this main part of the angular distribution, we may expand the trigonometric functions of \( \theta \) participating in Eq. (32), into the Taylor series in small \( \theta \), and keep only their leading terms: \( \sin \theta \approx \theta \), \( \cos \theta \approx 1 - \theta^2/2 \), so that \( (1 - \beta \cos \theta) \approx (1 + \gamma^2 \theta^2)/2 \). The resulting expression,

\[
\frac{d\mathcal{P}}{d\Omega} \approx \frac{2Z_0 q^2}{\pi^2} \beta^2 \gamma^8 \left(\frac{\gamma\theta}{1 + \gamma^2 \theta^2}\right)^5, \quad \text{for} \quad \gamma >> 1,
\]

(10.33)

describes a narrow “hollow cone” distribution of radiation, with a maximum at the angle

\[
\theta_0 = \frac{1}{2\gamma} << 1.
\]

(10.34)

Another important aspect of Eq. (33) is how extremely fast (as \( \gamma^8 \)) does the radiation density grow with the Lorentz factor \( \gamma \), i.e. with the particle’s energy \( \varepsilon = \gamma mc^2 \). Still, the total radiated power \( \mathcal{P} \) (into all observation angles) at linear acceleration is not too high for any practicable values of parameters. To show this, let us calculate \( \mathcal{P} \) for an arbitrary motion of the particle. First, let me demonstrate how \( \mathcal{P} \) may be found (or rather guessed) from the general relativistic arguments. In Sec. 8.2, we have derived Eq. (8.27) for the power of the electric dipole radiation for non-relativistic particle motion. That result is valid, in particular, for one charged particle whose electric dipole moment’s derivative over time may be expressed as \( d(qr)/dt = (q/m)p \), where \( p \) is the particle’s mechanical momentum (not its electric dipole moment). As the result, the Larmor formula (8.27) in free space, i.e. with \( v = c \) (but \( u \ll c \)) reduces to

\[
\frac{d\mathcal{P}}{d\Omega} = \frac{Z_0 q^2}{(4\pi)^2} \beta^2 \frac{\sin^2 \theta}{(1 - \beta \cos \theta)^5}.
\]

(10.32)
This is evidently not a Lorentz-invariant result, but it gives a clear hint of how such an invariant, that would be reduced to Eq. (35) in the non-relativistic limit, may be formed:

\[
\mathcal{P} = -\frac{Z_0 q^2}{6\pi m^2 c^2} \left( \frac{dp_a}{d\tau} \cdot \frac{dp^a}{d\tau} \right) = \frac{Z_0 q^2}{6\pi m^2 c^2} \left[ \frac{dp}{d\tau} \cdot \frac{dp}{d\tau} - \frac{1}{c^2} \left( \frac{d\varepsilon}{d\tau} \right)^2 \right].
\]  

(10.36)

Using the relativistic expressions, \( p = \gamma mc\beta \), \( \varepsilon = \gamma mc^2 \), and \( d\tau = dt/\gamma \), the last formula may be recast into the so-called Liénard extension of the Larmor formula:

\[
\mathcal{P} = \frac{Z_0 q^2}{6\pi} \gamma^4 \left[ \left( \beta \cdot \beta \right)^2 - \left( \beta \times \beta \right)^2 \right] = \frac{Z_0 q^2}{6\pi} \gamma^4 \left[ \left( \beta \cdot \beta \right)^2 + \gamma^2 \left( \beta \cdot \beta \right)^2 \right],
\]  

(10.37)

which may be also obtained by direct integration of Eq. (30) over the full solid angle, thus confirming our guess.

However, for some applications, it is beneficial to express \( \mathcal{P} \) via the time evolution of the particle’s momentum alone. For that, we may differentiate the fundamental relativistic relation (9.78), \( \varepsilon^2 = (mc^2)^2 + (pc)^2 \), over the proper time \( \tau \) to get

\[
2\varepsilon \frac{d\varepsilon}{d\tau} = 2c^2 p \frac{dp}{d\tau}, \quad \text{i.e.} \quad \frac{d\varepsilon}{d\tau} = \frac{c^2 p}{\varepsilon} p \frac{dp}{d\tau} = u \frac{dp}{d\tau},
\]  

(10.38)

where, at the last step, the magnitude of the relativistic vector relation \( c^2 p/\varepsilon = u \), mentioned in Sec. 9.3, has been used. Plugging Eq. (38) into Eq. (36), we may rewrite it as

\[
\mathcal{P} = \frac{Z_0 q^2}{6\pi m^2 c^2} \left[ \frac{dp}{d\tau} - \beta^2 \left( \frac{dp}{d\tau} \right)^2 \right].
\]  

(10.39)

Please note the difference between the squared derivatives in this expression: in the first of them we have to differentiate the momentum vector \( p \) first, and only then form a scalar by squaring the resulting vector derivative, while in the second case, only the magnitude of the vector has to be differentiated. For example, for circular motion with a constant speed (to be analyzed in detail in the next section), the second term vanishes, while the first one does not.

However, if we return to the simplest case of linear acceleration (Fig. 4), then \( (dp/d\tau)^2 = (dp/d\tau)^2 \), and Eq. (39) is reduced to

\[
\mathcal{P} = \frac{Z_0 q^2}{6\pi m^2 c^2} \left( \frac{dp}{d\tau} \right)^2 \left( 1 - \beta^2 \right) = \frac{Z_0 q^2}{6\pi m^2 c^2} \left( \frac{dp}{d\tau} \right)^2 \frac{1}{\gamma^2} = \frac{Z_0 q^2}{6\pi m^2 c^2} \left( \frac{dp}{dt_{ret}} \right)^2,
\]  

(10.40)

i.e. formally coincides with the non-relativistic relation (35). To get a better feeling of the magnitude of this radiation, we may combine Eq. (9.144) with \( \mathbf{B} = 0 \), and Eq. (9.148) with \( \mathbf{E} \parallel \mathbf{u} \) to get

\[
\frac{dp}{dt_{ret}} = \frac{\mathbf{F}}{\gamma m c^2},
\]  

where \( \gamma = \frac{1}{\sqrt{1 - \beta^2}} \) is the Lorentz factor, \( \beta = \frac{p}{mc} \) is the particle’s velocity, and \( \mathbf{E} \) and \( \mathbf{B} \) are the electric and magnetic field vectors, respectively.

---

9 The second form of Eq. (10.37), which is frequently more convenient for applications, may be readily obtained from the first one by applying MA Eq. (7.7a) to the vector product.
$d\Omega/dz'$, where $z'$ is the particle’s coordinate at the moment $t_{ret}$. The last relation allows us to rewrite Eq. (40) in the following form:

$$\mathcal{P} = \frac{Z_0 q^2}{6\pi m^2 c^2} \left(\frac{d\Omega}{dz}\right)^2 = \frac{Z_0 q^2}{6\pi m^2 c^2} \frac{d\Omega}{dz} \frac{dt_{ret}}{dz'} = \frac{Z_0 q^2}{6\pi m^2 c^2} \frac{d\Omega}{dt_{ret}} \frac{dt}{dz'}.$$  \hspace{1cm} (10.41)

For the most important case of ultra-relativistic motion ($u \rightarrow c$), this result reduces to

$$\frac{\mathcal{P}}{d\Omega/dt_{ret}} \approx \frac{2}{3} \frac{d(\Omega/mc^2)}{d(z'/r_c)},$$  \hspace{1cm} (10.42)

where $r_c$ is the classical radius of the particle, defined by Eq. (8.41). This formula shows that the radiated power, i.e. the change of the particle’s energy due to radiation, is much smaller than that due to the accelerating field, unless energy as large as $\sim mc^2$ is gained on the classical radius of the particle. For example, for an electron, with $r_c \approx 3 \times 10^{-15}$ m and $mc^2 = mc^2 \approx 0.5$ MeV, such an acceleration would require the accelerating electric field of the order of $(0.5 \text{ MV})/(3 \times 10^{-15} \text{ m}) \sim 1 \times 10^4 \text{ MV/m}$, while practicable accelerating fields are below $10^3 \text{ MV/m}$ – limited by the electric breakdown effects. (As described by the factor $m^2$ in the denominator of Eq. (41), for heavier particles such as protons, the relative losses are even lower.) Such negligible radiative losses of energy is actually a large advantage of linear accelerators – such as the famous 2-mile-long SLAC,\footnote{See, e.g., https://www6.slac.stanford.edu/.} which can accelerate electrons or positrons to energies up to 50 GeV, i.e. to $\gamma \approx 10^5$. If obtaining radiation from the accelerated particles is the goal, it may be readily achieved by bending their trajectories using additional magnetic fields – see the next section.

### 10.3. Synchrotron radiation

Now let us consider a charged particle being accelerated in the direction perpendicular to its velocity $\mathbf{u}$ (for example by the magnetic component of the Lorentz force), so that its speed $u$, and hence the magnitude $p$ of its momentum, do not change. In this case, the second term in the square brackets of Eq. (39) vanishes, and it yields

$$\mathcal{P} = \frac{Z_0 q^2}{6\pi m^2 c^2} \left(\frac{dp}{d\tau}\right)^2 = \frac{Z_0 q^2}{6\pi m^2 c^2} \left(\frac{dp}{dt_{ret}}\right)^2 \gamma^2.$$  \hspace{1cm} (10.43)

Comparing this expression with Eq. (40), we see that for the same acceleration magnitude, the electromagnetic radiation is a factor of $\gamma^2$ larger. For modern accelerators, with $\gamma \sim 10^4$-$10^5$, such a factor creates an enormous difference. For example, if a particle is on a cyclotron orbit in a constant magnetic field (as was analyzed in Sec. 9.6), both $\mathbf{u}$ and $p = \gamma m u$ obey Eq. (9.150), so that

$$\left|\frac{dp}{dt_{ret}}\right| = \omega_c p = \frac{u}{R} p = \beta^2 \gamma \frac{mc^2}{R},$$  \hspace{1cm} (10.44)

(where $R$ is the orbit’s radius), so that for the power of this synchrotron radiation, Eq. (43) yields

$$\mathcal{P} = \frac{Z_0 q^2}{6\pi} \beta^4 \gamma^4 \frac{c^2}{R^2}.$$  \hspace{1cm} (10.45)
According to Eq. (9.153), at fixed magnetic field (in particle accelerators, limited to a few Tesla produced by the beam-bending magnets), the synchrotron orbit radius \( R \) scales as \( \gamma \), so that according to Eq. (45), \( P \) scales as \( \gamma^2 \), i.e. grows as the square of the particle’s energy \( E \propto \gamma \). For example, for typical parameters of the first electron cyclotrons (such as the General Electric’s machine in that the synchrotron radiation was first noticed in 1947), \( R \sim 1 \text{ m}, \ E \sim 0.3 \text{ GeV} \ (\gamma \sim 600), \) Eq. (45) gives a very modest electron energy loss per one revolution:

\[
\mathcal{P} \approx 2\pi\mathcal{P}_0 \approx 2\pi\mathcal{P}_0/c \sim 1 \text{ keV}.
\]

However, already by the mid-1970s, electron accelerators, with \( R \sim 100 \text{ m}, \) could give each particle an energy \( E \sim 10 \text{ GeV} \), and the energy loss per revolution grew to \( \sim 10 \text{ MeV} \), becoming the major energy loss mechanism. For proton accelerators, such energy loss is much less of a problem, because \( \gamma \) of an ultra-relativistic particle (at fixed \( E \)) is proportional to \( 1/m \), so that the estimates, at the same \( R \), should be scaled back by \((m_p/m_e)^4 \sim 10^{13}\). Nevertheless, in the giant modern accelerators such as the already mentioned LHC (with \( R \approx 4.3 \text{ km} \) and \( E \) up to 7 TeV), the synchrotron radiation loss per revolution is rather noticeable (\( \mathcal{P}\Delta t \sim 6 \text{ keV} \)), leading not as much to particle deceleration as to a substantial photoelectron emission from the beam tube’s walls, creating harmful defocusing effects.

However, what is bad for particle accelerators and storage rings is good for the so-called synchrotron light sources – the electron accelerators designed especially for the generation of intensive synchrotron radiation – with the spectrum extending well beyond the visible light range. Let us now analyze the angular and spectral distributions of such radiation. To calculate the angular distribution, let us select the coordinate axes as shown in Fig. 5, with the origin at the current location of the orbiting particle, the \( z \)-axis directed along its instant velocity (i.e. the vector \( \mathbf{\beta} \)), and the \( x \)-axis toward the orbit’s center.

In the general case, the unit vector \( \mathbf{n} \) toward the radiation’s observer is not within any of the coordinate planes, and hence has to be described by two angles – the polar angle \( \theta \) and the azimuthal angle \( \varphi \) between the \( x \)-axis and the projection \( 0P \) of the vector \( \mathbf{n} \) to the plane \([x, y]\). Since the length of the segment \( 0P \) is \( \sin\theta \), the Cartesian components of the relevant vectors are as follows:

\[
\mathbf{n} = \{\sin \theta \cos \varphi, \sin \theta \sin \varphi, \cos \theta\}, \quad \mathbf{\beta} = \{0, 0, \beta\}, \quad \text{and} \quad \mathbf{\dot{\beta}} = \{\dot{\beta}, 0, 0\}.
\]

Plugging these expressions into the general Eq. (30), we get

\[
\frac{d\mathcal{P}}{d\Omega} = \frac{2Z^2 q^2}{\pi^2} \left\| \mathbf{\dot{\beta}} \right\|^2 \gamma^6 f(\theta, \varphi) \quad \text{where}
\]

\[
f(\theta, \varphi) = \frac{1}{8\gamma^6 (1 - \beta \cos \theta)^3} \left[ 1 - \frac{\sin^2 \theta \cos^2 \varphi}{\gamma^2 (1 - \beta \cos \theta)^2} \right],
\]

Fig. 10.5. The synchrotron radiation problem’s geometry.
According to this result, just as at the linear acceleration, in the ultra-relativistic limit, most radiation goes into a narrow cone (of a width $\Delta \theta \sim \gamma^{-1} << 1$) around the vector $\mathbf{\beta}$, i.e. around the instant direction of particle’s propagation. For such small angles, and $\gamma >> 1$,

$$f(\theta, \varphi) \approx \frac{1}{(1 + \gamma^2 \varphi^2)^3} \left[ 1 - \frac{4\gamma^2 \theta^2 \cos^2 \varphi}{(1 + \gamma^2 \varphi^2)^2} \right].$$

(10.48)

The left panel of Fig. 6 shows a color-coded contour map of this angular distribution $f(\theta, \varphi)$, as observed on a distant plane normal to the particle’s instant velocity (in Fig. 5, parallel to the plane $[x, y]$), while its right panel shows it as a function of $\theta$ in two perpendicular directions: within the particle rotation plane (in the direction parallel to the $x$-axis, i.e. at $\varphi = 0$) and perpendicular to this plane (along the $y$-axis, i.e. at $\varphi = \pm \pi/2$). The result shows, first of all, that, in contrast to the case of linear acceleration, the narrow radiation cone is now not hollow: the intensity maximum is reached at $\theta = 0$, i.e. exactly in the direction of the particle’s motion direction. Second, the radiation cone is not axially-symmetric: within the particle rotation plane, the intensity drops faster (and even has nodes at $\theta = \pm 1/\gamma$).

As Fig. 5 shows, the calculated angular distribution (47) of the synchrotron radiation is in the (inertial) reference frame whose origin coincides with the particle’s position at this a particular instant, i.e. its radiation pattern is time-independent only in a frame moving with the particle. This pattern enables a semi-quantitative description of the radiation by an ultra-relativistic particle from the point of view of a stationary observer: if the observation point is on (or very close to) the rotation plane,\(^{11}\) it is being “struck” by the narrow radiation cone once each rotation period $T \approx 2\pi R/c$, each “strike” giving a pulse of a short duration $\Delta t_{\text{ret}} << 1/\omega_c$ – see Fig. 7.\(^{12}\)

\(^{11}\) It is easy (and hence is left for the reader’s exercise) to show that if the observation point is much off-plane (say, is located on the particle orbit’s axis), the radiation is virtually monochromatic, with frequency $\omega_c$. (As we know from Sec. 8.2, in the non-relativistic limit $u << c$ this is true for any observation point.)

\(^{12}\) The fact that the in-plane component of each electric field’s pulse $E(t)$ is asymmetric with respect to its central point, and hence vanishes at that point (as Fig. 7b shows), readily follows from Eq. (19).
The evaluation of the time duration $\Delta t$ of each pulse requires some care: its estimate $\Delta t_{\text{ret}} \sim 1/\gamma \omega_c$ is correct for the duration of the retarded time interval during that its cone is aimed at the observer. However, due to the time compression effect, discussed in detail in Sec. 1 and described by Eq. (16), the pulse duration as seen by the observer is a factor of $1/(1 - \beta)$ shorter, so that

$$\Delta t = (1 - \beta) \Delta t_{\text{ret}} \sim \frac{1 - \beta}{\gamma \omega_c} \sim \frac{1}{\gamma^3 \omega_c} \sim \gamma^{-3} \tau, \quad \text{for } \gamma \gg 1. \quad (10.49)$$

![Diagram](image)

Fig. 10.7. (a) The synchrotron radiation cones (at $\gamma \gg 1$) for two close values of $t_{\text{ret}}$, and (b) the in-plane component of the electric field, observed in the rotation plane, as a function of time $t$ – schematically.

From the Fourier theorem, we can expect the frequency spectrum of such radiation to consist of numerous ($N - \gamma^3 \gg 1$) harmonics of the particle rotation frequency $\omega_c$, with comparable amplitudes. However, if the orbital frequency fluctuates even slightly ($\delta \omega_c/\omega_c > 1/N \sim 1/\gamma^3$), as it happens in most practical systems, the radiation pulses are not coherent, so that the average radiation power spectrum may be calculated as that of one pulse, multiplied by the number of pulses per second. In this case, the spectrum is continuous, extending from low frequencies all the way to approximately

$$\omega_{\text{max}} \sim 1/\Delta t \sim \gamma^3 \omega_c. \quad (10.50)$$

In order to verify and quantify this result, let us calculate the spectrum of radiation, due to a single pulse. For that, we should first make the general notion of the radiation spectrum quantitative. Let us represent an arbitrary electric field (say that of the synchrotron radiation we are studying now), observed at a fixed point $r$, as a function of the observation time $t$, as a Fourier integral:13

$$E(t) = \int_{-\infty}^{+\infty} E_0 e^{-i\omega t} \, dt. \quad (10.51)$$

This expression may be plugged into the formula for the total energy of the radiation pulse (i.e. of the loss of particle’s energy $\mathcal{E}$) per unit solid angle:14

---

13 In contrast to the single-frequency case (i.e. a monochromatic wave), we may avoid taking the real part of the complex function $(E_0 e^{-i\omega t})$ by requiring that in Eq. (51), $E_{\omega} = E_0^*$. However, it is important to remember the factor $1/2$ required for the transition to a monochromatic wave of frequency $\omega_0$ and with real amplitude $E_0$: $E_{\omega} = E_0 \left[\delta(\omega - \omega_0) + \delta(\omega + \omega_0)\right]/2$.

14 Note that the expression under this integral differs from $d\mathcal{P}/d\Omega$ defined by Eq. (29) by the absence of the term $(1 - \beta \cdot n) = \partial_{\text{ret}} \chi / \partial t$ – see Eq. (16). This is natural, because this is the wave energy arriving at the observation point $r$ during the time interval $dt$ rather than $dt_{\text{ret}}$. 
\[- \frac{d\mathcal{E}}{d\Omega} \equiv \int_{-\infty}^{+\infty} S_n(t) R^2 dt = \frac{R^2}{Z_0} \int_{-\infty}^{+\infty} |\mathbf{E}(t)|^2 dt. \]  

(10.52)

This substitution, followed by a natural change of the integration order, yield

\[- \frac{d\mathcal{E}}{d\Omega} = \frac{R^2}{Z_0} \int_{-\infty}^{+\infty} \int_{-\infty}^{+\infty} \mathbf{E}_\omega \cdot \mathbf{E}_{-\omega'} \int dt \ e^{-i(\omega+\omega')t}. \]  

(10.53)

But the inner integral (over \(t\)) is just \(2\pi \delta(\omega + \omega')\).\(^{15}\) This delta-function kills one of the frequency integrals (say, one over \(\omega'\)), and Eq. (53) gives us a result that may be recast as

\[- \frac{d\mathcal{E}}{d\Omega} = \int_{0}^{+\infty} I(\omega) d\omega, \quad \text{with} \quad I(\omega) = \frac{4\pi R^2}{Z_0} \mathbf{E}_\omega \cdot \mathbf{E}_{-\omega} \equiv \frac{4\pi R^2}{Z_0} \mathbf{E}_\omega \mathbf{E}^*_{-\omega}, \]  

(10.54)

where the evident frequency symmetry of the scalar product \(\mathbf{E}_\omega \cdot \mathbf{E}_{-\omega}\) has been utilized to fold the integral of \(I(\omega)\) to positive frequencies only. The first of Eqs. (54) makes the physical sense of the function \(I(\omega)\) clear: this is the so-called spectral density of the electromagnetic radiation (per unit solid angle).\(^{16}\)

To calculate the spectral density, we can express the function \(\mathbf{E}_\omega\) via \(\mathbf{E}(t)\) using the Fourier transform reciprocal to Eq. (51):

\[\mathbf{E}_\omega = \frac{1}{2\pi} \int_{-\infty}^{+\infty} \mathbf{E}(t)e^{i\omega t} dt. \]  

(10.55)

In the particular case of radiation by a single point charge, we may use here the second (radiative) term of Eq. (19):

\[\mathbf{E}_\omega = \left(\frac{q}{2\pi}\right) \frac{1}{4\pi \varepsilon_0 c R} \int_{-\infty}^{+\infty} \left[ \mathbf{n} \times \left(\mathbf{n} - \mathbf{\beta}\right) \times \mathbf{\beta} \right] \frac{1}{(1 - \mathbf{\beta} \cdot \mathbf{n})^3} e^{i\omega t} dt. \]  

(10.56)

Since the vectors \(\mathbf{n}\) and \(\mathbf{\beta}\) are more natural functions of the radiation (retarded) time \(t_{\text{ret}}\), let us use Eqs. (5) and (16) to exclude the observation time \(t\) from this integral:

\[\mathbf{E}_\omega = \frac{q}{4\pi \varepsilon_0 c R} \int_{-\infty}^{+\infty} \left[ \mathbf{n} \times \left(\mathbf{n} - \mathbf{\beta}\right) \times \mathbf{\beta} \right] \exp\left(i\omega \left(t_{\text{ret}} + \frac{R_{\text{ret}}}{c}\right)\right) dt_{\text{ret}}. \]  

(10.57)

Assuming that the observer is sufficiently far from the particle,\(^{17}\) we may treat the unit vector \(\mathbf{n}\) as a constant and also use the approximation (8.19) to reduce Eq. (57) to

\[\mathbf{E}_\omega = \frac{1}{2\pi} \frac{q}{4\pi \varepsilon_0 c R} \exp\left(i\omega \frac{t_{\text{ret}}}{c}\right) \int_{-\infty}^{+\infty} \left[ \mathbf{n} \times \left(\mathbf{n} - \mathbf{\beta}\right) \times \mathbf{\beta} \right] \exp\left(i\omega \left(t - \frac{\mathbf{n} \cdot \mathbf{r}'}{c}\right)\right) dt_{\text{ret}}. \]  

(10.58)

\(^{15}\) See, e.g. MA Eq. (14.4).

\(^{16}\) The notion of spectral density may be readily generalized to random processes – see, e.g., SM Sec. 5.4.

\(^{17}\) According to the estimate (49), for a synchrotron radiation’s pulse, this restriction requires the observer to be much farther than \(\Delta r' \sim c\Delta t \sim R/\gamma^2\) from the particle. With the values \(R \sim 10^4\) m and \(\gamma \sim 10^5\) mentioned above, \(\Delta r' \sim 10^{-11}\) m, so this requirement is satisfied for any realistic radiation detector.
Plugging this expression into Eq. (54), and then using the definitions $c \equiv 1/(\varepsilon_0\mu_0)^{1/2}$ and $Z_0 \equiv (\mu_0/\varepsilon_0)^{1/2}$, we get\(^{18}\)

$$I(\omega) = \frac{Z_0 q^2}{16\pi^3} \int_{-\infty}^{\infty} \left[ \mathbf{n} \times \left( \mathbf{n} - \mathbf{\beta} \right) \right] \exp\left\{ i \omega \left( t - \mathbf{n} \cdot \mathbf{r}' \right) / c \right\} \ dt_{\text{ret}}^2. \quad (10.59)$$

This result may be further simplified by noticing that the fraction before the exponent may be represented as a full derivative over $t_{\text{ret}}$,

$$\left[ \mathbf{n} \times \left( \mathbf{n} - \mathbf{\beta} \right) \right]_{\text{ret}} \equiv \left[ \mathbf{n} \times \left( \mathbf{n} - \mathbf{\beta} \right) \times \frac{d\mathbf{\beta}}{dt} \right]_{\text{ret}} \equiv \frac{d}{dt} \left[ \mathbf{n} \times \left( \mathbf{n} \times \mathbf{\beta} \right) \right]_{\text{ret}}, \quad (10.60)$$

and working out the resulting integral by parts. At this operation, the time differentiation of the parentheses in the exponent gives $d[t_{\text{ret}} - \mathbf{n} \cdot \mathbf{r}'(t_{\text{ret}})/c]/dt_{\text{ret}} = (1 - \mathbf{n} \cdot \mathbf{u}/c)_{\text{ret}} \equiv (1 - \mathbf{\beta} \cdot \mathbf{n})_{\text{ret}}$, leading to the cancellation of the remaining factor in the denominator and hence to a very simple general result: \(^{19}\)

$$I(\omega) = \frac{Z_0 q^2 \omega^2}{16\pi^3} \int_{-\infty}^{\infty} \left[ \mathbf{n} \times \mathbf{\beta} \right] \exp\left\{ i \omega \left( t - \mathbf{n} \cdot \mathbf{r}' \right) / c \right\} \ dt_{\text{ret}}^2. \quad (10.61)$$

Now returning to the particular case of the synchrotron radiation, it is beneficial to choose the origin of time $t_{\text{ret}}$ so that at $t_{\text{ret}} = 0$, the angle $\alpha$ between the vectors $\mathbf{n}$ and $\mathbf{\beta}$ takes its smallest value $\theta_0$, i.e., in terms of Fig. 5, the vector $\mathbf{n}$ is within the plane $[y, z]$. Fixing this direction of the axes, so that they do not move in further times, we can redraw that figure as shown in Fig. 8.

In this “lab” reference frame, the vector $\mathbf{n}$ does not depend on time, while the vectors $\mathbf{r}'(t_{\text{ret}})$ and $\mathbf{\beta}_{\text{ret}}$ do depend on it via the angle $\alpha \equiv \omega t_{\text{ret}}$:

$$\mathbf{n} \equiv \{0, \sin \theta_0, \cos \theta_0\}, \quad \mathbf{r}'(t_{\text{ret}}) = \{R(1 - \cos \alpha), 0, R \sin \alpha\}, \quad \mathbf{\beta}_{\text{ret}} \equiv \{\beta \sin \alpha, 0, \beta \cos \alpha\}. \quad (10.62)$$

Now an easy multiplication yields

---

\(^{18}\) Note that for our current purposes of calculation of the spectral density of radiation by a single particle, the factor $\exp\{i\omega'/c\}$ has got canceled. However, as we have seen in Chapter 8, this factor plays the central role at interference of radiation from several (many) sources. Such interference is important, in particular, in undulators and free-electron lasers – the devices to be (qualitatively) discussed below.

\(^{19}\) Actually, this simplification is not occasional. According to Eq. (10b), the expression under the derivative in the last form of Eq. (60) is just the transverse component of the vector potential $\mathbf{A}$ (give or take a constant factor), and from the discussion in Sec. 8.2 we know that this component determines the electric dipole radiation of the particle, which dominates the radiation field in our current case of a particle with a non-zero electric charge.
\[ \mathbf{n} \times (\mathbf{n} \times \mathbf{\beta})_{ret} = \beta \{ \sin \alpha, \sin \theta_0 \cos \theta_0 \cos \alpha, -\sin^2 \theta_0 \sin \alpha \}, \quad (10.63) \]

\[ \left[ \exp \left\{ i\omega \left( t - \frac{\mathbf{n} \cdot \mathbf{r}'}{c} \right) \right\} \right]_{ret} = \exp \left\{ i\omega \left( t_{ret} - \frac{R}{c} \cos \theta_0 \sin \alpha \right) \right\}. \quad (10.64) \]

As we already know, in the (most interesting) ultra-relativistic limit \( \gamma > 1 \), most radiation is confined to short pulses, so that only small angles \( \alpha \sim \omega_\Delta t_{ret} \sim \gamma^{-1} \) may contribute to the integral in Eq. (61). Moreover, since most radiation goes to small angles \( \theta \sim \theta_0 \sim \gamma^{-1} \), it makes sense to consider only such small angles. Expanding both trigonometric functions of these small angles, participating in parentheses of Eq. (64), into the Taylor series, and keeping only the leading terms, we get

\[ t_{ret} - \frac{R}{c} \cos \theta_0 \sin \alpha \approx t_{ret} - \frac{R}{c} \omega t_{ret} + \frac{R}{c} \frac{\theta^2_0}{2} \omega t_{ret} + \frac{R}{c} \frac{\omega^3}{6} t_{ret}. \quad (10.65) \]

Since \( (R/c)\omega_k = u/c = \beta \approx 1 \), in the two last terms we may approximate this parameter by 1. However, it is crucial to distinguish the difference of the two first terms, proportional to \( (1 - \beta)t_{ret} \), from zero; as we have done before, we may approximate it with \( t_{ret}/2 \gamma^2 \). On the right-hand side of Eq. (63), which does not have such a critical difference, we may be more bold, taking

\[ \beta \{ \sin \alpha, \sin \theta_0 \cos \theta_0 \cos \alpha, -\sin^2 \theta_0 \sin \alpha \} \approx \{ \alpha, \theta_0, 0 \} \equiv \{ \omega_\xi t_{ret}, \theta_0, 0 \}, \quad (10.66) \]

As a result, Eq. (61) is reduced to

\[ I(\omega) = \frac{Z_0 q^2}{16\pi^3} \left| a_x \mathbf{n}_x + a_y \mathbf{n}_y \right|^2 \equiv \frac{Z_0 q^2}{16\pi^3} \left( |a_x|^2 + |a_y|^2 \right), \quad (10.67) \]

where \( a_x \) and \( a_y \) are the dimensionless factors,

\[ a_x \equiv \omega \int_{-\infty}^{+\infty} \omega_\xi t_{ret} \exp \left\{ i\omega \left( (\theta^2_0 + \gamma^{-2}) t_{ret} + \frac{\omega^3_\xi}{3} t_{ret}^3 \right) \right\} dt_{ret}, \]

\[ a_y \equiv \omega \int_{-\infty}^{+\infty} \theta_0 \exp \left\{ i\omega \left( (\theta^2_0 + \gamma^{-2}) t_{ret} + \frac{\omega^3_\xi}{3} t_{ret}^3 \right) \right\} dt_{ret}, \quad (10.68) \]

that describe the frequency spectra of two components of the synchrotron radiation, with mutually perpendicular directions of polarization. Defining the following dimensionless parameter

\[ \nu \equiv \frac{\omega}{3\omega_\xi} \left( \theta^2_0 + \gamma^{-2} \right)^{3/2}, \quad (10.69) \]

which is proportional to the observation frequency, and changing the integration variable to \( \xi \equiv \omega_\Delta t_{ret} (\theta^2_0 + \gamma^{-2})^{1/2} \), the integrals (68) may be reduced to the modified Bessel functions of the second kind, but with fractional indices:

---

20 This expression confirms that the in-plane (\( x \)) component of the electric field is an odd function of \( t_{ret} \) and hence of \( t - t_0 \) (see its sketch in Fig. 7b), while the normal (\( y \)) component is an even function of this difference. Also note that for an observer exactly in the rotation plane (\( \theta_0 = 0 \)) the latter component equals zero for all times – the fact which could be predicted from the very beginning because of the evident mirror symmetry of the problem with respect to the particle rotation plane.
\[
a_x = \frac{\omega}{\omega_c} \left( \theta_0^2 + \gamma^{-2} \right)^{1/2} \int_{-\infty}^{\infty} \xi \exp \left( \frac{3}{2} i \nu \left( \xi + \frac{\xi^3}{3} \right) \right) d\xi = \frac{2\sqrt{3} i}{(\theta_0^2 + \gamma^{-2})^{1/2}} vK_{2/3}(v),
\]
\[
a_y = \frac{\omega}{\omega_c} \theta_0 \left( \theta_0^2 + \gamma^{-2} \right)^{1/2} \int_{-\infty}^{\infty} \exp \left( \frac{3}{2} i \nu \left( \xi + \frac{\xi^3}{3} \right) \right) d\xi = \frac{2\sqrt{3} \theta_0}{\theta_0^2 + \gamma^{-2}} vK_{1/3}(v).
\]

Figure 9a shows the dependence of the Bessel factors, defining the amplitudes \(a_x\) and \(a_y\), on the normalized observation frequency \(v\). It shows that the radiation intensity changes with frequency rather slowly (note the log-log scale of the plot) until the normalized frequency, defined by Eq. (69), is increased beyond \(\sim 1\). For most important observation angles \(\theta_0 \sim \gamma\) this means that our estimate (50) is indeed correct, though formally the frequency spectrum extends to infinity.\(^{21}\)

Naturally, the spectral density integrated over the full solid angle exhibits a similar frequency behavior. Without performing the integration,\(^{22}\) let me just give the result (also valid for \(\gamma \gg 1\) only) for the reader’s reference:

\[
\int \int f(\omega) d\Omega = \frac{\sqrt{3}}{4\pi} \gamma^2 \zeta \int_{\zeta}^{\infty} K_{5/3}(\xi) d\xi, \quad \text{where} \quad \zeta = \frac{2}{3} \frac{\omega}{\omega_c \gamma^3}.
\]

Figure 9b shows the dependence of this integral on the normalized frequency \(\zeta\). (This plot is sometimes called the “universal flux curve”.) In accordance with the estimate (50), it reaches the maximum at

\[
\zeta_{\text{max}} \approx 0.3, \quad \text{i.e.} \omega_{\text{max}} \approx \frac{\omega_c}{2} \gamma^3.
\]

\(^{21}\) The law of the spectral density decrease at large \(\nu\) may be readily obtained from the second of Eqs. (2.158), which is valid even for any (even non-integer) Bessel function index \(n\): \(a_x \propto a_y \propto \nu^{1/2} \exp\{-v\nu\}.\) Here the exponential factor is certainly most important.

\(^{22}\) For that, and many other details, the interested reader may be referred, for example, to the fundamental review collection by E. Koch et al. (eds.) Handbook on Synchrotron Radiation (in 5 vols.), North-Holland, 1983-1991, or to a more concise monograph by A. Hofmann, The Physics of Synchrotron Radiation, Cambridge U. Press, 2007.
For example, in the National Synchrotron Light Source (NSLS-II) in the Brookhaven National Laboratory, near the SBU campus, with the ring circumference of 792 m, the electron revolution period $T$ is 2.64 μs. Calculating $\omega_c$ as $2\pi/T = 2.4 \times 10^6$ s$^{-1}$, for the achieved $\gamma \approx 6 \times 10^3$ ($\mathcal{E} \approx 3$ GeV), we get $\omega_{max} \approx 3 \times 10^{17}$ s$^{-1}$ (the photon energy $\hbar \omega_{max} \approx 200$ eV), corresponding to soft X-rays. In the light of this estimate, the reader may be surprised by Fig. 10, which shows the calculated spectra of the radiation that this facility was designed to produce, with the intensity maxima at photon energies up to a few keV.

![Design brightness of various synchrotron radiation sources of the NSLS-II facility.](https://www.bnl.gov/ps/docs/pdf/SourceProperties.pdf)
The reason for this discrepancy is that in the NLLS-II, and in all modern synchrotron light sources, most radiation is produced not by the circular orbit itself (which is, by the way, not exactly circular, but consists of a series of straight and bend-magnet sections), but by such bend sections, and the devices called wigglers and undulators: strings of several strong magnets with alternating field direction (Fig. 11), that induce periodic bending (wiggling”) of the electron’s trajectory, with the synchrotron radiation emitted at each bend.

The difference between the wigglers and the undulators is more quantitative than qualitative: the former devices have a larger spatial period \( \lambda_u \) (the distance between the adjacent magnets of the same polarity, see Fig. 11), giving enough space for the electron beam to bend by an angle larger than \( \gamma^{-1} \), i.e. larger than the radiation cone’s width. As a result, the radiation arrives to an in-plane observer as a periodic sequence of individual pulses – see Fig. 12a.

\[ \Delta t \approx \frac{\lambda_u}{2\gamma^2c} \]

The shape of each pulse, and hence its frequency spectrum, are essentially similar to those discussed above,\(^{24}\) but with much higher local values of \( \omega_c \) and hence \( \omega_{\text{max}} \) – see Fig. 10. Another difference is a much higher frequency of the pulses. Indeed, the fundamental Eq. (16) allows us to calculate the time distance between them, for the observer, as

\[^{24}\text{Indeed, the period } \lambda_u \text{ is typically a few centimeters (see the numbers in Fig. 10), i.e. is much larger than the interval } \Delta r' \sim R/\gamma^3 \text{ estimated above. Hence the synchrotron radiation results may be applied locally, to each electron beam’s bend. (In this context, a simple problem for the reader: use Eqs. (19) and (63) to explain the difference between shapes of the in-plane electric field pulses emitted at opposite magnetic poles of the wiggler, which is schematically shown in Fig. 12a.)} \]
\[ \Delta t \approx \frac{\partial t}{\partial t_{\text{rel}}} \Delta t_{\text{rel}} \approx (1 - \beta) \frac{\lambda_u}{u} \approx \frac{1}{2 \gamma^2} \frac{\lambda_u}{c} << \frac{\lambda_u}{c}, \]  

(10.73)

where the first two relations are valid at \( \lambda_u \ll R \) (the relation typically satisfied very well, see the numbers in Fig. 10), and the last two relations assume the ultra-relativistic limit. As a result, the radiation intensity, that is proportional to the number of the poles, is much higher than that from the bend magnets – see Fig. 10 again.

The situation is different in undulators – similar structures with a smaller spatial period \( \lambda_u \), in which the electron’s velocity vector oscillates with an angular amplitude smaller than \( \gamma^{-1} \). As a result, the radiation pulses overlap (Fig. 12b) and the radiation waveform is closer to sinusoidal one. As a result, the radiation spectrum narrows to the central frequency

\[ \omega_0 = \frac{2 \pi}{\Delta t} \approx 2 \frac{\gamma^2}{\lambda_u} \frac{2 \pi c}{\lambda_u}. \]  

(10.74)

For example, for the LSNL-II undulators with \( \lambda_u = 2 \text{ cm} \), this formula predicts a radiation peak at phonon energy \( \hbar \omega_0 \approx 4 \text{ keV} \), in a reasonable agreement with the results of quantitative calculations, shown in Fig. 10.\(^{26}\) Due to the spectrum narrowing, the intensity of undulators radiation is higher than that of wigglers using the same electron beam.

This spectrum-narrowing trend is brought to its logical conclusion in the so-called free-electron lasers\(^{27}\) whose basic structure is the same as that of wigglers and undulators (Fig. 11), but the radiation at each beam bend is so intense and narrow-focused that it affects the electron motion downstream the radiation cone. As a result, the radiation spectrum narrows around the central frequency (74), and its power grows as a square of the number \( N \) of electrons in the structure (rather than proportionately to \( N \) in wigglers and undulators).

Finally, note that wigglers, undulators, and free-electron lasers may be also used at the end of a linear electron accelerator (such as SLAC) which, as was noted above, may provide extremely high values of \( \gamma \), and hence radiation frequencies, due to the absence of the radiation energy losses at the electron acceleration stage. Very unfortunately, I do not have time/space to discuss (very interesting) physics of these devices in more detail.\(^{28}\)

---

25 This important formula may be also derived in the following way. Due to the relativistic length contraction (9.20), the undulator structure period as perceived by beam electrons is \( \lambda' = \lambda_u / \gamma \), so that the central frequency of the radiation in the reference frame moving with the electrons is \( \omega_{0}' = 2 \pi / \lambda' = 2 \pi \gamma / \lambda_u \). For the lab-frame observer, this frequency is Doppler-upshifted in accordance with Eq. (9.44): \( \omega_0 = \omega_{0}' [(1 + \beta)/(1 - \beta)]^{1/2} \approx 2 \gamma \omega_{0}' \), giving the same result as Eq. (74).

26 Some of the difference is due to the fact that those plots show the spectral density of the number of photons \( n = \mathcal{E} / \hbar \omega_0 \) per second, which peaks at a frequency below that of the density of power, i.e. of the energy \( \mathcal{E} \) per second.

27 This name is somewhat misleading, because in contrast to the usual (“quantum”) lasers, the free-electron laser is essentially a classical device, and the dynamics of electrons in it is very similar to that in vacuum-tube microwave generators, such as the magnetrons briefly discussed in Sec. 9.6.

10.4. Bremsstrahlung and Coulomb losses

Surprisingly, a very similar mechanism of radiation by charged particles works at a much smaller spatial scale, namely at their scattering by charged particles of the propagation medium. This effect, traditionally called by its German name *bremsstrahlung* (“brake radiation”), is responsible, in particular, for the continuous part of the frequency spectrum of the radiation produced in standard vacuum X-ray tubes, at the electrons’ collisions with a metallic “anticathode”. 29

The bremsstrahlung in condensed matter is generally a rather complicated phenomenon, because of the simultaneous involvement of many particles, and (frequently) some quantum electrodynamic effects. This is why I will give only a very brief glimpse at the theoretical description of this effect, for the simplest case when the scattering of incoming, relatively light charged particles (such as electrons, protons, \(\alpha\)-particles, etc.) is produced by atomic nuclei, which remain virtually immobile during the scattering event (Fig. 13a). This is a reasonable approximation if the energy of incoming particles is not too low; otherwise, most scattering is produced by atomic electrons whose dynamics is substantially quantum – see below.

To calculate the frequency spectrum of radiation emitted during a single scattering event, it is convenient to use a byproduct of the last section’s analysis, namely Eq. (59) with the replacement (60): 30

\[
I(\omega) = \frac{1}{4\pi^2 c} \frac{q^2}{4\pi\varepsilon_0} \int_{-\infty}^{\infty} \left[ \left\langle \frac{d}{dt} \frac{n \times (n \times \beta)}{1 - \beta \cdot n} \right\rangle dt \right] \exp \left\{ i\alpha \left( t - \frac{n \cdot r'}{c} \right) \right\} dt, \quad (10.75)
\]

A typical duration \(\tau\) of a single scattering event we are discussing is of the order of \(a_0/c \approx (10^{10} \text{ m})/(3\times10^8 \text{ m/s}) \approx 10^{-18} \text{ s}\) in solids, and only an order of magnitude longer in gases at ambient conditions. This is why for most frequencies of interest, from zero all the way up to *at least* soft X-rays, 31 we can

---

29 Such X-ray radiation had been first observed experimentally, though not correctly interpreted by N. Tesla in 1887, i.e. before it was re-discovered and studied in detail by W. Röntgen.

30 In publications on this topic (whose development peak was in the 1920-1930s), the Gaussian units are more common, and the letter \(Z\) is usually reserved for expressing charges as multiples the fundamental charge \(e\), rather than for the wave impedance. This is why, in order to avoid confusion and facilitate the comparison with other texts, in this section I (still staying with the SI units used through my series) will use the fraction \(1/\varepsilon_0c\), instead of its equivalent \(Z_0\), for the free-space wave impedance, and write the coefficients in a form that makes the transfer to the Gaussian units trivial: it is sufficient to replace all \((qq'/4\pi\varepsilon_0)_{\text{SI}}\) with \((qq')_{\text{Gaussian}}\). In the (rare) cases when I spell out the charge values, I will use a different font: \(q \equiv \tilde{q}e\), \(q' \equiv \tilde{q}'e\).

31 A more careful analysis shows that this approximation is actually quite reasonable up to much higher frequencies, of the order of \(\gamma^2/\tau\).
use the so-called low-frequency approximation, taking the exponent in Eq. (75) for \( l \) through the whole collision event, i.e. the integration interval. This approximation immediately yields

\[
I(\omega) = \frac{1}{4\pi^2c} \frac{q^2}{4\pi \varepsilon_0} \frac{n \times (n \times \beta_{\text{fin}}) - n \times (n \times \beta_{\text{ini}})}{1 - \beta_{\text{fin}} \cdot n - 1 - \beta_{\text{ini}} \cdot n}^2.
\] (10.76)

In the non-relativistic limit (\( \beta_{\text{ini}}, \beta_{\text{fin}} \ll 1 \)), this formula in reduced to the result

\[
I(\omega) = \frac{1}{4\pi^2c} \frac{q^2}{4\pi \varepsilon_0} \frac{\mathbf{q}^2}{m^2c^2} \sin^2 \theta
\]

(which may be derived from Eq. (8.27) as well), where \( \mathbf{q} \) is the momentum transferred from the scattering center to the scattered charge (Fig. 13b):32

\[
\mathbf{q} \equiv \mathbf{p}_{\text{fin}} - \mathbf{p}_{\text{ini}} = m\Delta \mathbf{u} = mc\Delta \mathbf{\beta} = mc(\beta_{\text{fin}} - \beta_{\text{ini}}),
\]

and \( \theta \) (not to be confused with the particle scattering angle \( \theta' \) shown in Fig. 13) is the angle between the vector \( \mathbf{q} \) and the direction \( \mathbf{n} \) toward the observer – at the collision moment.

The most important feature of the result (77)-(78) is the frequency-independent (“white”) spectrum of the radiation, very typical for any rapid leaps, which may be approximated as delta-functions of time.33 (Note, however, that Eq. (77) implies a fixed value of \( q \), so that the statistics of this parameter, to be discussed in a minute, may “color” the radiation.) Note also the “doughnut-shaped” angular distribution of the radiation, typical for non-relativistic systems, with the symmetry axis directed along the momentum transfer vector \( \mathbf{q} \). In particular, this means that in typical cases when \( q \ll p \), i.e. when the vector \( \mathbf{q} \) is nearly normal to the vector \( \mathbf{p}_{\text{ini}} \) (see, e.g., the example shown in Fig. 13b), the bremsstrahlung produces a significant radiation flow in the direction back to the particle source – the fact significant for the operation of X-ray tubes. Now integrating Eq. (77) over all wave propagation angles, just as we did for the instant radiation power in Sec. 8.2, we get the following spectral density of the particle energy loss,

\[
\frac{-d\varepsilon}{d\omega} = \frac{1}{4\pi} \int I(\omega) d\Omega = \frac{2}{3\pi c^2} \frac{q^2}{4\pi^2 \varepsilon_0} \frac{\mathbf{q}^2}{m^2c^2}.
\]

32 Please note the font-marked difference between this variable (\( q \)) and the particle’s electric charge (\( q \)).

33 This is the foundation, in particular, of the so-called High-Harmonic Generation (HHG) effect, discovered in 1977, which takes place at the irradiation of gases by intensive laser beams. The high electric field of the beam strips valent electrons from initially neutral atoms, and accelerates them away from the remaining ions, just to slam them back into the ions as the field’s polarity changes in time. The electrons change their momentum sharply during their recombination with the ions, resulting in a bremsstrahlung-like radiation. The spectrum of radiation from each such event obeys Eq. (77), but since the ionization/acceleration/recombination cycles repeat periodically with the frequency \( \omega_0 \) of the laser field, the final spectrum consists of many equidistant lines, with frequencies \( n\omega_0 \). The classical theory of the bremsstrahlung does not give a cutoff \( \omega_{\text{max}} = n_{\text{max}}\omega_0 \) of the spectrum, but such a limit is imposed by quantum mechanics: \( \hbar \omega_{\text{max}} \sim E_p \), where the so-called ponderomotive energy \( E_p = (eE_0/\omega_0)^2/4m_e \) is the average kinetic energy given to a free electron by the periodic electric field of the laser beam, with amplitude \( E_0 \). In practice, \( n_{\text{max}} \) may be as high as \( \sim 100 \), enabling alternative compact sources of X-ray radiation. For a detailed quantitative theory of this effect, see, for example, M. Lewenstein et al., Phys. Rev. A 49, 2117 (1994).
In most applications of the bremsstrahlung theory (as in most scattering problems\textsuperscript{34}), the impact parameter \( b \) (Fig. 13a), and hence the scattering angle \( \theta' \) and the transferred momentum \( q \), have to be considered random. For elastic (\( \beta_{\text{ini}} = \beta_{\text{fin}} \equiv \beta \)) Coulomb collisions we can use the well-known \textit{Rutherford formula} for the differential cross-section of scattering\textsuperscript{35}

\[
\frac{d\sigma}{d\Omega'} = \left( \frac{qq'}{4\pi\varepsilon_0} \right)^2 \left( \frac{1}{2pc\beta} \right)^2 \frac{1}{\sin^4(\theta'/2)}.
\] (10.80)

Here \( d\sigma = 2\pi bdb \) is the elementary area of the sample cross-section (as visible from the direction of incident particles) corresponding to particle scattering into an elementary body angle\textsuperscript{36}

\[
d\Omega' = 2\pi \sin \theta' d\theta'.
\] (10.81)

Differentiating the geometric relation, which is evident from Fig. 13b,

\[
q = 2p \sin \theta',
\] (10.82)

we may represent Eq. (80) in a more convenient form

\[
\frac{d\sigma}{dq} = 8\pi \left( \frac{qq'}{4\pi\varepsilon_0} \right)^2 \frac{1}{u^2 q^3}.
\] (10.83)

Now combining Eqs. (79) and (83), we get

\[
-\frac{dE}{d\omega} \frac{d\sigma}{dq} = 16 \frac{q^2}{3} \left( \frac{qq'}{4\pi\varepsilon_0 mc^2} \right)^2 \frac{1}{c\beta^2 q} \ln \frac{q_{\text{max}}}{q_{\text{min}}}.
\] (10.84)

This product is called the \textit{differential radiation cross-section}. When integrated over all values of \( q \) (which is equivalent to averaging over all values of the impact parameter), it gives a convenient measure of the radiation intensity. Indeed, after the multiplication by the volume density \( n \) of independent scattering centers, such integral yields the particle’s energy loss per unit bandwidth of radiation per unit path length, \(-d^2\varepsilon/d\omega dx\). A minor problem here is that the integral of \( 1/q \) formally diverges at both infinite and vanishing values of \( q \). However, these divergences are very weak (logarithmic), and the integral converges due to virtually any reason unaccounted for in our simple analysis. The standard, though slightly approximate way to account for these effects is to write

\[
-\frac{d^2\varepsilon}{d\omega dx} \approx \frac{16}{3} n \frac{q^2}{4\pi\varepsilon_0} \left( \frac{qq'}{4\pi\varepsilon_0 mc^2} \right)^2 \frac{1}{c\beta^2 \ln \frac{q_{\text{max}}}{q_{\text{min}}}},
\] (10.85)

and then plug, instead of \( q_{\text{max}} \) and \( q_{\text{min}} \), the scales of the most important effects limiting the range of the transferred momentum’s magnitude. At the classical-mechanics analysis, according to Eq. (82), \( q_{\text{max}} = \)

\textsuperscript{34} See, e.g., CM Sec. 3.5 and QM Sec. 3.3.

\textsuperscript{35} See, e.g., CM Eq. (3.73) with \( \alpha = qq'/4\pi \omega_0 \). In the form used in Eq. (80), the Rutherford formula is also valid for small-angle scattering of relativistic particles, the criterion being \( |\Delta \beta| \ll 2/\gamma \).

\textsuperscript{36} Again, the angle \( \theta' \) and the differential \( d\Omega' \), describing the scattered \textit{particles} (see Fig. 13) should not be confused with the parameters \( \theta \) and \( d\Omega \) describing the \textit{radiation} emitted at the scattering event.
$2p \equiv 2mu$. To estimate $q_{\text{min}}$, let us note that the very small momentum transfer takes place when the impact parameter $b$ is very large and hence the effective scattering time $\tau \sim b/v$ is very long. Recalling the condition of the low-frequency approximation, we may associate $q_{\text{min}}$ with $\tau \sim 1/\omega$ and hence with $b \sim u\tau \sim v/\omega$. Since for the small scattering angles, $q$ is close to the impulse $F \tau \sim (qq'/4\pi\varepsilon_0 b^2)\tau$ of the Coulomb force, we get the estimate $q_{\text{min}} \sim (qq'/4\pi\varepsilon_0)\omega/u^2$, and Eq. (85) should be used with

$$\ln \frac{q_{\text{max}}}{q_{\text{min}}} = \ln \left( \frac{2mu^3}{\omega} \sqrt[4]{\frac{qq'}{4\pi\varepsilon_0}} \right).$$

(10.86)

This is the Bohr’s formula for what is called the classical bremsstrahlung. We see that the low momentum cutoff indeed makes the spectrum slightly colored, with more energy going to lower frequencies. There is even a formal divergence at $\omega \to 0$; however, this divergence is integrable, so it does not present a problem for finding the total energy radiative losses $(-d\varepsilon/dx)$ as an integral of Eq. (86) over all radiated frequencies $\omega$. A larger problem for this procedure is the upper integration limit, $\omega \to \infty$, at which the integral diverges. This means that our approximate description, which considers the collision as an elastic process, becomes invalid, and needs to be amended by taking into account the difference between the initial and final kinetic energies of the particle due to radiation of the energy quantum $\hbar\omega$ of the emitted photon, so that

$$p_{\text{fin}}^2/2m - p_{\text{ini}}^2/2m = \hbar\omega, \quad \text{i.e.} \quad \frac{p_{\text{ini}}^2}{2m} = \varepsilon, \quad \frac{p_{\text{fin}}^2}{2m} = \varepsilon - \hbar\omega, \quad .$$

(10.87)

As a result, taking into account that the minimum and maximum values of $q$ correspond to, respectively, the parallel and antiparallel alignments of the vectors $p_{\text{ini}}$ and $p_{\text{fin}}$, we get

$$\ln \frac{q_{\text{max}}}{q_{\text{min}}} = \ln \left( \frac{p_{\text{ini}} + p_{\text{fin}}}{p_{\text{ini}} - p_{\text{fin}}} \right) \equiv \ln \left( \frac{p_{\text{ini}} + p_{\text{fin}}}{2m} \right) = \ln \left( \frac{\varepsilon + \hbar\omega}{\varepsilon - \hbar\omega} \right)$$

$$= \ln \left( \frac{\varepsilon^{1/2} + (\varepsilon - \hbar\omega)^{1/2}}{\varepsilon^{1/2} - (\varepsilon - \hbar\omega)^{1/2}} \right)^2 = \ln \left( \frac{\varepsilon^{1/2} + (\varepsilon - \hbar\omega)^{1/2}}{\hbar\omega} \right)^2.$$

(10.88)

Plugged into Eq. (85), this expression yields the so-called Bethe-Heitler formula for quantum bremsstrahlung. Note that at this approach, $q_{\text{max}}$ is close to that of the classical approximation, but $q_{\text{min}}$ is of the order of $\hbar\omega/u$, so that

$$q_{\text{min}} \bigg|_{\text{classical}} \sim \frac{\alpha \tilde{Z} \tilde{Z}'}{\beta},$$

(10.89)

where $\tilde{Z}$ and $\tilde{Z}'$ are the particles’ charges in the units of $e$, and $\alpha$ is the dimensionless fine structure (“Sommerfeld”) constant,

$$\alpha \equiv \frac{e^2}{4\pi\varepsilon_0 \hbar c} \bigg|_{\text{SI}} \equiv \frac{e^2}{\hbar c} \bigg|_{\text{Gaussian}} \approx \frac{1}{137} \ll 1,$$

(10.90)

which is one of the basic notions of quantum mechanics. Due to the smallness of the constant, the ratio (89) is smaller than 1 for most cases of practical interest, and since the integral of (84) over \( \eta \) is limited by the largest of all possible cutoffs \( \eta_{\text{min}} \), it is the Bethe-Heitler formula which should be used.

Now nothing prevents us from calculating the total radiative losses of energy per unit length:

\[
- \frac{d \varepsilon}{d x} = \int_{0}^{\eta_{\text{max}}} \left( - \frac{d \varepsilon}{d \omega d \eta} \right) d \omega = \frac{16}{3} n \frac{q^2}{4 \pi \varepsilon_{0} c} \left( \frac{qq'}{4 \pi \varepsilon_{0} mc^2} \right)^2 \frac{1}{\beta^2} \frac{2}{h} \int_{0}^{\alpha_{\text{max}}} \ln \frac{\varepsilon^{1/2} - (\varepsilon - h \omega)^{1/2}}{(h \omega)^{1/2}} d \omega, \tag{10.91}
\]

where \( h \omega_{\text{max}} = \epsilon \) is the maximum energy of the radiation quantum. By introducing the dimensionless integration variable \( \xi \equiv h \omega / \epsilon = 2 h \omega (m \gamma^2 / 2) \), this integral is reduced to the table one, and we get

\[
- \frac{d \varepsilon}{d x} = \frac{16}{3} n \frac{q^2}{4 \pi \varepsilon_{0} c} \left( \frac{qq'}{4 \pi \varepsilon_{0} mc^2} \right)^2 \frac{1}{\beta^2} \frac{2}{h} \frac{u^2}{\gamma^2 b^2 + \gamma^2 u^2 t^2} \int_{0}^{\alpha_{\text{max}}} \frac{1}{\xi} d \xi = \frac{qq'}{4 \pi \varepsilon_{0} b u}. \tag{10.92}
\]

In my usual style, at this point I would give you an estimate of the losses for a typical case; however, let me first discuss a parallel energy loss mechanism, the so-called Coulomb losses, due to the transfer of mechanical impulse from the scattered particle to the scattering centers. (This energy eventually goes into an increase of the thermal energy of the scattering medium, rather than to the electromagnetic radiation.)

Using Eqs. (9.139) for the electric field of a linearly moving charge \( q \), we can readily find the momentum it transfers to the counterpart charge \( q' \):

\[
\Delta p' = \left( \frac{\Delta p}{\gamma} \right)_{\gamma} = \int_{-\infty}^{\infty} (\gamma p')_{\gamma} d t = \int_{-\infty}^{\infty} q' E_{x} d t = \frac{qq'}{4 \pi \varepsilon_{0} b u} \int_{-\infty}^{\infty} \frac{\gamma b}{\gamma^2 u^2 + \gamma^2 u^2 b^2} \frac{1}{\gamma^2 u^2 + \gamma^2 u^2 b^2} d t = \frac{qq'}{4 \pi \varepsilon_{0} b u}. \tag{10.93}
\]

Hence, the kinetic energy acquired by the scattering particle (and hence to the loss of the energy \( \varepsilon \) of the incident particle) is

\[
- \Delta \varepsilon = \frac{(\Delta p')^2}{2 m'} = \frac{qq'^2}{4 \pi \varepsilon_{0} b u}. \tag{10.94}
\]

Such elementary energy losses have to be summed up over all collisions, with random values of the impact parameter \( b \). At the scattering center density \( n \), the number of collisions per small path length \( dx \) per small range \( db \) is \( dN = n 2 \pi b db \) \( dx \), so that

\[
- \frac{d \varepsilon}{d x} = \int (- \Delta \varepsilon) dN = n \frac{qq'}{4 \pi \varepsilon_{0} b u} \int_{b_{\text{min}}}^{b_{\text{max}}} \frac{2 \pi}{b_{\text{min}}} d b = 4 \pi n \frac{qq'}{4 \pi \varepsilon_{0} b u} \ln B \frac{b_{\text{max}}}{b_{\text{min}}}, \quad \text{where } B \equiv \frac{b_{\text{max}}}{b_{\text{min}}}. \tag{10.95}
\]

Here the logarithmic integral over \( b \) was treated similarly to that over \( \eta \) in the bremsstrahlung theory. This approach is adequate, because the ratio \( b_{\text{max}} / b_{\text{min}} \) is much larger than 1. Indeed, \( b_{\text{min}} \) may be estimated from \( (\Delta p')_{\max} \sim p = \gamma m u \). For this value, Eq. (93) with \( q' \sim q \) gives \( b_{\text{min}} \sim r_{c} \) (see Eq. (8.41) and

---

38 See, e.g., QM Secs. 4.4, 6.3, 6.4, 9.3, 9.5, and 9.7.
39 See, e.g., MA Eq. (6.14).
40 According to Eq. (9.139), \( E_{x} = 0 \), and the net impulse of the longitudinal force \( q' E_{x} \) is zero.
its discussion), which, for elementary particles, is of the order of $10^{-15}$ m. On the other hand, for the most important case when the charges $q'$ belong to electrons (which, according to Eq. (94), are the most efficient Coulomb energy absorbers, due to their extremely low mass $m'$), $b_{\text{max}}$ may be estimated from the condition $\tau = b/\gamma u \sim 1/\omega_{\text{max}}$, where $\omega_{\text{max}} \sim 10^{16}$ s$^{-1}$ is the characteristic frequency of electron transitions in atoms. (Below this frequency, our classical analysis of scatterer’s motion is invalid, while quantum theory excludes the energy transfer.) From here, we have the estimate $b_{\text{max}} \sim \gamma u / \omega_{\text{max}}$, so that

$$B \equiv \frac{b_{\text{max}}}{b_{\text{min}}} \sim \frac{\gamma u}{r_c \omega_0},$$

(10.96)

for $\gamma \sim 1$ and $u \sim c \approx 3 \times 10^8$ m/s giving $b_{\text{max}} \sim 3 \times 10^{-8}$ m, so that $B \sim 10^9$ (give or take a couple orders of magnitude – this does not change the estimate ln$B \approx 20$ too much). 41

Now we can compare the non-radiative Coulomb losses (95) with the radiative losses due to the bremsstrahlung, given by Eq. (92):

$$\frac{-d\mathcal{E}_{\text{radiation}}}{-d\mathcal{E}_{\text{Coulomb}}} \sim \frac{m'}{m} \beta^2 \frac{1}{\ln B},$$

(10.97)

Since $\alpha \sim 10^{-2} << 1$, for non-relativistic particles ($\beta << 1$) the bremsstrahlung losses of energy are much lower (this is why we did not need to rush with their estimate), and only for ultra-relativistic particles, the relation may be opposite.

According to Eq. (95), for electron-electron scattering ($q = q' = -e$, $m' = m_e$), 42 at the value $n = 6 \times 10^{26}$ m$^{-3}$ typical for air at ambient conditions, the characteristic length of energy loss,

$$l_c \equiv \frac{\mathcal{E}}{(-d\mathcal{E}/dx)},$$

(10.98)

for electrons with kinetic energy $\mathcal{E} = 6$ keV is close to $2 \times 10^{-4}$ m $\equiv 0.2$ mm. (This is why we need high vacuum in particle accelerators and electron microscope columns!) Since $l_c \propto \mathcal{E}^2$, more energetic particles penetrate to matter deeper, until the bremsstrahlung steps in, and limits this trend at very high energies.

### 10.5. Density effects and the Cherenkov radiation

For condensed matter, the Coulomb loss estimate made in the last section is not quite suitable, because it is based on the upper cutoff $b_{\text{max}} \sim \gamma u / \omega_{\text{max}}$. For the example given above, the incoming electron velocity $u$ is close to $5 \times 10^7$ m/s, and for the typical value $\omega_{\text{max}} \sim 10^{16}$ s$^{-1}$ ($\hbar \omega_{\text{max}} \sim 10$ eV), this

---

41 A quantum analysis (carried out by Hans Bethe in 1940) replaces, in Eq. (95), $\ln B$ with $\ln(2 \gamma^2 m u^2 / \hbar \langle \omega \rangle) - \beta^2$, where $\langle \omega \rangle$ is the average frequency of the atomic quantum transitions weight by their oscillator strength. This refinement does not change the estimate given below. Note that both the classical and quantum formulas describe a fast increase (as $1/\beta$) of the energy loss rate $(-d\mathcal{E}/dx)$ at $\gamma \to 1$, and its slow increase (as $\ln \gamma$) at $\gamma \to \infty$, so that the losses have a minimum at $(\gamma - 1) \sim 1$.

42 Actually, the above analysis has neglected the change of momentum of the incident particle. This is legitimate at $m' << m$, but for $m = m'$ the change approximately doubles the energy losses. Still, this does not change the order of magnitude of the estimate.
cutoff $b_{\text{max}}$ is of the order of $\sim 5 \times 10^{-9}$ m = 5 nm. Even for air at ambient conditions, this cutoff is larger than the average distance ($\sim 2$ nm) between the molecules, so that at the high end of the impact parameter range, at $b \sim b_{\text{max}}$, the Coulomb loss events in adjacent molecules are not quite independent, and the theory needs some corrections. For condensed matter, with much higher particle density $n$, most collisions satisfy the following condition:

$$nb^3 \gg 1,$$

(10.99)

and the treatment of Coulomb collisions as independent events is inadequate. However, this condition enables the opposite approach: treating the medium as a continuum. In the time-domain formulation, used in the previous sections of this chapter, this would be a very complex problem, because it would require an explicit description of the medium dynamics. Here the frequency-domain approach, based on the Fourier transform in both time and space, helps a lot, provided that the functions $\varepsilon(\omega)$ and $\mu(\omega)$ are considered known – either calculated or taken from experiment. Let us have a good look at this approach, because it gives some interesting (and practically important) results.

In Chapter 6, we have used the macroscopic Maxwell equations to derive Eqs. (6.118), which describe the time evolution of electrodynamic potentials in a linear medium with frequency-independent $\varepsilon$ and $\mu$. Looking for all functions participating in Eqs. (6.118) in the form of plane-wave expansion

$$f(\mathbf{r}, t) = \int d^3k \int d\omega f_{k,\omega} e^{i(k \cdot \mathbf{r} - \omega t)},$$

(10.100)

and requiring all coefficients at similar exponents to be balanced, we get their Fourier images:

$$\left(k^2 - \omega^2 \varepsilon \mu\right) \phi_{k,\omega} = \frac{\rho_{k,\omega}}{\varepsilon}, \quad \left(k^2 - \omega^2 \varepsilon \mu\right) \mathbf{A}_{k,\omega} = \mu \mathbf{j}_{k,\omega}.$$  

(10.101)

As was discussed in Chapter 7, in such a Fourier form, the macroscopic Maxwell theory remains valid even for the dispersive (but isotropic and linear!) media, so that Eqs. (101) may be generalized as

$$\left[k^2 - \omega^2 \varepsilon(\omega) \mu(\omega)\right] \phi_{k,\omega} = \rho_{k,\omega} \frac{\varepsilon(\omega)}{\varepsilon(\omega) - \mu(\omega)} \mu(\omega) \mathbf{j}_{k,\omega}, \quad \left[k^2 - \omega^2 \varepsilon(\omega) \mu(\omega)\right] \mathbf{A}_{k,\omega} = \mu(\omega) \mathbf{j}_{k,\omega},$$

(10.102)

The evident advantage of these equations is that their formal solution is trivial:

$$\phi_{k,\omega} = \frac{\rho_{k,\omega}}{\varepsilon(\omega) \left[k^2 - \omega^2 \varepsilon(\omega) \mu(\omega)\right]}, \quad \mathbf{A}_{k,\omega} = \frac{\mu(\omega) \mathbf{j}_{k,\omega}}{\left[k^2 - \omega^2 \varepsilon(\omega) \mu(\omega)\right]},$$

(10.103)

so that the “only” remaining things to do is to, first, calculate the Fourier transforms of the functions $\rho(\mathbf{r}, t)$ and $\mathbf{j}(\mathbf{r}, t)$, describing stand-alone charges and currents, using the transform reciprocal to Eq. (100), with one factor $1/2\pi$ per each scalar dimension,

$$f_{k,\omega} = \frac{1}{(2\pi)^d} \int d^3r \int dt f(\mathbf{r}, t)e^{-i(k \cdot \mathbf{r} - \omega t)},$$

(10.104)

43 All integrals here and below are in infinite limits, unless specified otherwise.

44 As was discussed in Sec. 7.2, the Ohmic conductivity of the medium (generally, also a function of frequency) may be readily incorporated into the dielectric permittivity: $\varepsilon(\omega) \rightarrow \varepsilon_0(\omega) + i\sigma(\omega)/\omega$. In this section, I will assume that such incorporation, which is especially natural for high frequencies, has been performed, so that the current density $\mathbf{j}(\mathbf{r}, t)$ describes only stand-alone currents – for example, the current (105) of the incident particle.
and then carry out the integration (100) of Eqs. (103).

For our current problem of a single charge \( q \), uniformly moving in the medium with velocity \( u \),

\[
\rho(r, t) = q \delta(r - ut), \quad j(r, t) = qu \delta(r - ut),
\]

(10.105)

the first task is easy:

\[
\rho_{k,\omega} = \frac{q}{(2\pi)^4} \int d^3 r \int dt \, q \delta(r - ut) e^{-i(k \cdot r - \omega t)} = \frac{q}{(2\pi)^4} \int e^{i(\omega t - k \cdot u)} dt = \frac{q}{(2\pi)^3} \delta(\omega - k \cdot u).
\]

(10.106)

Since the expressions (105) for \( \rho(r, t) \) and \( j(r, t) \) differ only by a constant factor \( u \), it is clear that the absolutely similar calculation for the current gives

\[
j_{k,\omega} = \frac{qu}{(2\pi)^3} \delta(\omega - k \cdot u).
\]

(10.107)

Let us summarize what we have got by now, plugging Eqs. (106) and (107) into Eqs. (103):

\[
\Phi_{k,\omega} = \frac{1}{(2\pi)^3} q \delta(\omega - k \cdot u), \quad A_{k,\omega} = \frac{1}{(2\pi)^3} \frac{\mu(\omega)q u \delta(\omega - k \cdot u)}{k^2 - \omega^2 \epsilon(\omega) \mu(\omega)} = \mathcal{E}(\omega) \mu(\omega) u \Phi_{k,\omega},
\]

(10.108)

Now, at the last calculation step, namely the integration (100), we are starting to pay a heavy price for the easiness of the first steps. This is why let us think well what exactly do we need from it. First of all, for the calculation of power losses, the electric field is more convenient to use than the potentials, so let us calculate the Fourier images of \( E \) and \( B \). Plugging the expansion (100) into the basic relations (6.7), and again requiring the balance of exponent’s coefficients, we get

\[
E_{k,\omega} = -ik \Phi_{k,\omega} + i\omega A_{k,\omega} = i[\omega \mathcal{E}(\omega) \mu(\omega) u - k] \Phi_{k,\omega}, \quad B_{k,\omega} = i/k \times A_{k,\omega} = i\epsilon(\omega) \mu(\omega) k \times u \Phi_{k,\omega},
\]

(10.109)

so that Eqs. (100) and (108) yield

\[
E(r, t) = \int d^3 k \int d\omega \, E_{k,\omega} e^{ik \cdot r - \omega t} = \frac{iq}{(2\pi)^3} \int d^3 k \int d\omega \, \frac{\omega \mathcal{E}(\omega) \mu(\omega) u - k}{\mathcal{E}(\omega) [k^2 - \omega^2 \mathcal{E}(\omega) \mu(\omega)]} \delta(\omega - k \cdot u) e^{ik \cdot r - \omega t}.
\]

(10.110)

This formula may be rewritten as the temporal Fourier integral (51), with an \( r \)-dependent amplitude

\[
E_{\omega}(r) = \int E_{k,\omega} e^{ik \cdot r} d^3 k = \frac{iq}{(2\pi)^3} \int \frac{\omega \mathcal{E}(\omega) \mu(\omega) u - k}{\mathcal{E}(\omega) [k^2 - \omega^2 \mathcal{E}(\omega) \mu(\omega)]} e^{ik \cdot r} d^3 k.
\]

(10.111)

Let us calculate the Cartesian components of this partial Fourier image \( E_{\omega} \) at a point separated by distance \( b \) from the particle’s trajectory. Selecting the coordinates and time origin as shown in Fig. 9.11a, we have \( r = \{0, b, 0\} \), so that only \( E_x \) and \( E_y \) are different from zero. In particular, according to Eq. (111),

\[
(E_x)_{\omega} = \frac{iq}{(2\pi)^3 \mathcal{E}(\omega)} \int dk_x \int dk_y \int dk_z \frac{\omega \mathcal{E}(\omega) \mu(\omega) u - k_x}{k_x^2 - \omega^2 \mathcal{E}(\omega) \mu(\omega)} \delta(\omega - k_x u) \exp ik_y b.
\]

(10.112)

The delta-function kills one integral (over \( k_z \)) of the three, and we get
\[(E_x)_\omega = \frac{iq}{(2\pi)^3 \epsilon(\omega)u} \left[ \omega \epsilon(\omega) \mu(\omega) u - \frac{\omega}{u} \right] \int \exp\{ik_y b\} dk_y \int \frac{dk_z}{\omega^2 / u^2 + k_y^2 + k_z^2 - \omega^2 \epsilon(\omega) \mu(\omega)}. \quad (10.113)\]

The internal integral (over \(k_z\)) may be readily reduced to the table integral \[d\xi(1 + \xi^2),\] in infinite limits, equal to \(\pi.\) The result may be represented as

\[(E_x)_\omega = -\frac{i\pi q k^2}{(2\pi)^3 \omega \epsilon(\omega)} \int \exp\{ik_y b\} \left( k_y^2 + \kappa^2 \right)^{1/2} dk_y, \quad (10.114)\]

where the parameter \(\kappa\) (generally, a complex function of frequency) is defined as

\[\kappa^2(\omega) \equiv \omega^2 \left( \frac{1}{u^2} - \epsilon(\omega) \mu(\omega) \right). \quad (10.115)\]

The last integral may be expressed via the modified Bessel function of the second kind:

\[(E_x)_\omega = -\frac{iq u \kappa^2}{(2\pi)^3 \omega \epsilon(\omega)} K_0(\kappa b). \quad (10.116)\]

A very similar calculation yields

\[(E_x)_\omega = -\frac{q \kappa}{(2\pi)^3 \epsilon(\omega)} K_1(\kappa b). \quad (10.117)\]

Now, instead of rushing to make the final integration (51) over \(\omega\) to calculate \(E(t)\), let us realize that what we need most is actually the total energy loss through the whole time of particle’s passage over an elementary distance \(dx\). According to Eq. (4.38), the energy loss per unit volume is

\[-\frac{d\epsilon}{dV} = \int j \cdot E dt, \quad (10.118)\]

where \(j\) is the current of the bound charges in the medium, and should not be confused with the standalone particle’s current (105). This integral may be readily expressed via the partial Fourier image \(E_{\omega}\) and the similarly defined image \(j_{\omega}\), just as it was done at the derivation of Eq. (54):

\[-\frac{d\epsilon}{dV} = \int dt \int d\omega e^{-i\omega t} \int d\omega' e^{-i\omega' t} j_{\omega} \cdot E_{\omega'} = 2\pi \int d\omega j_{\omega} \cdot E_{\omega} \delta(\omega + \omega') = 2\pi \int j_{\omega} \cdot E_{-\omega} d\omega. \quad (10.119)\]

Let us incorporate the effective Ohmic conductivity \(\sigma_{\epsilon}(\omega)\) into the complex permittivity \(\epsilon(\omega)\) just as this was discussed in Sec. 7.2, using Eq. (7.46) to write

\[j_{\omega} = \sigma_{\epsilon}(\omega) E_{\omega} = -i \omega \epsilon(\omega) E_{\omega}. \quad (10.120)\]

As a result, Eq. (119) yields

---

45 See, e.g., MA Eq. (6.5a).
46 Of course, the frequency-dependent parameter \(\kappa(\omega)\) should not be confused with the dc low-frequency dielectric constant \(\kappa \equiv \epsilon(0)/\epsilon_0\), which was discussed in Chapter 3.
47 As a reminder, the main properties of these functions are listed in Sec. 2.7 – see, in particular, Fig. 2.22 and Eqs. (2.157)-(2.158).
\[-\frac{dE}{dV} = -2\pi i \int \mathcal{E}(\omega) \mathbf{E}_\omega \cdot \mathbf{E}_{-\omega} \omega d\omega = 4\pi \operatorname{Im} \int_0^\infty \mathcal{E}(\omega) |E_\omega|^2 \omega d\omega. \quad (10.121)\]

(The last step was possible due to the property \(\mathcal{E}(-\omega) = \mathcal{E}^*(\omega)\), which was discussed in Sec. 7.2.)

Finally, just as in the last section, we have to average the energy loss rate over random values of the impact parameter \(b\):

\[-\frac{dE}{dx} = \int \left( -\frac{dE}{dV} \right) d^2 b \approx 2\pi \int_{b_{\text{min}}}^\infty \left( -\frac{dE}{dV} \right) bdb = 8\pi^2 \int_{b_{\text{min}}}^\infty bdb \int_0^\infty \left( |E_x|^2 + |E_y|^2 \right) \operatorname{Im} \mathcal{E}(\omega) \omega d\omega. \quad (10.122)\]

Due to the divergence of the functions \(K_0(\xi)\) and \(K_1(\xi)\) at \(\xi \to 0\) we have to cut the resulting integral over \(b\) at some \(b_{\text{min}}\) where our theory loses legitimacy. (On that limit, we are not doing much better than in the past section). Plugging in the calculated expressions (116) and (117) for the field components, swapping the integrals over \(\omega\) and \(b\), and using the recurrence relations (2.142), which are valid for any Bessel functions, we finally get:

\[-\frac{dE}{dx} = 2q^2 \int_0^\infty \left( \kappa^* b_{\text{min}} \right) K_1(\kappa^* b_{\text{min}}) K_0(\kappa^* b_{\text{min}}) \frac{d\omega}{\omega \epsilon(\omega)} \left( \kappa^* \right) \left( \kappa^* \right). \quad (10.123)\]

This general result is valid for an arbitrary linear medium, with arbitrary dispersion relations \(\epsilon(\omega)\) and \(\mu(\omega)\). (The last function participates in Eq. (123) only via Eq. (115) that defines the parameter \(\kappa\).) To get more concrete results, some particular model of the medium should be used. Let us explore the Lorentz oscillator model, which was discussed in Sec. 7.2, in its form (7.33) suitable for the transition to the quantum-mechanical description of atoms:

\[\epsilon(\omega) = \epsilon_0 + \frac{nq^2}{m} \sum_j \frac{f_j}{(\omega_j^2 - \omega^2)^2}, \quad \text{with} \quad \sum_j f_j = 1; \quad \mu(\omega) = \mu_0. \quad (10.124)\]

If the damping of the effective atomic oscillators is low, \(\delta_j \ll \omega_j\), as it typically is, and the particle’s speed \(u\) is much lower than the typical wave’s phase velocity \(v\) (and hence \(c\)), then for most frequencies Eq. (115) gives

\[\kappa^2(\omega) \equiv \omega^2 \left( \frac{1}{u^2} - \frac{1}{v^2(\omega)} \right) \approx \frac{\omega^2}{u^2}, \quad (10.125)\]

i.e. \(\kappa \approx \kappa^* \approx \omega/\mu\) is real. In this case, Eq. (123) may be shown to reduce to Eq. (95) with

\[b_{\text{max}} = \frac{1.123u}{\langle \omega \rangle}. \quad (10.126)\]

The good news here is that both approaches (the microscopic analysis of Sec. 4 and the macroscopic analysis of this section) give essentially the same result. The same fact may be also perceived as bad news: the treatment of the medium as a continuum does not give any new results here. The situation somewhat changes at relativistic velocities, at which such treatment provides noticeable corrections (called density effects), in particular reducing the energy loss estimates.

Let me, however, skip these details and focus on a much more important effect described by our formulas. Consider the dependence of the electric field components on the impact parameter \(b\), i.e. on
the closest distance between the particle’s trajectory and the field observation point. If \( \kappa^2 > 0 \), then \( \kappa \) is real, and we can use, in Eqs. (116)-(117), the asymptotic formula (2.158),
\[
K_\kappa(\xi) \to \left( \frac{\pi}{2\xi} \right)^{1/2} e^{-\xi}, \quad \text{at} \quad \xi \to \infty,
\]
(10.127)
to conclude that the complex amplitudes \( E_\omega \) of both components \( E_x \) and \( E_y \) of the electric field decrease with \( b \) exponentially. However, let us consider what happens at frequencies where \( \kappa^2(\omega) < 0 \), i.e.
\[
\kappa(\omega) \equiv \frac{1}{v^2(\omega)} < \frac{1}{u^2} < \frac{1}{c^2} \equiv \varepsilon_0 \mu_0.
\]
(10.128)
(This condition means that the particle’s velocity is larger than the phase velocity of the waves, at this particular frequency.) In these intervals, the parameter \( \kappa(\omega) \) is purely imaginary,\(^{48}\) so that the functions \( \exp\{i\kappa b\} \) in the asymptotes (127) of Eqs. (116)-(117) become just phase factors, and the field component amplitudes fall very slowly:
\[
|E_x(\omega)| \propto |E_y(\omega)| \propto \frac{1}{b^{1/2}}.
\]
(10.129)
This means that the Poynting vector drops as \( 1/b \), so that its flux through a surface of a round cylinder of radius \( b \), with the axis on the particle trajectory (i.e. the power flow from the trajectory), does not depend on \( b \) at all. This is a wave emission – the famous Cherenkov radiation.\(^{49}\)

The direction \( \mathbf{n} \) of its propagation may be readily found taking into account that at large distances from the particle’s trajectory, the emitted wave has to be locally planar and transverse \((\mathbf{n} \perp \mathbf{E})\), so that the so-called Cherenkov angle \( \theta \) between the vector \( \mathbf{n} \) and the particle’s velocity \( \mathbf{u} \) may be simply found from the ratio of the electric field components – see Fig. 14a:
\[
\tan \theta = -\frac{E_x}{E_y}.
\]
(10.130)

Fig. 10.14. (a) The Cherenkov radiation’s propagation angle \( \theta \), and (b) its interpretation.

\(^{48}\) Strictly speaking, the inequality \( \kappa^2(\omega) < 0 \) does not make sense for a medium with a complex product \( \varepsilon(\omega)\mu(\omega) \), and hence complex \( \kappa^2(\omega) \). However, in a typical medium where particles can propagate over substantial distances, the imaginary part of the product \( \varepsilon(\omega)\mu(\omega) \) does not vanish only in very limited frequency intervals, much more narrow than the intervals that we are discussing now – please have one more look at Fig. 7.5.

\(^{49}\) This radiation was observed experimentally by Pavel Alekseevich Cherenkov (in older Western texts, “Čerenkov”) in 1934, with the observations explained by Ilya Mikhailovich Frank and Igor Yevgenyevich Tamm in 1937. Note, however, that the effect had been predicted theoretically as early as in 1889 by the same O. Heaviside, whose name was mentioned in this course so many times – and whose genius I believe is still underappreciated.
The ratio on the right-hand side may be calculated by plugging the asymptotic formula (127) into Eqs. (116) and (117) and calculating their ratio:

\[
\tan \theta = -\frac{E_x}{E_y} = \frac{iku}{\omega} = \left[\varepsilon(\omega)\mu(\omega)u^2 - 1\right]^{1/2} = \left(\frac{u^2}{v^2(\omega)} - 1\right)^{1/2},
\]
so that

\[
\cos \theta = \frac{v(\omega)}{u} < 1.
\]

Remarkably, this direction does not depend on the emission time \( t_{\text{ret}} \), so that the radiation of frequency \( \omega \), at each instant, forms a hollow cone led by the particle. This simple result allows an evident interpretation (Fig. 14b): the cone’s interior is just the set of all observation points that have already been reached by the radiation, propagating with the speed \( v(\omega) < u \), emitted from all previous points of the particle’s trajectory by the given time \( t \). This phenomenon is closely related to the so-called Mach cone in fluid dynamics,\(^{50}\) besides that in the Cherenkov radiation, there is a separate cone for each frequency (of the range in which \( v(\omega) < u \)): the smaller is the \( \varepsilon(\omega)\mu(\omega) \) product, i.e. the higher is the wave velocity \( v(\omega) = 1/\left[\varepsilon(\omega)\mu(\omega)\right]^{1/2} \), and the broader is the cone, so that the earlier the corresponding “shock wave” arrives to an observer. Please note that the Cherenkov radiation is a unique radiative phenomenon: it takes place even if a particle moves without acceleration, and (in agreement with our analysis in Sec. 2), is impossible in the free space, where \( v(\omega) = c = \text{const} \) is larger than \( u \) for any particle.

The intensity of the Cherenkov radiation intensity may be also readily found by plugging the asymptotic expression (127), with imaginary \( \kappa \), into Eq. (123). The result is

\[
-\frac{d\mathcal{E}}{dx} \approx \left(\frac{\kappa e}{4\pi}\right)^2 \int_{v(\omega)<u} \omega \left[1 - \frac{v^2(\omega)}{u^2}\right] d\omega.
\]

For non-relativistic particles \( (u << c) \), the Cherenkov radiation condition \( u > v(\omega) \) may be fulfilled only in relatively narrow frequency intervals where the product \( \varepsilon(\omega)\mu(\omega) \) is very large (usually, due to optical resonance peaks of the electric permittivity – see Fig. 7.5 and its discussion). In this case, the emitted light consists of a few nearly monochromatic components. On the contrary, if the condition \( u > v(\omega) \), i.e. \( u^2/\varepsilon(\omega)\mu(\omega) > 1 \) is fulfilled in a broad frequency range (as it is for ultra-relativistic particles in condensed media), the radiated power, according to Eq. (132), is dominated by higher frequencies of the range – hence the famous bluish color of the Cherenkov radiation glow from water nuclear reactors – see Fig. 15.

The Cherenkov radiation is broadly used for the detection of radiation in high energy experiments for particle identification and speed measurement (since it is easy to pass the particles through layers of various density and hence of various dielectric constant values) – for example, in the so-called Ring Imaging Cherenkov (RICH) detectors that have been designed for the DELPHI experiment\(^{51}\) at the Large Electron-Positron Collider (LEP) in CERN.

---

\(^{50}\) Its brief discussion may be found in CM Sec. 8.6.

A little bit counter-intuitively, the formalism described in this section is also very useful for the description of an apparently rather different effect – the so-called transition radiation that takes place when a charged particle crosses a border between two media.\textsuperscript{52} The effect may be interpreted as the result of the time dependence of the electric dipole formed by the moving charge $q$ and its mirror image $q'$ in the counterpart medium – see Fig. 16.

In the non-relativistic limit, this effect allows a straightforward description combining the electrostatics picture of Sec. 3.4 (see Fig. 3.9 and its discussion), and Eq. (8.27), corrected for the media polarization effects. However, if the particle’s velocity $u$ is comparable with the phase velocity of waves in either medium, the adequate theory of the transition radiation becomes very close to that of the Cherenkov radiation.

In comparison with the Cherenkov radiation, the transition radiation is rather weak, and its practical use (mostly for the measurement of the relativistic factor $\gamma$, to which the radiation intensity is nearly proportional) requires multi-layered stacks.\textsuperscript{53} In these systems, the radiation emitted at sequential borders may be coherent, and the system’s physics becomes close to that of the free-electron lasers, mentioned in Sec. 4.

\textsuperscript{52} The effect was predicted theoretically in 1946 by V. Ginzburg and I. Frank, and only later observed experimentally.

\textsuperscript{53} See, e.g., Sec. 5.3 in K. Kleinknecht’s monograph cited above.
10.6. Radiation’s back-action

An attentive and critically-minded reader could notice that so far our treatment of charged particle dynamics has never been fully self-consistent. Indeed, in Sec. 9.6 we have analyzed particle’s motion in various external fields, ignoring the fields radiated by particle itself, while in Sec. 8.2 and earlier in this chapter these fields have been calculated (admittedly, just for a few simple cases), but, again, their back-action on the emitting particle has been ignored. Only in very few cases we have taken the back effects of the radiation implicitly, via the energy conservation arguments. However, even in these cases, the near-field effects, such as the first term in Eq. (19), which affect the moving particle most, have been ignored.

At the same time, it is clear that in sharp contrast with electrostatics, the interaction of a moving point charge with its own field cannot be always ignored. As the simplest example, if an electron is made to fly through a resonant cavity, thus inducing electromagnetic oscillations in it, and then is forced (say, by an appropriate static field) to return into the cavity before the oscillations have decayed, its motion will certainly be affected by the oscillating fields, just as if they had been induced by another source. There is no conceptual problem with applying the Maxwell theory to such “field-particle rendezvous” effects; moreover, it is the basis of the engineering design of such vacuum electron devices as klystrons, magnetrons, and free-electron lasers.

A problem arises only when no clear “rendezvous” point is enforced by boundary conditions, so that the most important self-field effects are at \( R \equiv |r - r'| \to 0 \), the most evident example being the charged particle’s radiation into free space, described earlier in this chapter. We already know that such radiation takes away a part of the charge’s kinetic energy, i.e. has to cause its deceleration. One should wonder, however, whether such self-action effects might be described in a more direct, non-perturbative way.

As the first attempt, let us try a phenomenological approach based on the already derived formulas for the radiation power \( \mathcal{P} \). For the sake of simplicity, let us consider a non-relativistic point charge \( q \) in free space, so that \( \mathcal{P} \) is described by Eq. (8.27), with the electric dipole moment’s derivative over time equal to \( qu \):

\[
\mathcal{P} = \frac{Z_0 q^2}{6\varepsilon_0^2} \hat{u}^2 \equiv \frac{2}{3c^3} q^2 \frac{\hat{u}^2}{4\varepsilon_0^2}.
\]  

The most naïve approach would be to write the equation of particle’s motion in the form

\[
m\ddot{u} = F_{\text{ext}} + F_{\text{self}},
\]

and try to calculate the radiation back-action force \( F_{\text{self}} \) by requiring its instant power, \( -F_{\text{self}} \cdot \dot{u} \), to be equal to \( \mathcal{P} \). However, this approach (say, for a 1D motion) would give a very unnatural result,

\[
F_{\text{self}} \propto \frac{\hat{u}^2}{u},
\]

that might diverge at some points of the particle’s trajectory. This failure is clearly due to the retardation effect: as the reader may recall, Eq. (133) results from the analysis of radiation fields in the far-field zone, i.e. at large distances \( R \) from the particle, e.g., from the second term in Eq. (19), i.e. when the non-radiative first term (which is much larger at small distances, \( R \to 0 \)) is ignored.
Before exploring the effects of this term, let us, however, make one more try at Eq. (133), considering its average effect on some periodic motion of the particle. (A possible argument for this step is that at the periodic motion, the retardation effects may be perhaps averaged out – just at the transfer from Eq. (8.27) to Eq. (8.28).) To calculate the average, let us write

$$ \overline{\ddot{u}} = \frac{1}{\mathcal{T}} \int_0^{\mathcal{T}} \dot{\mathbf{u}} \cdot \mathbf{u} \, dt, \quad (10.136) $$

and integrate this identity, over the motion period $\mathcal{T}$, by parts:

$$ \overline{\mathcal{F}} = 2 \frac{q^2}{3c^3} \frac{1}{4\pi\varepsilon_0} \overline{(\mathbf{u})^2} = 2 \frac{q^2}{3c^3} \frac{1}{4\pi\varepsilon_0} \left( \overline{\mathbf{u} \cdot \mathbf{u}} \right) = \frac{1}{\mathcal{T}} \int_0^{\mathcal{T}} 2 \frac{q^2}{3c^3} \mathbf{u} \cdot \mathbf{u} \, dt. \quad (10.137) $$

One the other hand, the back-action force would give

$$ \overline{\mathcal{F}} = -\frac{1}{\mathcal{T}} \int_0^{\mathcal{T}} \mathbf{F}_{\text{self}} \cdot \mathbf{u} \, dt. \quad (10.138) $$

These two averages coincide if$^{54}$

$$ \mathbf{F}_{\text{self}} = 2 \frac{q^2}{3c^3} \frac{1}{4\pi\varepsilon_0} \dot{\mathbf{u}}, \quad (10.139) $$

This is the so-called Abraham-Lorentz force for self-action. Before going after a more serious derivation of this formula, let us estimate its scale, representing Eq. (139) as

$$ \mathbf{F}_{\text{self}} = m \tau \dot{\mathbf{u}}, \quad \text{with} \quad \tau = \frac{2}{3mc^3} \frac{q^2}{4\pi\varepsilon_0}, \quad (10.140) $$

where the constant $\tau$ evidently has the dimension of time. Recalling the definition (8.41) of the classical radius $r_c$ of the particle, Eq. (140) for $\tau$ may be rewritten as

$$ \tau = \frac{2 r_c}{3c}. \quad (10.141) $$

For the electron, $\tau$ is of the order of $10^{-23}$ s, so that the right-hand side of Eq. (139) is very small. This means that in most cases the Abrahams-Lorentz force is either negligible or leads to the same results as the perturbative treatments of energy loss we have used earlier in this chapter.

However, Eq. (140) brings some unpleasant surprises. For example, let us consider a 1D oscillator with the own frequency $\omega_0$. For it, Eq. (134), with the back-action force given by Eq. (140), takes the form

$$ m\dddot{x} + m\omega_0^2 \dot{x} = m \tau \ddot{x}. \quad (10.142) $$

$^{54}$ Just for the reader’s reference, this formula may be readily generalized to the relativistic case, in the 4-form:

$$ F_{\text{self}}^\alpha = 2 \frac{1}{3mc^3} \frac{q^2}{4\pi\varepsilon_0} \left[ \frac{d^2 p^\alpha}{d\tau^2} + \frac{p^\alpha}{(mc)^2} \left( \frac{dp_\beta}{d\tau} \frac{dp_\beta}{d\tau} \right) \right], $$

- the so-called Abraham-Lorentz-Dirac force.
Looking for the solution to this linear differential equation in the usual exponential form, \( x(t) \propto \exp\{\lambda t\} \), we get the following characteristic equation,

\[
\lambda^2 + \omega_0^2 = \tau \lambda^3.
\]  

(10.143)

It may look like that for any “reasonable” value of \( \omega_0 \ll 1/\tau \sim 10^{23} \text{ s}^{-1} \), the right-hand side of this nonlinear algebraic equation may be treated as a perturbation. Indeed, looking for its solutions in the natural form \( \lambda = \pm i\omega_0 + \lambda' \), with \( |\lambda'| \ll \omega_0 \), expanding both parts of Eq. (143) in the Taylor series in the small parameter \( \lambda' \), and keeping only the terms linear in \( \lambda' \), we get

\[
\lambda' \approx -\frac{\omega_0^2 \tau}{2}.
\]  

(10.144)

This means that the energy of free oscillations decreases in time as \( \exp\{2\lambda' t\} = \exp\{-\omega_0^2 \tau t\} \); this is exactly the radiative damping analyzed earlier. However, Eq. (143) is deceiving; it has the third root corresponding to unphysical, exponentially growing (so-called run-away) solutions. It is easiest to see this for a free particle, with \( \omega_0 = 0 \). Then Eq. (143) becomes very simple,

\[
\lambda^2 = \tau \lambda',
\]  

(10.145)

and it is easy to find all its 3 roots explicitly: \( \lambda_1 = \lambda_2 = 0 \) and \( \lambda_3 = 1/\tau \). While the first two roots correspond to the values \( \lambda_\pm \) found earlier, the last one describes an exponential (and extremely rapid!) acceleration.

In order to remove this artifact, let us try to develop a self-consistent approach to the back-action effects, taking into account the near-field terms of particle fields. For that, we need to somehow overcome the divergence of Eqs. (10) and (19) at \( R \to 0 \). The most reasonable way to do this is to spread the particle’s charge over a ball of radius \( a \), with a spherically-symmetric (but not necessarily constant) density \( \rho(r) \), and in the end of calculations trace the limit \( a \to 0 \). Again sticking to the non-relativistic case (so that the magnetic component of the Lorentz force is not important), we should calculate

\[
F_{\text{self}} = \int_\mathcal{V}_\rho \rho(r)E(r,t)d^3r,
\]  

(10.146)

where the electric field is that of the charge itself, with the field of any elementary charge \( dq = \rho(r)d^3r \) described by Eq. (19).

To enable an analytical calculation, we need to make the assumption \( a \ll r_c \), treat the ratio \( R/r_c \sim a/r_c \) as a small parameter, and expand the resulting the right-hand side of Eq. (146) into the Taylor series in small \( R \). This procedure yields

\[
F_{\text{self}} = -\frac{2}{3} \frac{1}{4\pi\varepsilon_0} \sum_{n=0}^{\infty} \frac{(-1)^n}{n!} c^{n+2} u d^{n+1} \int_\mathcal{V}_\rho d^3r' \int_\mathcal{V}_\rho d^3r \rho(r)R^{n-1} \rho(r').
\]  

(10.147)

The distance \( R \) cancels only in the term with \( n = 1 \),

55 Note: this operation cannot be interpreted as describing a quantum spread due to the finite extent of point particle’s wavefunction. In quantum mechanics, different parts of the wavefunction of the same charged particle do not interact with each other!
showing that we have recovered (now in an apparently legitimate fashion) Eq. (139) for the Abrahams-Lorentz force. One could argue that in the limit \( a \rightarrow 0 \) the terms higher in \( R \sim a \) (with \( n > 1 \)) could be ignored. However, we have to notice that the main contribution into the series (147) is not described by Eq. (148) for \( n = 1 \), but is given by the much larger term with \( n = 0 \):

\[
F_0 = -\frac{2}{3} \frac{1}{4\pi\varepsilon_0} \frac{1}{c^2} \int \frac{d^3r}{r} \frac{d^3r'}{r'} \rho(r) \rho(r') \frac{1}{R} \equiv -\frac{4}{3} \frac{1}{4\pi\varepsilon_0} \frac{1}{c^2} \int \frac{d^3r}{r} \frac{d^3r'}{r'} \rho(r) \rho(r') \frac{1}{R} \equiv -\frac{4}{3} \frac{1}{4\pi\varepsilon_0} \frac{1}{c^2} U, \quad (10.149)
\]

where \( U \) is the electrostatic energy (1.59) of the static charge’s self–interaction. This term may be interpreted as the inertial “force”\(^{56}\) \((-m_e a)\) with the following effective electromagnetic mass:

\[
m_{ef} = \frac{4}{3} \frac{U}{c^2}. \quad (10.150)
\]

This is the famous (or rather infamous :-) 4/3 problem that does not allow to interpret the electron’s mass as that of its electric field. An (admittedly, rather formal) resolution of this paradox is possible only in quantum electrodynamics with its renormalization techniques – beyond the framework of this course.

Note, however, that these issues are only important for motions with frequencies of the order of \( 1/\tau \sim 10^{21} \text{ s}^{-1} \), i.e. at energies \( \varepsilon \sim \hbar/\tau \sim 10^8 \text{ eV} \), while other quantum electrodynamics effects may be observed at much lower frequencies, starting from \( \sim 10^{10} \text{ s}^{-1} \). Hence the 4/3 problem is by no means the only motivation for the transfer from classical to quantum electrodynamics. However, the reader should not think that their time spent on this course has been lost: quantum electrodynamics incorporates virtually all results of classical electrodynamics, and the basic transition to it is surprisingly straightforward.\(^{57}\) So, I look forward to welcoming the reader to the next, quantum-mechanics part of this series.

10.6. Exercise problems

10.1. Derive Eqs. (10) from Eqs. (1) by a direct (but careful!) integration.

10.2. Derive the radiation-related parts of Eqs. (19)-(20) from the Liénard-Wiechert potentials (10) by direct differentiation.

10.3. A point charge \( q \) that had been in a stationary position on a circle of radius \( R \), is carried over, along the circle, to the opposite position on the same diameter (see the figure on the right) as fast as only physically possible, and then is kept steady at this new position. Calculate and sketch the time dependence of its electric field \( E \) at the center of the circle.

\(^{57}\) See, e.g., QM Chapter 9.
10.4. Express the total power of electromagnetic radiation by a relativistic particle with electric charge \( q \) and rest mass \( m \), moving with velocity \( u \), via the external Lorentz force \( \mathbf{F} \) exerted on the particle.

10.5. A relativistic particle with the rest mass \( m \) and electric charge \( q \), initially at rest, is accelerated by a constant force \( \mathbf{F} \) until it reaches a certain velocity \( u \), and then moves by inertia. Calculate the total energy radiated during the acceleration.

10.6. Calculate
(i) the instantaneous power, and
(ii) the power spectrum
of the radiation emitted, into a unit solid angle, by a relativistic particle with charge \( q \), performing 1D harmonic oscillations with frequency \( \omega_0 \) and displacement amplitude \( a \).

10.7. Analyze the polarization and the spectral contents of the synchrotron radiation propagating in the direction perpendicular to the particle’s rotation plane. How do the results change if not one, but \( N > 1 \) similar particles move around the circle, at equal angular distances?

10.8. Calculate and analyze the time dependence of the energy of a charged relativistic particle performing synchrotron motion in a constant and uniform magnetic field \( \mathbf{B} \), and hence emitting the synchrotron radiation. Qualitatively, what is the particle’s trajectory?

*Hint: You may assume that the energy loss is relatively slow \(( -dE/dt \ll \omega_0 \epsilon )\), but should spell out the condition of validity of this assumption.*

10.9. Analyze the polarization of the synchrotron radiation propagating within the particle’s rotation plane.

10.10.* The basic quantum theory of radiation shows that the electric dipole radiation by a particle is allowed only if the change of its angular momentum’s magnitude \( L \) at the transition is of the order of the Planck’s constant \( \hbar \).

(i) Estimate the change of \( L \) of an ultra-relativistic particle due to its emission of a typical single photon of the synchrotron radiation.
(ii) Does quantum mechanics forbid such radiation? If not, why?

10.11. A relativistic particle moves along the \( z \)-axis, with velocity \( u_z \), through an undulator – a system of permanent magnets providing (in the simplest model) a perpendicular magnetic field, whose distribution near the axis is sinusoidal:

\[
\mathbf{B} = n_z B_0 \cos k_0 z.
\]

---

\(^{58}\) As the Maxwell equation for \( \nabla \times \mathbf{H} \) shows, such field distribution cannot be created in any non-vanishing volume of free space. However, it may be created on a line – e.g., on the particle’s trajectory.
Assuming that the field is so weak that it causes negligible deviations of particle’s trajectory from the straight line, calculate the angular distribution of the resulting radiation. What condition does this assumption impose on the system’s parameters?

10.12. Discuss possible effects of the interference of the undulator radiation from different periods of its static field distribution. In particular, calculate the angular positions of the power density maxima.

10.13. An electron, launched directly toward a plane surface of a perfect conductor, is instantly absorbed by it at the collision. Calculate the angular distribution and the frequency spectrum of the electromagnetic waves radiated at this collision, if the initial kinetic energy $T$ of the particle is much larger than the conductor’s workfunction $\psi$.\footnote{See Sec. 2.9, in particular Fig. 2.27a.} Is your result valid near the conductor’s surface?

10.14. A relativistic particle, with the rest mass $m$ and electric charge $q$, flies ballistically, with velocity $u$, by an immobile point charge $q'$, with an impact parameter $b$ so large that the deviations of its trajectory from the straight line are negligible. Calculate the total energy loss due to the electromagnetic radiation during the passage. Formulate the conditions of validity of your result.

Chapter 1. Introduction

This introductory chapter briefly reviews the major experimental motivations for quantum mechanics, and then discusses its simplest formalism – the Schrödinger’s wave mechanics. Much of this material (perhaps besides the last section) may be found in undergraduate textbooks, so that the discussion is rather brief, and focused on the most important conceptual issues.

1.1. Experimental motivations

By the beginning of the 1900s, physics (which by that time included what we now call non-relativistic classical mechanics, classical thermodynamics and statistics, and classical electrodynamics including the geometric and wave optics) looked like an almost completed discipline, with most human-scale phenomena reasonably explained, and just a couple of mysterious “dark clouds” on the horizon. However, rapid technological progress and the resulting development of more refined scientific instruments have led to a fast multiplication of observed phenomena that could not be explained on the classical basis. Let me list the most consequential of those experimental findings.

(i) The blackbody radiation measurements, pioneered by G. Kirchhoff in 1859, have shown that in the thermal equilibrium, the power of electromagnetic radiation by a fully absorbing (“black”) surface, per unit frequency interval, drops exponentially at high frequencies. This is not what could be expected from the combination of the classical electrodynamics and statistics, which predicted an infinite growth of the radiation density with frequency. Indeed, the classical electrodynamics shows that electromagnetic field modes evolve in time as harmonic oscillators, and that the number of these modes in a large free-space volume \(V \gg \lambda^3\), within a small frequency interval \(d\omega \ll \omega\) near some frequency \(\omega\), is

\[
dN = 2V \frac{d^3k}{(2\pi)^3} = 2V \frac{4\pi k^2 dk}{(2\pi)^3} = V \frac{\omega^2}{\pi^2 c^3} d\omega,
\]

where \(c \approx 3 \times 10^8\) m/s is the free-space speed of light, \(k = \omega/c\) the free-space wave number, and \(\lambda = 2\pi/k\) is the radiation wavelength. On the other hand, the classical statistics predicts that in the thermal equilibrium at temperature \(T\), the average energy \(E\) of each 1D harmonic oscillator should be equal to \(k_B T\), where \(k_B\) is the Boltzmann constant.

Combining these two results, we readily get the so-called Rayleigh-Jeans formula for the average electromagnetic wave energy per unit volume:

---

1 See, for example, D. Griffith, Quantum Mechanics, 2nd ed., Cambridge U. Press, 2016.
2 This famous expression was used in a 1900 talk by Lord Kelvin (born William Thomson) in reference to the blackbody radiation measurements and the results of the Michelson-Morley experiments, i.e. the precursors of the quantum mechanics and the relativity theory.
3 See, e.g., EM Sec. 7.8, in particular Eq. (7.211).
4 See, e.g., SM Sec. 2.2.
5 In the SI units, used through this series, \(k_B \approx 1.38 \times 10^{-23}\) J/K – see Appendix CA: Selected Physical Constants for the exact value.
that diverges at $\omega \to \infty$ – the so-called *ultraviolet catastrophe*. On the other hand, the blackbody radiation measurements, improved by O. Lummer and E. Pringsheim, and also by H. Rubens and F. Kurlbaum to reach a 1%-scale accuracy, were compatible with the phenomenological law suggested in 1900 by Max Planck:

$$u = \frac{\omega^2}{\pi^2 c^3 \exp\left(\frac{\hbar \omega}{k_B T}\right) - 1}.$$  \hfill (1.3a)

This law may be reconciled with the fundamental Eq. (1) if the following replacement is made for the average energy of each field oscillator:

$$k_B T \to \frac{\hbar \omega}{\exp(\hbar \omega / k_B T) - 1},$$  \hfill (1.3b)

with a constant factor

$$\hbar \approx 1.055 \times 10^{-34} \text{ J} \cdot \text{s},$$  \hfill (1.4)

now called the *Planck’s constant*.\(^6\) At low frequencies ($\hbar \omega \ll k_B T$), the denominator in Eq. (3) may be approximated as $\hbar \omega / k_B T$, so that the average energy (3b) tends to its classical value $k_B T$, and the Planck’s law (3a) reduces to the Rayleigh-Jeans formula (2). However, at higher frequencies ($\hbar \omega >> k_B T$), Eq. (3) describes the experimentally observed rapid decrease of the radiation density – see Fig. 1.

(ii) *The photoelectric effect*, discovered in 1887 by H. Hertz, shows a sharp lower boundary for the frequency of the incident light that may kick electrons out from metallic surfaces, regardless of light’s intensity. Albert Einstein, in one of his three famous 1905 papers, noticed that this threshold $\omega_{\text{min}}$ could be explained assuming that light consisted of certain particles (now called *photons*) with energy

\(^6\) Max Planck himself wrote $\hbar \omega$ as $h\nu$, where $\nu = \omega / 2\pi$ is the “cyclic” frequency (the number of periods per second), so that in early texts on quantum mechanics the term “Planck’s constant” referred to $h = 2\pi \hbar$, while $h$ was called “the Dirac constant” for a while. I will use the contemporary terminology, and abstain from using the “old Planck’s constant” $\hbar$ at all, to avoid confusion.
with the same Planck’s constant that participates in Eq. (3).\footnote{As a reminder, A. Einstein received his only Nobel Prize (in 1922) for exactly this work, rather than for his relativity theory, i.e. essentially for jumpstarting the quantum theory that he later questioned!} Indeed, with this assumption, at the photon absorption by an electron, its energy \( E = \hbar \omega \) is divided between a fixed energy \( U_0 \) (nowadays called the workfunction) of electron’s binding inside the metal, and the excess kinetic energy \( m_e v^2/2 > 0 \) of the freed electron – see Fig. 2. In this picture, the frequency threshold finds a natural explanation as \( \omega_{\text{min}} = \frac{U_0}{\hbar} \).\footnote{For most metals, \( U_0 \) is between 4 and 5 electron-volts (eV), so that the threshold corresponds to \( \lambda_{\text{max}} = \frac{2\pi}{\omega_{\text{min}}} = 2\pi/(U_0/\hbar) \approx 300 \text{ nm} \) – approximately at the border between the visible light and the ultraviolet radiation.}  Moreover, as was shown by Satyendra Nath Bose in 1924,\footnote{See, e.g., SM Sec. 2.5.} Eq. (5) explains Planck’s law (3).

\[
E = \hbar \omega, \tag{1.5}
\]

### (iii) The discrete frequency spectra

of the electromagnetic radiation by excited atomic gases could not be explained by classical physics. (Applied to the planetary model of atoms, proposed by Ernst Rutherford, classical electrodynamics predicts the collapse of electrons onto nuclei in \( \sim 10^{-10} \text{ s} \), due to the electric-dipole radiation of electromagnetic waves.\footnote{See, e.g., EM Sec. 8.2.} Especially challenging was the observation by Johann Jacob Balmer (in 1885) that the radiation frequencies of simple atoms may be well described by simple formulas. For example, for the lightest atom, the hydrogen, all radiation frequencies may be numbered with just two positive integers \( n \) and \( n' \):

\[
\omega_{n,n'} = \omega_0 \left( \frac{1}{n^2} - \frac{1}{n'^2} \right), \tag{1.6}
\]

with \( \omega_0 = \omega_{1,\infty} \approx 2.07 \times 10^{16} \text{ s}^{-1} \). This observation, and the experimental value of \( \omega_0 \), have found its first explanation in the famous 1913 theory by Niels Henrik David Bohr, which was a phenomenological precursor of the present-day quantum mechanics. In this theory, \( \omega_{n,n'} \) was interpreted as the frequency of a photon that obeys the Einstein’s formula (5), with its energy \( E_{n,n'} = \hbar \omega_{n,n'} \) being the difference between two quantized (discrete) energy levels of the atom (Fig. 3):\footnote{The non-relativistic approach to the problem may be justified \textit{a posteriori} by the fact the resulting energy scale \( E_{1s} \), given by Eq. (13), is much smaller than electron’s rest energy, \( m_e c^2 \approx 0.5 \text{ MeV} \).}

\[
E_{n,n'} = E_{n'} - E_n > 0. \tag{1.7}
\]

Bohr showed that Eq. (6) may be obtained from Eq. (7) and the non-relativistic\footnote{The non-relativistic approach to the problem may be justified \textit{a posteriori} by the fact the resulting energy scale \( E_{1s} \), given by Eq. (13), is much smaller than electron’s rest energy, \( m_e c^2 \approx 0.5 \text{ MeV} \).} classical mechanics, augmented with just one additional postulate, equivalent to the assumption that the angular
momentum \( L = m_evr \) of an electron moving with velocity \( v \) on a circular orbit of radius \( r \) about the hydrogen’s nucleus, a proton (assumed to be at rest because of its much higher mass), is quantized as

\[
L = \hbar n, \tag{1.8}
\]

where \( \hbar \) is again the same Planck’s constant (4), and \( n \) is an integer. (In the Bohr’s theory, \( n \) could not be equal to zero, though in the genuine quantum mechanics, it can.)

Indeed, it is sufficient to solve Eq. (8), \( m_evr = \hbar n \), together with the equation

\[
m_e \frac{v^2}{r} = \frac{e^2}{4\pi \varepsilon_0 r^2}, \tag{1.9}
\]

which expresses the 2nd Newton’s law for the electron rotating in the Coulomb field of the nucleus. (Here \( e \approx 1.6 \times 10^{-19} \text{C} \) is the fundamental electric charge, and \( m_e \approx 0.91 \times 10^{-30} \text{kg} \) is the electron’s rest mass.) The result for \( r \) is

\[
r = n^2 r_B, \quad \text{where} \quad r_B = \frac{\hbar^2 / m_e}{e^2 / 4\pi \varepsilon_0} \approx 0.0529 \text{nm}. \tag{1.10}
\]

The constant \( r_B \), called the Bohr radius, is the most important spatial scale of phenomena in atomic, molecular, and condensed-matter physics - as well as in all chemistry and biochemistry.

Now plugging these results into the non-relativistic expression for the full electron’s energy (with the free electron’s rest energy taken for the reference),

\[
E = \frac{m_e v^2}{2} - \frac{e^2}{4\pi \varepsilon_0 r}, \tag{1.11}
\]

we get the following simple expression for the energy levels (which, together with Eqs. (5) and (7), immediately gives Eq. (6) for the radiation frequencies):

\[
E_n = -\frac{E_H}{2n^2} < 0, \tag{1.12}
\]

where \( E_H \) is called the so-called Hartree energy constant (or just the “Hartree energy”)

\[
E_H = \left( \frac{e^2}{4\pi \varepsilon_0} \right)^2 \approx 4.360 \times 10^{-18} \text{ J} \approx 27.21 \text{ eV}. \tag{1.13a}
\]

12 Unfortunately, another name, the “Rydberg constant”, is sometimes used for either this energy unit or its half, \( E_H/2 \approx 13.6 \text{ eV} \). To add to the confusion, the same term “Rydberg constant” is used in some sub-fields of physics for the reciprocal free-space wavelength \( (1/\lambda_0 = \omega_0/2\pi) \) corresponding to the frequency \( \omega_0 = E_H/2\hbar \).
(Note the useful relations, which follow from Eqs. (10) and (13a):

\[
E_H = \frac{e^2}{4\pi\varepsilon_0 r_B^2} = \frac{\hbar^2}{m_e r_B^2}, \quad \text{i.e.,} \quad r_B = \frac{e^2 / 4\pi\varepsilon_0}{E_H} = \left(\frac{\hbar^2 / m_e}{E_H}\right)^{1/2};
\]  

(1.13b)

the first of them shows, in particular, that \(r_B\) is the distance at which the scales of the electron’s potential and kinetic energies, stripped of numerical coefficients, are equal.)

Note also that Eq. (8), in the form \(pr = \hbar n\), where \(p = m_ev\) is the electron momentum’s magnitude, may be rewritten as the condition than an integer number \((n)\) of wavelengths \(\lambda\) of certain (before the late 1920s, hypothetic) waves\(^{13}\) fits the circular orbit’s perimeter: \(2\pi r \equiv 2\pi n\hbar / p = n\lambda\). Dividing both parts of the last equality by \(n\), we see that for this statement to be true, the wave number \(k \equiv 2\pi / \lambda\) of the de Broglie waves should be proportional to the electron’s momentum \(p = mv\):

\[
p = \hbar k,
\]  

again with the same Planck’s constant as in Eq. (5).

(iv) The Compton effect\(^{14}\) is the reduction of frequency of X-rays at their scattering on free (or nearly-free) electrons – see Fig. 4.

The effect may be explained assuming that the X-ray photon also has a momentum that obeys the vector-generalized version of Eq. (14):

\[
p_{\text{photon}} = \hbar k = \frac{\hbar \omega}{c} \mathbf{n},
\]  

(1.15)

where \(k\) is the wavevector (whose magnitude is equal to the wave number \(k\), and whose direction coincides with the unit vector, \(\mathbf{n}\), directed along the wave propagation\(^{15}\)), and that the momenta magnitudes of both the photon and the electron are related to their energies \(E\) by the classical relativistic formula\(^{16}\)

\[
E^2 = (cp)^2 + (mc^2)^2.
\]  

(1.16)

(For a photon, the rest energy is zero, and this relation is reduced to Eq. (5): \(E = cp = \hbar k = \hbar \omega\).) Indeed, a straightforward solution of the following system of three equations,

\(^{13}\) This fact was first noticed and discussed in 1924 by Louis Victor Pierre Raymond de Broglie (in his PhD thesis!), so that instead of wavefunctions, especially of free particles, we are still frequently speaking of the de Broglie waves.

\(^{14}\) This effect was observed in 1922, and explained a year later by Arthur Holly Compton.

\(^{15}\) See, e.g., EM Sec. 7.1.

\(^{16}\) See, e.g., EM Sec. 9.3, in particular Eq. (9.78).
\[
\frac{\hbar \omega}{c} + m_e c^2 = \frac{\hbar \omega'}{c} + \left[ (cp)^2 + (m_c e^2)^2 \right]^{1/2},
\]
which describe, respectively, the conservation of the full energy of the system, and of the two relevant Cartesian components of its full momentum, at the scattering event - see Fig. 4), yields the result:

\[
\frac{1}{\hbar \omega'} = \frac{1}{\hbar \omega} + \frac{1}{m_e c^2} (1 - \cos \theta),
\]

which is traditionally represented as the relation between the initial and final values of the photon’s wavelength \( \lambda = 2\pi k = 2\pi(\omega/c) \): \( \lambda' = \lambda + \frac{2\pi \hbar}{m_e c} (1 - \cos \theta) \equiv \lambda + \lambda_c (1 - \cos \theta), \) with \( \lambda_c = \frac{2\pi \hbar}{m_e c} \).

\[\text{Compton effect}\]

(v) De Broglie wave diffraction. In 1927, Clinton Joseph Davisson and Lester Germer, and independently George Paget Thomson succeeded to observe the diffraction of electrons on solid crystals (Fig. 5). Specifically, they have found that the intensity of the elastic reflection of electrons from a crystal increases sharply when the angle \( \alpha \) between the incident beam of electrons and the crystal’s atomic planes, separated by distance \( d \), satisfies the following relation:

\[
2d \sin \alpha = n \lambda,
\]

where \( \lambda = 2\pi k = 2\pi\hbar/p \) is the de Broglie wavelength of the electrons, and \( n \) is an integer. As Fig. 5 shows, this is just the well-known condition, that the path difference \( \Delta l = 2ds\sin \alpha \) between the de Broglie waves reflected from two adjacent crystal planes coincides with an integer number of \( \lambda \), i.e. of the constructive interference of the waves.

To summarize, all the listed effects may be explained starting from two very simple (and similarly looking) formulas: Eq. (5) (at that stage, for photons only), and Eq. (15) for both photons and electrons - both relations involving the same Planck’s constant. This fact might give an impression of sufficient experimental evidence to declare the light consisting of discrete particles (photons), and, on

17 The constant \( \lambda_c \) that participates in this relation, is close to \( 2.46 \times 10^{-12} \) m, and is called the electron’s Compton wavelength. This term is somewhat misleading: as the reader can see from Eqs. (17)-(19), no wave in the Compton problem has such a wavelength – either before or after the scattering.

18 See, e.g., EM Sec. 8.4, in particular Fig. 8.9 and Eq. (8.82). Frequently, Eq. (21) is called the Bragg condition, due to the pioneering experiments by W. Bragg with X-ray scattering from crystals, which were started in 1912.

19 Later, spectacular experiments on diffraction and interference of heavier particles (with much smaller de Broglie wavelength), e.g., neutrons and even C_{60} molecules, have also been performed – see, e.g., a review by A. Zeilinger et al., Rev. Mod. Phys. 60, 1067 (1988) and a later publication by O. Nairz et al., Am. J. Phys. 71, 319 (2003). Nowadays, such interference of heavy particles is used, for example, for ultrasensitive measurements of gravity – see, e.g., a popular review by M. Arndt, Phys. Today 67, 30 (May 2014), and more recent experiments by S. Abend et al., Phys. Rev. Lett. 117, 203003 (2016).
the contrary, electrons being some “matter waves” rather than particles. However, by that time (the mid-1920s), physics has accumulated overwhelming evidence of wave properties of light, such as interference and diffraction. In addition, there was also strong evidence for lumped-particle (“corpuscular”) behavior of electrons. It is sufficient to mention the famous oil-drop experiments by Robert Andrew Millikan and Harvey Fletcher (1909-1913), in which only single (and whole!) electrons could be added to an oil drop, changing its total electric charge by multiples of electron’s charge (\(-e\)) – and never its fraction. It was apparently impossible to reconcile these observations with a purely wave picture, in which an electron and hence its charge need to be spread over the wave’s extension, so that its arbitrary part of it could be cut out using an appropriate experimental setup.

Thus the founding fathers of quantum mechanics faced a formidable task of reconciling the wave and corpuscular properties of electrons and photons - and other particles. The decisive breakthrough in that task has been achieved in 1926 by Ervin Schrödinger and Max Born, who formulated what is now known either formally as the *Schrödinger picture of non-relativistic quantum mechanics of the orbital motion* in the coordinate representation (this term will be explained later in the course), or informally just as the wave mechanics. I will now formulate the main postulates of this theory.

1.2. Wave mechanics postulates

Let us consider a spinless, non-relativistic point-like particle, whose classical dynamics may be described by a certain Hamiltonian function \(H(r, p, t)\), where \(r\) is the particle’s radius-vector and \(p\) is its momentum. Wave mechanics of such Hamiltonian particles may be based on the following set of postulates that are comfortingly elegant - though their final justification is given only by the agreement of all their corollaries with experiment.

20 See, e.g., EM Sec. 8.4.
21 The *orbital motion* is the historic (and rather misleading) term used for any motion of the particle as a whole.
22 Actually, in wave mechanics, the spin of the described particle has not to be equal zero. Rather, it is assumed that the spin’s effects on the orbital motion of the particle are negligible.
23 As a reminder, for many systems (including those whose kinetic energy is a quadratic-homogeneous function of generalized velocities, like \(mv^2/2\)), \(H\) coincides with the total energy \(E\) – see, e.g., CM Sec. 2.3.
24 Note that this restriction is very important. In particular, it excludes from our current discussion the particles whose interaction with their environment results in irreversible effects, in particular the friction leading to particle energy’s decay. Such “open” systems need a more general description, which will be discussed in Chapter 7.
25 Generally, quantum mechanics, as any theory, may be built on different sets of postulates (“axioms”) leading to the same conclusions. In this text, I will not try to beat down the number of postulates to the absolute possible
(i) Wavefunction and probability. Such variables as $r$ or $p$ cannot be always measured exactly, even at “perfect conditions” when all external uncertainties, including measurement instrument imperfection, macroscopic uncertainties of the initial state preparation, and unintended particle interactions with its environment, have been removed.\textsuperscript{26} Moreover, $r$ and $p$ of the same particle can never be measured exactly simultaneously. Instead, even the most detailed description of the particle’s state, allowed by Nature,\textsuperscript{27} is given by a certain complex function $\Psi(r, t)$, called the wavefunction (or “wave function”), which generally enables only probabilistic predictions of the measured values of $r$, $p$, and other directly measurable variables - in quantum mechanics, usually called observables.

Specifically, the probability $dW$ of finding a particle inside an elementary volume $dV \equiv d^3r$ is proportional to this volume, and hence may be characterized by a volume-independent probability density $w \equiv dW/d^3r$, which in turn is related to the wavefunction as

$$w = |\Psi(r, t)|^2 \equiv \Psi^*(r, t)\Psi(r, t), \quad (1.22a)$$

where the sign * denotes the usual complex conjugation. As a result, the total probability of finding the particle somewhere inside a volume $V$ may be calculated as

$$W = \int_V w d^3r = \int_V \Psi^*\Psi d^3r. \quad (1.22b)$$

In particular, if the volume $V$ contains the particle definitely (i.e. with the 100% probability, $W = 1$), Eq. (22b) is reduced to the so-called normalization condition

$$\int_V \Psi^*\Psi d^3r = 1. \quad (1.22c)$$

(ii) Observables and operators. With each observable $A$, quantum mechanics associates a certain linear operator $\hat{A}$, such that, in the perfect conditions mentioned above, the average measured value (also called the expectation value) of $A$ is expressed as\textsuperscript{28}

$$\langle A \rangle = \int_V \Psi^* \hat{A} \Psi d^3r, \quad (1.23)$$

where $\langle \ldots \rangle$ means the statistical average, i.e. the result of averaging the measurement results over a large ensemble (set) of macroscopically similar experiments, and $\Psi$ is the normalized wavefunction, which obeys Eq. (22c). Note immediately that for Eqs. (22) and (23) to be compatible, the identity (or “unit”) operator defined by the relation

minimum, not only because this would require longer argumentation, but chiefly because such attempts typically result in making certain implicit assumptions hidden from the reader – the practice as common as regrettable.

\textsuperscript{26} I will imply such perfect conditions in the further narrative, until the discussion of particle’s interaction with environment in Chapter 7 and beyond.

\textsuperscript{27} This is one more important caveat. As will be discussed in detail in Chapter 7, in many cases even Hamiltonian systems cannot be described by certain wavefunctions, and allow only a more general (and less precise) description, e.g., by the density matrix.

\textsuperscript{28} This key measurement postulate is sometimes called the Born rule, though sometimes this term is used for the (less general) Eqs. (22).
has to be associated with a particular type of measurement, namely with the particle’s detection.

(iii) The Hamiltonian operator and the Schrödinger equation. Another particular operator, the Hamiltonian $\hat{H}$, whose observable is the particle’s energy $E$, also plays in wave mechanics a very special role, because it participates in the Schrödinger equation,

$$i\hbar \frac{\partial \Psi}{\partial t} = \hat{H}\Psi,$$

that determines the wavefunction’s dynamics, i.e. its time evolution.

(iv) The radius-vector and momentum operators. In the wave mechanics, i.e. in the coordinate representation, the vector operator of particle’s radius-vector $\mathbf{r}$ just multiplies the wavefunction by this vector, while the operator of the particle’s momentum\(^{29}\) is proportional to the spatial derivative:

$$\hat{\mathbf{r}} = \mathbf{r}, \quad \hat{\mathbf{p}} = -i\hbar \nabla,$$

where $\nabla$ is the del (or “nabla”) vector operator.\(^{30}\) Thus in the Cartesian coordinates,

$$\hat{\mathbf{r}} = \{x, y, z\}, \quad \hat{\mathbf{p}} = -i\hbar \left\{ \frac{\partial}{\partial x}, \frac{\partial}{\partial y}, \frac{\partial}{\partial z} \right\}.$$

(v) The correspondence principle. In the limit when quantum effects are insignificant, e.g., when the characteristic scale of action\(^{31}\) (i.e. the product of the relevant energy and time scales of the problem) is much larger than Planck’s constant $\hbar$, all wave mechanics results have to tend to those given by classical mechanics. Mathematically, this correspondence is achieved by duplicating the classical relations between various observables by similar relations between the corresponding operators. For example, for a free particle, the Hamiltonian (which in this particular case corresponds to the kinetic energy $T = p^2/2m$ alone) has the form

$$\hat{H} = \hat{T} = \hat{p}^2/2m = -\frac{\hbar^2}{2m} \nabla^2.$$

Now, even before a deeper discussion of the postulates’ physics (offered in the next section), we may immediately see that they indeed provide a formal way toward the resolution of the apparent contradiction between the wave and corpuscular properties of particles. Indeed, for a free particle, the Schrödinger equation (25), with the substitution of Eq. (27), takes the form

$$i\hbar \frac{\partial \Psi}{\partial t} = -\frac{\hbar^2}{2m} \nabla^2 \Psi,$$

\(^{29}\) For an electrically charged particle in the magnetic field, this relation is valid for its canonical momentum – see Sec. 3.1 below.

\(^{30}\) See, e.g., Secs. 8-10 of the Selected Mathematical Formulas appendix (below, referred to as MA). Note that according to these formulas, the del operator follows all the geometric rules of the usual vectors. This is, by definition, true for other vector operators of quantum mechanics - to be discussed below.

\(^{31}\) See, e.g., CM Sec. 10.3.
whose particular, but most important solution is a plane, single-frequency ("monochromatic") traveling wave,

\[ \Psi(r, t) = ae^{i(kr - \omega t)}, \tag{1.29} \]

where \( a \), \( k \) and \( \omega \) are constants. Indeed, plugging Eq. (29) into Eq. (28), we immediately see that the plane wave, with an arbitrary complex amplitude \( a \), is indeed a solution of this Schrödinger equation, provided a specific dispersion relation between the wave number \( k \equiv |k| \) and the frequency \( \omega \).

\[ \hbar \omega = \frac{(\hbar k)^2}{2m}. \tag{1.30} \]

The constant \( a \) may be calculated, for example, assuming that the wave (29) is extended over a certain volume \( V \), while beyond it, \( \Psi = 0 \). Then from the normalization condition (22c) and Eq. (29), we get\(^3\)

\[ |a|^2 V = 1. \tag{1.31} \]

Now we can use Eqs. (23), (26) and (27) to calculate the expectation values of the particle’s momentum \( \mathbf{p} \) and energy \( E \) (which, for a free particle, coincides with its Hamiltonian function \( H \)). The result is

\[ \langle \mathbf{p} \rangle = \hbar \mathbf{k}, \quad \langle E \rangle = \langle H \rangle = \frac{(\hbar k)^2}{2m}; \tag{1.32} \]

according to Eq. (30), the last equality may be rewritten as \( \langle E \rangle = \hbar \omega \).

Next, Eq. (23) enables us to calculate not only the average (in the math speak, the first moment) of an observable, but also its higher moments, notably the second moment (in physics, usually called either the variance or dispersion):

\[ \langle \Delta^2 \rangle \equiv \langle (A - \langle A \rangle)^2 \rangle = \langle A^2 \rangle - \langle A \rangle^2, \tag{1.33} \]

and hence its uncertainty, alternatively called the “root mean square (r.m.s.) fluctuation”,

\[ \Delta A \equiv \langle \Delta^2 \rangle^{1/2}, \tag{1.34} \]

that characterizes the scale of deviations \( \Delta A \equiv A - \langle A \rangle \) of the measurement results from the average. In the particular case when the uncertainty \( \Delta A \) equals zero, every measurement of the observable \( A \) will give the value \( \langle A \rangle \); such a state is said to have a definite value of the variable. For example, in application to the wavefunction (29), these relations yield \( \Delta E = 0, \Delta \mathbf{p} = 0 \). This means that in the plane-wave, monochromatic state (29), the energy and momentum of the particle have definite values, so that the statistical average signs in Eqs. (32) might be removed. Thus, these relations are reduced to the experimentally-inferred Eqs. (5) and (15) - though the relation of \( k \) and \( \omega \) to experimental observations still has to be clarified.

\(^{32}\) See, e.g., CM Sec. 6.4 and/or EM Sec. 7.1.

\(^{33}\) For infinite space (\( V \to \infty \)), Eq. (31) yields \( a \to 0 \), i.e. wavefunction (29) vanishes. This formal problem may be readily resolved considering sufficiently long wave packets – see Sec. 2.2 below.
Hence the wave mechanics postulates indeed may describe the observed wave properties of non-relativistic particles. (For photons, we would need its relativistic generalization – see Chapter 9 below.) On the other hand, due to the linearity of the Schrödinger equation (25), any sum of its solutions is also a solution – the so-called linear superposition principle. For a free particle, this means that any set of plane waves (29) is also a solution of this equation. Such sets, with close values of \( k \) and hence \( p = \hbar k \) (and, according to Eq. (30), of \( \omega \) as well), may be used to describe spatially localized “pulses”, called wave packets — see Fig. 6. In Sec. 2.1, I will prove (or rather reproduce H. Weyl’s proof :-) that the wave packet’s extension \( \delta x \) in any direction (say, \( x \)) is related to the width \( \delta k_x \) of the distribution of the corresponding component of its wave vector as \( \delta x \delta k_x \geq \frac{\hbar}{2} \), and hence, according to Eq. (15), to the width \( \delta \varphi_k \) of the momentum component distribution as

\[
\delta x \cdot \delta \varphi_k \geq \frac{\hbar}{2}.
\]  

(1.35)

This is the famous Heisenberg’s uncertainty principle, which quantifies the first postulate’s point that the coordinate and the momentum cannot be defined exactly simultaneously. However, since the Planck’s constant, \( \hbar \approx 10^{-34} \) J
\( \cdot \) s, is extremely small on the human scale of things, it still allows for particle’s localization in a very small volume even if the momentum spread in the wave packet is also small on that scale. For example, according to Eq. (35), a 0.1% spread of momentum of a 1 keV electron (\( p \approx 1.7\times10^{-24} \) kg
\( \cdot \) m/s) allows its wave packet to be as small as \( \sim 3\times10^{-10} \) m. (For a heavier particle such as a proton, the packet would be even tighter.) As a result, wave packets may be used to describe the particles that are quite point-like from the macroscopic point of view.

In a nutshell, this is the main idea of the wave mechanics, and the first part of this course (Chapters 1-3) will be essentially a discussion of various effects described by this approach. During this discussion, however, we will not only witness wave mechanics’ many triumphs within its applicability domain, but also gradually accumulate evidence for its handicaps, which will force an eventual transfer to a more general formalism – to be discussed in Chapter 4 and beyond.

1.3. Postulates’ discussion

The wave mechanics’ postulates listed in the previous section (hopefully, familiar to the reader from their undergraduate studies) may look very simple. However, the physics of these axioms is very deep, leading to some counter-intuitive conclusions, and their in-depth discussion requires solutions of
several key problems of wave mechanics. This is why in this section I will give only an initial, admittedly superficial discussion of the postulates, and will be repeatedly returning to the conceptual foundations of quantum mechanics throughout the course, especially in Chapter 10.

First of all, the fundamental uncertainty of observables, which is in the core of the first postulate, is very foreign to the basic ideas of classical mechanics, and historically has made the quantum mechanics so hard to swallow for many star physicists, notably including A. Einstein – despite his 1905 work, which essentially launched the whole field! However, this fact has been confirmed by numerous experiments, and (more importantly) there has not been a single confirmed experiment which would contradict this postulate, so that quantum mechanics was long ago was promoted from a theoretical hypothesis to the rank of a reliable scientific theory.

One more remark in this context is that Eq. (25) itself is deterministic, i.e. conceptually enables an exact calculation of the wavefunction’s distribution in space at any instant $t$, provided that its initial distribution, and the particle’s Hamiltonian, are known exactly. Note that in the classical statistical mechanics, the probability density distribution $w(r, t)$ may be also calculated from deterministic differential equations, for example, the Liouville equation. The quantum-mechanical description differs from that situation in two important aspects. First, in the perfect conditions outlined above (the best possible initial state preparation and measurements), the Liouville equation reduces to the 2nd Newton law of classical mechanics, i.e. the statistical uncertainty disappears. In quantum mechanics this is not true: the quantum uncertainty, such as described by Eq. (35), persists even in this limit. Second, the wavefunction $\Psi(r, t)$ gives more information than just $w(r, t)$, because besides the modulus of $\Psi$, involved in Eq. (22), this complex function also has the phase $\varphi \equiv \arg \Psi$, which may affect some observables, describing, in particular, the interference of the de Broglie waves.

Next, it is very important to understand that the relation between the quantum mechanics and experiment, given by the second postulate, necessarily involves another key notion: that of the corresponding statistical ensemble. Such ensemble may be defined as a set of many experiments carried out at apparently (macroscopically) similar conditions, including the initial conditions, which nevertheless may lead to different measurement results (outcomes). Note that the probability of a certain ($n^{th}$) outcome of an experiment may be only defined for a certain statistical ensemble, as the limit

$$W_n \equiv \lim_{M \to \infty} \frac{M_n}{M}, \quad \text{with } M \equiv \sum_{n=1}^{N} M_n,$$

(1.36) Probability: definition

where $M$ is the total number of experiments, $M_n$ is the number of outcomes of the $n^{th}$ type, and $N$ is the number of different outcomes.

Note that a particular choice of an ensemble may affect probabilities $W_n$ very significantly. For example, if we pull out playing cards at random from a standard pack of 52 different cards of 4 suits, the probability $W_n$ of getting a certain card (e.g., the queen of spades) is 1/52. However, if the cards of a certain suit (say, hearts) had been taken out from the pack in advance, the probability of getting the queen of spades is higher, 1/39. It is important that we would also get the last number for the probability even if we had used the full 52-card pack, but by some reason discarded results of all experiments giving us any rank of hearts. Hence, the ensemble definition (or its re-definition in the middle of the game) may change outcome probabilities.

34 See, e.g., SM Sec. 6.1.
In the wave mechanics, with its fundamental relation (22) between \( W \) and \( \Psi \), this means not only the outcome probabilities, but the wavefunction itself also may depend on the statistical ensemble we are using, i.e. not only on the preparation of the system and the experimental setup, but also on the subset of outcomes taken into account. The sometimes accounted attribution of the wavefunction to a single experiment, both before and after the measurement, may lead to very unphysical interpretations of the results, including a wavefunction’s evolution not described by the Schrödinger equation (the so-called wave packet reduction), subluminal action on distance, etc. Later in the course we will see that minding the fundamentally statistical nature of quantum mechanics, and in particular the dependence of wavefunctions on the statistical ensembles’ definition (or redefinition), readily resolves some, though not all, paradoxes of quantum measurements.

Note, however, again that the standard quantum mechanics, as discussed in Chapters 1-6 of this course, is limited to statistical ensembles with the least uncertainty of the considered systems, i.e. with best possible knowledge about their state.\(^35\) This condition requires, first, the least uncertain initial preparation of the system, and second, its total isolation from the rest of the world, or at least from its disordered part (the “environment”), in the course of its evolution in time. Only such ensembles may be described by certain wavefunctions. A detailed discussion of more general ensembles, which are necessary if these conditions are not satisfied, will be given in Chapters 7, 8, and 10.

Finally, regarding Eq. (23), a better feeling of this definition may be obtained by its comparison with the general definition of the expectation value (i.e. the statistical average) in the probability theory. Namely, let each of \( N \) possible outcomes in a set of \( M \) experiments give a certain value \( A_n \) of observable \( A \); then

\[
\langle A \rangle \equiv \lim_{M \to \infty} \frac{1}{M} \sum_{n=1}^{N} A_n M_n = \sum_{n=1}^{N} A_n W_n .
\]

Taking into account Eq. (22), which relates \( W \) and \( \Psi \), the structures of Eq. (23) and the final form of Eq. (37) are similar. Their exact relation will be further discussed in Sec. 4.1.

### 1.4. Continuity equation

The wave mechanics postulates survive one more sanity check: they satisfy the natural requirement that the particle does not appear or vanish in the course of the quantum evolution.\(^36\) Indeed, let us use Eq. (22b) to calculate the rate of change of the probability \( W \) to find a particle within a certain volume \( V \):

\[
\frac{dW}{dt} = \frac{d}{dt} \int_V \Psi \Psi^* \, d^3 r .
\]

---

\(^{35}\) The reader should not be surprised by the use of the notion of “knowledge” (or “information”) in this context. Indeed, due to the statistical character of experiment outcomes, quantum mechanics (or at least its relation to experiment) is intimately related to the information theory. In contrast to much of classical physics, which may be discussed without any reference to information, in quantum mechanics, as in classical statistical physics, such abstraction is possible only in some very special (and not the most interesting) cases.

\(^{36}\) Note that this requirement may be violated in the relativistic quantum theory – see Chapter 9.
Assuming for simplicity that the boundaries of the volume $V$ do not move, it is sufficient to carry out the partial differentiation of the product $\Psi \Psi^*$ inside the integral. Using the Schrödinger equation (25), together with its complex conjugate,

$$-i\hbar \frac{\partial \Psi^*}{\partial t} = (\hat{H}\Psi)^*,$$  \hspace{1cm} (1.39)

we readily get

$$\frac{dW}{dt} = \int_V \frac{\partial}{\partial t} \left( \Psi \Psi^* \right) d^3 r \equiv \int_V \left( \Psi^* \frac{\partial \Psi}{\partial t} + \Psi \frac{\partial \Psi^*}{\partial t} \right) d^3 r = \frac{1}{i\hbar} \int_V \left[ \Psi^* \left( \hat{H}\Psi \right) - \Psi \left( \hat{H}\Psi^* \right) \right] d^3 r. \hspace{1cm} (1.40)$$

Let the particle move in a field of external forces (not necessarily constant in time), so that its classical Hamiltonian function $H$ is the sum of the particle’s kinetic energy $T = \frac{p^2}{2m}$ and its potential energy $U(r, t)$. According to the correspondence principle, and Eq. (27), the Hamiltonian operator may be represented as the sum:

$$\hat{H} = \hat{T} + \hat{U} = \frac{\hat{p}^2}{2m} + U(r, t) = -\frac{\hbar^2}{2m} \nabla^2 + U(r, t). \hspace{1cm} (1.41)$$

At this stage, we should notice that this operator, when acting on a real function, returns a real function. Hence, the result of its action on an arbitrary complex function $\Psi = a + ib$ (where $a$ and $b$ are real) is

$$\hat{H}\Psi = \hat{H}(a + ib) = \hat{H}a + i\hat{H}b,$$  \hspace{1cm} (1.42)

where $\hat{H}a$ and $\hat{H}b$ are also real, while

$$(\hat{H}\Psi)^* = (\hat{H}(a + ib))^* = \hat{H}(a - ib) = \hat{H}(a - ib) = \hat{H}\Psi^*.$$  \hspace{1cm} (1.43)

This means that Eq. (40) may be rewritten as

$$\frac{dW}{dt} = \frac{1}{i\hbar} \int_V \left[ \Psi^* \hat{H}\Psi - \Psi \hat{H}\Psi^* \right] d^3 r = -\frac{\hbar^2}{2m} \frac{1}{i\hbar} \int_V \left[ \Psi^* \nabla^2 \Psi - \Psi \nabla^2 \Psi^* \right] d^3 r. \hspace{1cm} (1.44)$$

Now, let us use general rules of vector calculus to write the following identity:

$$\nabla \cdot \left( \Psi^* \nabla \Psi - \Psi \nabla \Psi^* \right) = \Psi^* \nabla^2 \Psi - \Psi \nabla^2 \Psi^*,$$  \hspace{1cm} (1.45)

A comparison of Eqs. (44) and (45) shows that we may write

$$\frac{dW}{dt} = -\int_V \left( \nabla \cdot \mathbf{j} \right) d^3 r,$$  \hspace{1cm} (1.46)

---

37 As a reminder, such description is valid not only for conservative forces (in that case $U$ has to be time-independent), but also for any force $\mathbf{F}(r, t)$ that may be expressed via the gradient of $U(r, t)$ – see, e.g., CM Chapters 2 and 10. (A good example when such a description is impossible is given by the magnetic component of the Lorentz force – see, e.g., EM Sec. 9.7, and also Sec. 3.1 below.)

38 Historically, this was the main step made (in 1926) by E. Schrödinger on the background of L. de Broglie’s idea. The probabilistic interpretation of the wavefunction was put forward, almost simultaneously, by M. Born.

39 In Chapter 4, we will discuss a more general family of Hermitian operators, which have this property.

40 See, e.g., MA Eq. (11.4a), combined with the del operator’s definition $\nabla^2 \equiv \nabla \cdot \nabla$. 
where the vector $j$ is defined as

$$j \equiv \frac{i\hbar}{2m} \left( \Psi \nabla \Psi^* - \text{c.c.} \right) \equiv \frac{\hbar}{m} \text{Im} \left( \Psi^* \nabla \Psi \right),$$  \hspace{1cm} (1.47)

where c.c. means the complex conjugate of the previous expression – in this case, $(\Psi \nabla \Psi^*)^*$, i.e. $\Psi^* \nabla \Psi$. Now using the well-known divergence theorem,\(^{41}\) Eq. (46) may be rewritten as the **continuity equation**

$$\frac{dW}{dt} + I = 0, \quad \text{with } I \equiv \int_S j_n d^2r,$$  \hspace{1cm} (1.48)

where $j_n$ is the component of the vector $j$ along the outwardly directed normal to the closed surface $S$ that limits the volume $V$, i.e. the scalar product $j \cdot n$, where $n$ is the unit vector along this normal.

Equalities (47) and (48) show that if the wavefunction on the surface vanishes, the total probability $W$ of finding the particle within the volume does not change, providing the required sanity check. In the general case, Eq. (48) says that $dW/dt$ equals the flux $I$ of the vector $j$ through the surface, with the minus sign. It is clear that this vector may be interpreted as the **probability current density** - and $I$, as the total **probability current** through the surface $S$. This interpretation may be further supported by rewriting Eq. (47) for the wavefunction represented in the polar form $\Psi = ae^{i\phi}$, with real $a$ and $\phi$:

$$j = a^2 \frac{\hbar}{m} \nabla \phi.$$  \hspace{1cm} (1.49)

Note that for a real wavefunction, or even for a wavefunction with an arbitrary but space-constant phase $\phi$, the probability current density vanishes. On the contrary, for the traveling wave (29), with a constant probability density $w = a^2$, Eq. (49) yields a non-zero (and physically very transparent) result:

$$j = w \frac{\hbar}{m} \kappa = w \frac{p}{m} = w\mathbf{v},$$  \hspace{1cm} (1.50)

where $\mathbf{v} = p/m$ is particle’s velocity. If multiplied by the particle’s mass $m$, the probability density $w$ turns into the (average) mass density $\rho$, and the probability current density - into the **mass flux density** $\rho \mathbf{v}$. Similarly, if multiplied by the total electric charge $q$ of the particle, with $w$ turning into the **charge density** $\sigma$, $j$ becomes the electric current density. As the reader (hopefully :-) knows, both these currents satisfy classical continuity equations similar to Eq. (48).\(^{42}\)

Finally, let us recast the continuity equation, rewriting Eq. (46) as

$$\int_V \left( \frac{\partial w}{\partial t} + \nabla \cdot j \right) d^3r = 0.$$  \hspace{1cm} (1.51)

Now we may argue that this equality may be true for any choice of the volume $V$ only if the expression under the integral vanishes everywhere, i.e. if

$$\frac{\partial w}{\partial t} + \nabla \cdot j = 0.$$  \hspace{1cm} (1.52)

This differential form of the continuity equation may be more convenient than its integral form (48).

\(^{41}\) See, e.g., MA Eq. (12.2).

\(^{42}\) See, e.g., respectively, CM 8.3 and EM Sec. 4.1.
1.5. Eigenstates and eigenvalues

Now let us discuss the most important corollaries of wave mechanics’ linearity. First of all, it uses only linear operators. This term means that the operators must obey the following two rules:

\[
\left(\hat{A}_1 + \hat{A}_2\right)\Psi = \hat{A}_1\Psi + \hat{A}_2\Psi,
\]

where \(\Psi_n\) are arbitrary wavefunctions, while \(c_n\) are arbitrary constants (in quantum mechanics, frequently called \(c\)-numbers, to distinguish them from operators and wavefunctions). The most important examples of linear operators are given by:

(i) the multiplication by a function, such as for the operator \(\hat{r}\) given by Eq. (26), and

(ii) the spatial or temporal differentiation of the wavefunction, such as in Eqs. (25)-(27).

Next, it is of key importance that the Schrödinger equation (25) is also linear. (We have already used this fact when we discussed wave packets in the last section.) This means that if each of several functions \(\Psi_n\) are (particular) solutions of Eq. (25) with a certain Hamiltonian, then their arbitrary linear combination

\[
\Psi = \sum_n c_n \Psi_n
\]

is also a solution of the same equation.

Let us use this linearity to accomplish an apparently impossible feat: immediately find the general solution of the Schrödinger equation for the most important case when the system’s Hamiltonian does not depend on time explicitly – for example, like in Eq. (41) with time-independent potential energy \(U = U(r)\), when the Schrödinger equation has the form

\[
\left(i\hbar \frac{\partial}{\partial t}\right) \Psi = -\frac{\hbar^2}{2m} \nabla^2 \Psi + U(r)\Psi.
\]

First of all, let us prove that the following product,

\[
\Psi_n = a_n(t)\psi_n(r),
\]

qualifies as a (particular) solution of such an equation. Indeed, plugging Eq. (57) into Eq. (25) with any time-independent Hamiltonian, using the fact that in this case

\[
\hat{H}a_n(t)\psi_n(r) = a_n(t)\hat{H}\psi_n(r),
\]

By the way, if any equality involving operators is valid for an arbitrary wavefunction, the latter is frequently dropped from notation, resulting in an operator equality. In particular, Eq. (53) may be readily used to prove that the linear operators are commutative: \(\hat{A}_2 + \hat{A}_1 = \hat{A}_1 + \hat{A}_2\), and associative: \(\hat{A}_1 + (\hat{A}_2 + \hat{A}_3) = (\hat{A}_1 + \hat{A}_2) + \hat{A}_3\).

At the first glance, it may seem strange that the linear Schrödinger equation correctly describes quantum properties of systems whose classical dynamics is described by nonlinear equations of motion (e.g., an anharmonic oscillator – see, e.g., CM Sec. 5.2). Note, however, that statistical equations of classical dynamics (see, e.g., SM Chapters 5 and 6) also have this property, so it is not specific to quantum mechanics.
and dividing both parts of the equation by $a_n \psi_n$, we get
\[
\frac{ih}{a_n} \frac{da_n}{dt} = \hat{H} \psi_n, \quad (1.59)
\]

The left-hand side of this equation may depend only on time, while the right-hand side, only on coordinates. These facts may be only reconciled if we assume that each of these parts is equal to the (same) constant of the dimension of energy, which I will denote as $E_n$. As a result, we are getting two separate equations for the temporal and spatial parts of the wavefunction:

\[
\hat{H} \psi_n = E_n \psi_n, \quad (1.60)
\]
\[
\frac{ih}{a_n} \frac{da_n}{dt} = E_n a_n. \quad (1.61a)
\]

The latter of these equations, rewritten in the form
\[
\frac{da_n}{a_n} = -i \frac{E_n}{\hbar} dt, \quad (1.61b)
\]
is readily integrable, giving
\[
\ln a_n = -i \omega_n t + \text{const}, \quad \text{so that} \quad a_n = \text{const} \times \exp\left\{-i \omega_n t\right\}, \quad \text{with} \quad \omega_n = \frac{E_n}{\hbar}. \quad (1.62)
\]

Now plugging Eqs. (57) and (62) into Eq. (22), we see that in the quantum state described by Eqs. (57)-(62), the probability $w$ of finding the particle at a certain location does not depend on time:
\[
w \equiv \psi_n^* (r) \psi_n (r) = w(r). \quad (1.63)
\]

With the same substitution, Eq. (23) shows that the expectation value of any operator that does not depend on time explicitly is also time-independent:
\[
\langle A \rangle \equiv \int \psi_n^* (r) \hat{A} \psi_n (r) d^3 r = \text{const.} \quad (1.64)
\]

Due to this property, the states described by Eqs. (57)-(62), are called stationary; they are fully defined by the possible solutions (called eigenfunctions) of the stationary (or “time-independent”) Schrödinger equation (60).

Note that for the time-independent Hamiltonian (41), the stationary Schrödinger equation (60),
\[
- \frac{\hbar^2}{2m} \nabla^2 \psi_n + U(r) \psi_n = E_n \psi_n, \quad (1.65)
\]
is a linear, homogeneous differential equation for the function $\psi_n$, with a priori unknown parameter $E_n$. Such equations fall into the mathematical category of eigenproblems, in which the eigenfunctions $\psi_n$

---

45 This argumentation, leading to variable separation, is very common in mathematical physics – see, e.g., its discussion in CM Sec. 6.5 and EM Sec. 2.5 and beyond.

46 From the German root eigen, meaning “particular” or “characteristic”.

47 In contrast, the full Schrödinger equation (25) is frequently called time-dependent or non-stationary.
and eigenvalues $E_n$ should be found simultaneously, i.e. self-consistently.\footnote{Eigenvalues of energy are frequently called eigenenergies, and it is often said that eigenfunction $\psi_n$ and eigenenergy $E_n$ together characterize the $n^{th}$ stationary eigenstate of the system.} Mathematics tells us that for such equations with space-confined eigenfunctions $\psi_n$, tending to zero at $r \to \infty$, the spectrum of eigenvalues is discrete. It also proves that the eigenfunctions corresponding to different eigenvalues are orthogonal, i.e. that space integrals of the products $\psi_n \psi_n^*$ vanish for all pairs with $n \neq n'$. Due to the Schrödinger equation’s linearity, each of these functions may be multiplied by a proper constant coefficient to make their set orthonormal:

$$\int \psi_n^* \psi_n^* d^3r = \delta_{n,n'} = \begin{cases} 1, & \text{if } n = n', \\ 0, & \text{if } n \neq n'. \end{cases} \quad (1.66)$$

Moreover, the eigenfunctions $\psi_n(r)$ form a full set, meaning that an arbitrary function $\Psi(r)$, in particular the actual wavefunction $\Psi$ of the system in the initial moment of its evolution (which I will take for $t = 0$, with a few exceptions), may be represented as a unique expansion over the eigenfunction set:\footnote{If the reader has any doubt in these properties of linear, homogeneous differential equations, I may recommend reviewing Sec. 9.3 of the wonderful handbook by G. Korn and T. Korn, listed in MA Sec. 16(ii).}

$$\Psi(r,0) = \sum_n c_n \psi_n(r). \quad (1.67)$$

The expansion coefficients $c_n$ may be readily found by multiplying both parts of Eq. (67) by $\psi_n^*$, integrating the result over the space, and using Eq. (66). The result is

$$c_n = \int \psi_n^* (r) \Psi(r,0) d^3r. \quad (1.68)$$

Now let us consider the following wavefunction

$$\Psi(r,t) = \sum_n c_n a_n(t) \psi_k(r) = \sum_n c_n \exp\left\{ -i \frac{E_n}{\hbar} t \right\} \psi_n(r). \quad (1.69)$$

Since each term of the sum has the form (57) and satisfies the Schrödinger equation, so does the sum as the whole. Moreover, if the coefficients $c_n$ are derived in accordance with Eq. (68), then the solution (69) satisfies the initial conditions as well. At this moment we can use one more bit of help from mathematicians, who tell us that the linear, partial differential equation of type (65), with fixed initial conditions, may have only one (unique) solution. This means that in our case of motion in a time-independent potential Hamiltonian, Eq. (69) gives the general solution of the Schrödinger equation (65).

So, we have succeeded in our apparently over-ambitious goal. Now let us pause this mad mathematical dash for a minute, and discuss this key result.

### 1.6. Time evolution

For the time-dependent factor, $a_n(t)$, of each component (57) of the general solution (69), our procedure gave a very simple and universal result (62), describing a linear change of the phase $\varphi_n \equiv \arg(a_n)$ of this complex function in time, with the constant rate

$$\frac{d\varphi_n}{dt} = -\omega_n = -\frac{E_n}{\hbar}, \quad (1.70)$$
so that the real and imaginary parts of $a_n$ oscillate sinusoidally with this frequency. The relation (70) coincides with Einstein’s conjecture (5), but could these oscillations of the wavefunctions represent a physical reality? Indeed, for photons, described by Eq. (5), $E$ may be (and as we will see in Chapter 9, is) the actual, well-defined energy of one photon, and $\omega$ is the frequency of the radiation so quantized. However, for non-relativistic particles, described by wave mechanics, the potential energy $U$, and hence the full energy $E$, are defined to an arbitrary constant, because we may measure them from an arbitrary reference level. How can such a change of the energy reference level (which may be made just in our mind) alter the frequency of oscillations of a variable?

According to Eqs. (22)-(23), this time evolution of a wavefunction does not affect the particle’s probability distribution, or even any observable (including the energy $E$, provided that it is always referred to the same origin as $U$), in any stationary state. However, as will be proved later in the course, using the combination of Einstein’s formula (5) with the Bohr’s assumption (7),

$$\hbar \omega_{n'} = E_{n'} - E_n,$$

the difference of the eigenfrequencies $\omega_n$ (evidently, independent on the energy reference) of two eigenstates is absolutely physical, because it determines the measurable frequency of the electromagnetic radiation (or possibly a wave of a different physical nature) emitted or absorbed at the quantum transition between the states.

As one more example, consider two similar, independent particles 1 and 2, each in the same (say, the lowest-energy, ground) eigenstate, but with the potential energies (and hence the ground state energies $E_{1,2}$) different by a constant $\Delta U = U_1 - U_2$. Then, according to Eq. (70), the difference $\phi \equiv \phi_1 - \phi_2$ of their wavefunction phases evolves in time with a reference-independent rate

$$\frac{d\phi}{dt} = -\frac{\Delta U}{\hbar}.$$

Certain measurement instruments, weakly coupled to each particle, may allow an observation of this evolution, while keeping the particle’s quantum dynamics virtually unperturbed, i.e. Eq. (70) intact. Perhaps the most dramatic measurement of this type is possible using the Josephson effect in weak links between two superconductors – see Fig. 7.50

As a brief reminder,51 superconductivity may be explained by a specific coupling between conduction electrons in solids, that leads, at low temperatures, to the formation of the so-called Cooper pairs. Such pairs, each consisting of two electrons with opposite spins and momenta, behave as Bose

50 The effect was predicted in 1962 by Brian Josephson, then a graduate student, and observed soon after that.
51 For a more detailed discussion, including the derivation of Eq. (75), see e.g. EM Chapter 6.
particles, and form a coherent Bose-Einstein condensate.\textsuperscript{52} Most properties of such a condensate may be described by a single, common wavefunction $\Psi$, evolving in time just as that of a free particle, with the effective potential energy $U = q\phi = -2e\phi$, where $\phi$ is the electrochemical potential,\textsuperscript{53} and $q = -2e$ is the electric charge of a Cooper pair. As a result, for the system shown in Fig. 7, in which an externally applied voltage $V$ fixes the difference $\phi_1 - \phi_2$ between the electrochemical potentials of two bulk superconductors, Eq. (72) takes the form

$$\frac{d\phi}{dt} = \frac{2e}{\hbar} V,$$

(1.73)

where $V = \phi_1 - \phi_2$ is the applied voltage. If the link between the superconductors is weak enough, the electric current $I$ of the Cooper pairs (called the supercurrent) through the link may be approximately described by the following simple relation,\textsuperscript{54}

$$I = I_c \sin \varphi,$$

(1.74)

where $I_c$ is some constant, dependent on the weak link’s strength. Now combining Eqs. (73) and (74), we see that if the applied voltage $V$ is constant in time, the current oscillates sinusoidally, with the so-called Josephson frequency

$$\omega_J \equiv \frac{2e}{\hbar} V,$$

(1.75)

as high as $\sim 484$ MHz per each microvolt of applied dc voltage. This effect may be readily observed experimentally: though its direct detection is a bit tricky, it is easy to observe the phase locking (synchronization)\textsuperscript{55} of the Josephson oscillations by an external microwave signal of frequency $\omega$. Such phase locking results in the relation $\omega_j = n\omega$ fulfilled within certain current intervals, and hence in the formation, on the weak-link’s dc $I$-$V$ curve, of virtually vertical current steps at dc voltages

$$V_n = n \frac{\hbar \omega}{2e},$$

(1.76)

where $n$ is an integer.\textsuperscript{56} Since frequencies may be stabilized and measured with very high precision, this effect is being used in highly accurate standards of dc voltage.

1.7. Spatial dependence

In contrast to the simple and universal time dependence (62) of the stationary states, the spatial distributions of their wavefunction $\psi_n(r)$ need to be calculated from the problem-specific stationary Schrödinger equation (65). The solution of this equation for various particular cases is a major focus of the next two chapters. For now, let us consider just the simplest example, which nevertheless will be the

\textsuperscript{52} A detailed discussion of the Bose-Einstein condensation may be found, e.g., in SM Sec. 3.4.
\textsuperscript{53} For more on this notion see, e.g. SM Sec. 6.3.
\textsuperscript{54} In some cases, the function $I(\phi)$ may somewhat deviate from Eq. (74), but these deviations do not affect its fundamental $2\pi$-periodicity. As a result, no corrections to the fundamental relations (75)-(76) have ever been found (yet :-).
\textsuperscript{55} For the discussion of this general effect, see, e.g., CM Sec. 5.4.
\textsuperscript{56} If $\omega$ is not too high, the size of these current steps may be calculated from Eqs. (73) and (74). Let me leave this task for the reader’s exercise.
basis for our discussion of more complex problems, namely a particle confined inside a rectangular hard-wall box. Such confinement may be described by the following potential energy:

$$U({\mathbf{r}}) = \begin{cases} 0, & \text{for } 0 < x < a_x, \; 0 < y < a_y, \; \text{and } 0 < z < a_z, \\ +\infty, & \text{otherwise}. \end{cases} \quad (1.77)$$

The only way to keep the product $U({\mathbf{r}})\psi_n$ in Eq. (65) finite outside the box, is to have $\psi = 0$ in these regions. Also, the function have to be continuous everywhere, to avoid the divergence of its Laplace operator - which would give an unphysical divergence of its kinetic energy (27). Hence, in this case we may solve the stationary Schrödinger equation (60) just inside the box, i.e. with $U = 0$, so that it takes a simple form\(^{58}\)

$$-\frac{\hbar^2}{2m} \nabla^2 \psi_n = E_n \psi_n, \quad (1.78a)$$

with zero boundary conditions on all the walls. For our particular geometry, it is natural to express the Laplace operator in the Cartesian coordinates \{x, y, z\} aligned with the box sides, with the origin at one of the corners of its rectangular $a_x \times a_y \times a_z$ volume, so that we get the following boundary problem:

$$-\frac{\hbar^2}{2m} \left( \frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} + \frac{\partial^2}{\partial z^2} \right) \psi_n = E_n \psi_n, \quad \text{for } 0 < x < a_x, \; 0 < y < a_y, \; \text{and } 0 < z < a_z, \quad (1.78b)$$

with $\psi_n = 0$ for: $x = 0$ and $a_x$; $y = 0$ and $a_y$; $z = 0$ and $a_z$.

This problem may be readily solved using the same variable separation method as was used in Sec. 5, now to separate the Cartesian spatial variables from each other, by looking for a partial solution of Eq. (78) in the form

$$\psi({\mathbf{r}}) = X(x)Y(y)Z(z). \quad (1.79)$$

(It is convenient to postpone assigning function indices for a minute.) Plugging this expression into Eq. (78b) and dividing all terms by the product $XYZ$, we get

$$-\frac{\hbar^2}{2m} \frac{1}{X} \frac{d^2 X}{dx^2} - \frac{\hbar^2}{2m} \frac{1}{Y} \frac{d^2 Y}{dy^2} - \frac{\hbar^2}{2m} \frac{1}{Z} \frac{d^2 Z}{dz^2} = E. \quad (1.80)$$

Now let us repeat the standard argumentation of the variable separation method: since each term on the left-hand side of this equation may be only a function of the corresponding argument, the equality is possible only if each of them is a constant – in our case, with the dimensionality of energy. Calling these constants $E_x$, etc., we get three similar 1D equations

\(^{57}\) Another common name for such potentials, especially of lower dimensionality, is the potential well, in our current case with a flat “bottom” and infinitely high “walls”. Note that sometimes, very unfortunately, such potential profiles are called “quantum wells”. (This term seems to imply that the particle’s confinement in such a well is a phenomenon specific for quantum mechanics. However, as we will repeatedly see in this course, the opposite is true: quantum effects do as much as they only can to overcome the particle’s confinement in a potential well, letting it partly penetrate in the “classically forbidden” regions beyond the well’s walls.)

\(^{58}\) Rewritten as $\nabla^2 f + k^2 f = 0$, this is just the Helmholtz equation, which describes waves of any nature (with the wave vector $k$) in a uniform, isotropic, linear medium – see, e.g., EM Secs. 7.5-7.9 and 8.5.
with Eq. (80) turning into the following energy-matching condition:

$$E_x + E_y + E_z = E.$$  \tag{1.82}

All three ordinary differential equations (81), and their solutions, are similar. For example, for $$X(x)$$, we have the following 1D Helmholtz equation

$$\frac{d^2 X}{dx^2} + k_x^2 X = 0,$$

with $$k_x^2 \equiv \frac{2mE_x}{\hbar^2}$$, \hspace{1cm} (1.83)

and simple boundary conditions: $$X(0) = X(a_x) = 0$$. Let me hope that the reader knows how to solve this well-known 1D boundary problem - describing, for example, the usual mechanical waves on a guitar string. The problem allows an infinite number of sinusoidal standing-wave eigenfunctions, with the eigenenergy values (frequently called the energy levels) are used as horizontal axes for plotting the eigenfunctions - despite their completely different dimensionality.

$$E_x = \frac{\hbar^2}{2m} k_x^2 = \frac{\pi^2 \hbar^2}{2ma_x^2} n_x^2 \equiv E_{x1} n_x^2.$$ \hspace{1cm} (1.85)

Figure 8 shows these simple results, using a somewhat odd but very graphic and hence common representation, in that the eigenenergy values (frequently called the energy levels) are used as horizontal axes for plotting the eigenfunctions - despite their completely different dimensionality.

$$E_{x1} / E_{x1} \quad X(x) \quad n_x = 3$$

$$n_x = 2$$

$$n_x = 1$$

$$x$$

Fig. 1.8. The lowest eigenfunctions (solid lines) and eigenvalues (dashed lines) of equation (83) for a potential well of length $$a_x$$. Solid black lines show the effective potential energy profile for the 1D eigenproblem (83).

Due to the similarity of all Eqs. (81), $$Y(y)$$ and $$Z(z)$$ are absolutely similar functions of their arguments, and may also be numbered by integers (say, $$n_y$$ and $$n_z$$) independent of $$n_x$$, so that the spectrum of values of the total energy (82) is

$$E_{n_x, n_y, n_z} = \frac{\pi^2 \hbar^2}{2m} \left( \frac{n_x^2}{a_x^2} + \frac{n_y^2}{a_y^2} + \frac{n_z^2}{a_z^2} \right).$$ \hspace{1cm} (1.86)

\hspace{1cm}

59 The front coefficient in the last expression for $$X$$ ensures the (ortho)normality condition (66).
Thus, in this 3D problem, the role of the index \( n \) in the general Eq. (69) is played by a set of 3 independent integers \( \{n_x, n_y, n_z\} \). In quantum mechanics, such integers play a key role, and thus have a special name, the *quantum numbers*. Using them, the general solution of our simple problem may be represented as the sum

\[
\Psi(\mathbf{r}, t) = \sum_{n_x, n_y, n_z = 1}^{\infty} c_{n_x,n_y,n_z} \sin \frac{\pi n_x x}{a_x} \sin \frac{\pi n_y y}{a_y} \sin \frac{\pi n_z z}{a_z} \exp \left\{ -i \frac{E_{n_x,n_y,n_z}}{\hbar} t \right\},
\]

with the front coefficients that may be readily calculated from the initial wavefunction \( \Psi(\mathbf{r}, 0) \), using Eq. (68) - again with the replacement \( n \rightarrow \{n_x, n_y, n_z\} \). This simplest problem is a good illustration of typical results the wave mechanics gives for spatially-confined motion, including the discrete energy spectrum, and (in this case, evidently) orthogonal eigenfunctions. Perhaps most importantly, its solution shows that the lowest value of the particle’s kinetic energy (86), reached in the so-called *ground state* (in our case, the state with \( n_x = n_y = n_z = 1 \)) is above zero.

An example of the opposite case of a *continuous spectrum* for the unconfined motion of a free particle is given by the plane waves (29). With the account of relations \( E = \hbar \omega \) and \( \mathbf{p} = \hbar \mathbf{k} \), such wavefunction may be viewed as the product of the time-dependent factor (62) by the eigenfunction,

\[
\psi_k = a_k \exp \{i \mathbf{k} \cdot \mathbf{r}\},
\]

which is the solution of the stationary Schrödinger equation (78a) if it is valid in the whole space.\(^{60}\) The reader should not be worried too much by the fact that the fundamental solution (86) in free space is a *traveling wave* (having, in particular, a non-vanishing value of the probability current \( j \)), while those inside a quantum box are *standing waves*, with \( j = 0 \), even though the free space may be legitimately considered as the ultimate limit of a quantum box with volume \( V = a_x \times a_y \times a_z \to \infty \). Indeed, due to the linearity of wave mechanics, two traveling-wave solutions (88) with equal and opposite values of the momentum (and hence with the same energy) may be readily combined to give a standing-wave solution,\(^{61}\) for example, \( \exp \{i \mathbf{k} \cdot \mathbf{r}\} + \exp \{-i \mathbf{k} \cdot \mathbf{r}\} = 2 \cos(\mathbf{k} \cdot \mathbf{r}) \), with the net current \( j = 0 \). Thus, depending on convenience for a particular problem, we can represent the general solution as a sum of either traveling-wave or standing-wave eigenfunctions.

Since in the unlimited free space, there are no boundary conditions to satisfy, the Cartesian components of the wave vector \( \mathbf{k} \) in Eq. (88) can take any real values. (This is why it is more convenient to label these wavefunctions, and the corresponding eigenenergies,

\[
E_k = \frac{\hbar^2 k^2}{2m} \geq 0,
\]

with their wave vector \( \mathbf{k} \) rather than an integer index.) However, one aspect of continuous-spectrum systems requires a bit more math caution: the summation (69) should be replaced by the integration over a continuous index or indices - in our current case, three Cartesian components of the vector \( \mathbf{k} \). The main rule of such replacement may be readily extracted from Eq. (84): according to this relation, for

\(^{60}\) In some systems (e.g., a particle interacting with a potential well of a finite depth), a discrete energy spectrum within a certain interval of energies may coexist with a continuous spectrum in a complementary interval. However, the conceptual philosophy of eigenfunctions and eigenvalues remains the same in our current case.

\(^{61}\) This is, of course, the general property of waves of any physical nature, propagating in a linear medium – see, e.g., CM Sec. 6.5 and/or EM Sec. 7.3.
standing-wave solutions, the eigenvalues of \( k_x \) are \textit{equidistant}, i.e. separated by equal intervals \( \Delta k_x = \pi/a_x \) (with the similar relations for other two Cartesian components of vector \( \mathbf{k} \)). Hence the number of different eigenvalues of the standing wave vector \( \mathbf{k} \) (with \( k_x, k_y, k_z \geq 0 \)), within a volume \( d^3k \gg 1/V \) of the \( k \) space is

\[
dN = \frac{V}{(2\pi)^3} d^3k.
\]

(1.90)

For \( dN \gg 1 \), this expression is independent of the boundary conditions, and is frequently represented as the following \textit{summation rule}

\[
\lim_{k^3 \rightarrow \infty} \sum_k f(\mathbf{k}) = \int f(\mathbf{k})dN = V \left( \frac{V}{2\pi} \right)^3 \int f(\mathbf{k})d^3k,
\]

(1.91)

where \( f(\mathbf{k}) \) is an arbitrary function of \( \mathbf{k} \). Note that if the same wave vector \( \mathbf{k} \) corresponds to several internal quantum states (such as spin – see Chapter 4), the right-hand side of Eq. (91) requires its multiplication by the corresponding \textit{degeneracy factor} of orbital states.

### 1.8. Dimensionality reduction

To conclude this introductory chapter, let me discuss the conditions when the spatial dimensionality of a wave mechanics problem may be reduced.62 Naively, one may think that if the particle’s potential energy depends on just one spatial coordinate, say \( U = U(x, t) \), then its wavefunction has to be one-dimensional as well: \( \psi = \psi(x, t) \). Our discussion of the particular case \( U = \text{const} \) in the previous section shows that this assumption is wrong. Indeed, though this \textit{potential}63 is just a special case of the potential \( U(x, t) \), most of its eigenfunctions, given by Eqs. (87) or (88), do depend on other two coordinates. This is why the solutions \( \psi(x, t) \) of the 1D Schrödinger equation

\[
\frac{i\hbar}{\partial t} \Psi = -\frac{\hbar^2}{2m} \frac{\partial^2}{\partial x^2} \Psi + U(x,t)\Psi,
\]

(1.92)

which follows from Eq. (65) by assuming \( \partial\Psi/\partial y = \partial\Psi/\partial z = 0 \), are insufficient to form the general solution of Eq. (65) for this case.

This fact is easy to understand physically for the simplest case of a stationary 1D potential: \( U = U(x) \). The absence of the \( y \)- and \( z \)-dependence of the potential energy \( U \) may be interpreted as a potential well which is flat in two directions, \( y \) and \( z \). Repeating the arguments of the previous section for this case, we see that the eigenfunctions of a particle in such a well have the form

\[
\psi(\mathbf{r}) = X(x) \exp\{i(k_x y + k_z z)\},
\]

(1.93)

---

62 Most textbooks on quantum mechanics jump to the formal solution of 1D problems without such discussion, ignoring the fact that such dimensionality restriction is adequate only under very specific conditions.

63 Following tradition, I will frequently use this shorter form the term “potential energy”, returning to its full form in the cases where there is any chance of confusion of this notion with the “genuine” (say, electrostatic) potential.
where \( X(x) \) are the eigenfunction of the following stationary 1D Schrödinger equation:

\[
-\frac{\hbar^2}{2m} \frac{d^2 X}{dx^2} + U_{\text{ef}}(x) X = E X,
\]

(1.94)

where \( U_{\text{ef}}(x) \) is not the full potential energy of the particle, as it would follow from Eq. (92), but rather its effective value including the kinetic energy of lateral motion:

\[
U_{\text{ef}} \equiv U + (E_y + E_z) = U + \frac{\hbar^2}{2m} \left( k_y^2 + k_z^2 \right).
\]

(1.95)

In plain English, the particle’s partial wavefunction \( X(x) \), and its full energy, depends on its transverse momenta, which have continuous spectrum – see the discussion of Eq. (89). This means that Eq. (92) is adequate only if the condition \( k_y = k_z = 0 \) is somehow enforced, and in most physical problems, it is not. For example, if a de Broglie (or any other) plane wave \( \Psi(x, t) \) is incident on a potential step, it would be reflected exactly back, i.e. with \( k_y = k_z = 0 \), only if the wall’s surface is perfectly plane and exactly normal to the axis \( x \). Any imperfection (and they are so many of them in real physical systems :) may cause excitation of waves with non-vanishing values of \( k_y \) and \( k_z \), due the continuous character of the functions \( E_y(k_y) \) and \( E_z(k_z) \).

64 This problem is not specific for quantum mechanics. The classical motion of a particle in a 1D potential may be also unstable with respect to lateral perturbations, especially is the potential is time-dependent, i.e. capable of exciting low-energy lateral modes.

65 The term “quantum confinement”, sometimes used to describe this phenomenon, is as unfortunate as the “quantum well” term discussed above, because of the same reason: the confinement is a purely classical effect, and as we will repeatedly see in this course, the quantum-mechanical effects reduce, rather than enable it.

There is essentially one, perhaps counter-intuitive way to make the 1D solutions “robust” to small perturbations: it is to provide a rigid lateral confinement\(^6^5\) in two other directions. As the simplest example, consider a narrow quantum wire (Fig. 9a), provided by the potential

\[
U(r) = \begin{cases} 
U(x), & \text{for } 0 < y < a_y, \text{ and } 0 < z < a_z, \\
+\infty, & \text{otherwise.}
\end{cases}
\]

(1.96)

![Fig. 1.9. Partial confinement in: (a) two dimensions, and (b) one dimension.](image)

Performing the standard variable separation (79), we see that the corresponding stationary Schrödinger equation is satisfied if the partial wavefunction \( X(x) \) obeys Eqs. (94)-(95), but now with a discrete energy spectrum in the transverse directions:

\[
U_{\text{ef}} = U + \frac{\pi^2 \hbar^2}{2m} \left( \frac{n_y^2}{a_y^2} + \frac{n_z^2}{a_z^2} \right).
\]

(1.97)

If the lateral confinement is tight, \( a_y, a_z \to 0 \), then there is a large energy gap,
between the ground-state energy of the lateral motion (with \( n_y = n_z = 1 \)) and that for all its excited states. As a result, if the particle is initially placed into the lateral ground state, and its energy \( E \) is much smaller than \( \Delta U \), it would stay in such state, i.e. may be described by a 1D Schrödinger equation similar to Eq. (92) – even in the time-dependent case, if the characteristic frequency of energy variations is much smaller than \( \Delta U/\hbar \). Absolutely similarly, the strong lateral confinement in just one dimension (say, \( z \), see Fig. 9b) enables systems with a robust 2D evolution of the particle’s wavefunction.

The tight lateral confinement may ensure the dimensionality reduction even if the potential well is not exactly rectangular in the lateral direction(s), as described by Eq. (96), but is described by some \( x \)- and \( t \)-independent profile, if it still provides a sufficiently large energy gap \( \Delta U \). For example, many 2D quantum phenomena, such as the quantum Hall effect,\(^66\) have been studied experimentally using electrons confined at semiconductor heterojunctions (e.g., epitaxial interfaces GaAs/Al\(_x\)Ga\(_{1-x}\)As), where the potential well in the direction perpendicular to the interface has a nearly triangular shape, and provides the energy gap \( \Delta U \) of the order of \( 10^{-2} \) eV.\(^67\) This splitting energy corresponds to \( k_B T \) with \( T \sim 100 \) K, so that careful experimentation at liquid helium temperatures (4K and below) may keep the electrons performing purely 2D motion in the “lowest subband” (\( n_z = 1 \)).

Finally, note that in systems with reduced dimensionality, Eq. (90) for the number of states at large \( k \) (i.e., for an essentially free particle motion) should be replaced accordingly: in a 2D system of area \( A \gg 1/k^2 \),

\[
dN = \frac{A}{(2\pi)^2} d^2k , \quad (1.99)
\]

while in a 1D system of length \( l \gg 1/k \),

\[
dN = \frac{l}{2\pi} dk , \quad (1.100)
\]

with the corresponding changes of the summation rule (91). This change has important implications for the density of states on the energy scale, \( dN/dE \): it is straightforward (and hence left for the reader :-) to use Eqs. (90), (99), and (100) to show that for free 3D particles the density increases with \( E \) (proportionally to \( E^{1/2} \)), for free 2D particles it does not depend on energy at all, while for free 1D particles it scales as \( E^{-1/2} \), i.e. decreases with energy.

1.9. Exercise problems

1.1. The actual postulate made by N. Bohr in his original 1913 paper was not directly Eq. (8), but the assumption that at quantum leaps between adjacent large (quasiclassical) orbits with \( n \gg 1 \), the hydrogen atom either emits or absorbs energy \( \Delta E = \hbar \omega \), where \( \omega \) is its classical radiation frequency - according to classical electrodynamics, equal to the angular velocity of electron’s rotation.\(^68\) Prove that this postulate is indeed compatible with Eqs. (7)-(8).

\(^{66}\) To be discussed in Sec. 3.2.

\(^{68}\) See, e.g., EM Sec. 8.2.
1.2. Use Eq. (53) to prove that the linear operators of quantum mechanics are commutative: 
\[ \hat{A}_2 + \hat{A}_1 = \hat{A}_1 + \hat{A}_2, \]
and associative: 
\[ \left( \hat{A}_1 + \hat{A}_2 \right) + \hat{A}_3 = \hat{A}_1 + \left( \hat{A}_2 + \hat{A}_3 \right). \]

1.3. Prove that for any time-independent Hamiltonian operator \( \hat{H} \) and two arbitrary complex functions \( f(\mathbf{r}) \) and \( g(\mathbf{r}) \),
\[ \int f(\mathbf{r})\hat{H}g(\mathbf{r})d^3r = \int \hat{H}f(\mathbf{r})g(\mathbf{r})d^3r. \]

1.4. Prove that the Schrödinger equation (25) with the Hamiltonian operator given by Eq. (41), is Galilean form-invariant, provided that the wavefunction is transformed as
\[ \Psi'(\mathbf{r'},t') = \Psi(\mathbf{r},t)\exp \left\{ -i\frac{\mathbf{mv} \cdot \mathbf{r}}{\hbar} + i\frac{mv^2t}{2\hbar} \right\}, \]
where the prime sign denotes the variables measured in the reference frame \( 0' \) that moves, without rotation, with a constant velocity \( \mathbf{v} \) relatively to the “lab” frame \( 0 \). Give a physical interpretation of this transformation.

1.5. * Prove the so-called Hellmann-Feynman theorem: \(^{69}\)
\[ \frac{\partial E_n}{\partial \lambda} = \left\langle \frac{\partial H}{\partial \lambda} \right\rangle_n, \]
where \( \lambda \) is some \( c \)-number parameter, on which the time-independent Hamiltonian \( \hat{H} \), and hence its eigenenergies \( E_n \), depend.

1.6. * Use Eqs. (73) and (74) to analyze the effect of phase locking of Josephson oscillations on the dc current flowing through a weak link between two superconductors (frequently called the Josephson junction), assuming that an external microwave source applies to the junction a sinusoidal ac voltage with frequency \( \omega \) and amplitude \( A \).

1.7. Calculate \( \langle x \rangle, \langle p_x \rangle, \delta x, \) and \( \delta p_x \) for the eigenstate \( \{n_x, n_y, n_z\} \) of a particle in a rectangular, hard-wall box, described by Eq. (77), and compare the product \( \delta x \delta p_x \) with the Heisenberg’s uncertainty relation.

1.8. Looking at the lower (red) line in Fig. 8, it seems plausible that the 1D ground-state function (84) of the simple potential well (77) may be well approximated with an inverted quadratic parabola:
\[ X_{\text{trial}}(x) = C x (a_x - x), \]
where \( C \) is a normalization constant. Explore how good this approximation is.

---

\(^{69}\) Despite this common name of the equality, H. Hellmann (in 1937) and R. Feynman (in 1939) were not the first ones in the long list of physicists who have (apparently, independently) discovered it. Indeed, it was traced back at least to a 1922 paper by W. Pauli, and had been carefully proved by P. Güttinger in 1931.
1.9. A particle, placed in a hard-wall, rectangular box with sides $a_x$, $a_y$, and $a_z$, is in its ground state. Calculate the average force acting on each face of the box. Can the forces be characterized by a certain pressure?

1.10. A 1D quantum particle was initially in the ground state of a very deep, rectangular potential well of width $a$:

$$U(x) = \begin{cases} 0, & \text{for } -a/2 < x < +a/2, \\ +\infty, & \text{otherwise}. \end{cases}$$

At some instant, the well’s width is abruptly increased to a new value $a' > a$, leaving the potential symmetric with respect to the point $x = 0$, and then left constant. Calculate the probability that after the change, the particle is still in the ground state of the system.

1.11. At $t = 0$, a 1D particle of mass $m$ is placed into a hard-wall, flat-bottom potential well

$$U(x) = \begin{cases} 0, & \text{for } 0 < x < a, \\ +\infty, & \text{otherwise}, \end{cases}$$
in a 50/50 linear superposition of the lowest (ground) state and the first excited state. Calculate:

(i) the normalized wavefunction $\Psi(x, t)$ for arbitrary time $t \geq 0$, and
(ii) the time evolution of the expectation value $\langle x \rangle$ of the particle’s coordinate.

1.12. Calculate the potential profiles $U(x)$ for that the following wavefunctions,

(i) $\Psi = c \exp\{-a x^2 - ibt\}$, and
(ii) $\Psi = c \exp\{-a |x| - ibt\}$,

(with real coefficients $a > 0$ and $b$), satisfy the 1D Schrödinger equation for a particle with mass $m$. For each case, calculate $\langle x \rangle$, $\langle p_x \rangle$, $\hat{\alpha} \hat{x}$, and $\hat{p_x}$, and compare the product $\hat{\alpha} \hat{x} \hat{\alpha} \hat{p_x}$ with the Heisenberg’s uncertainty relation.

1.13. A 1D particle of mass $m$, moving in the field of a stationary potential $U(x)$, has the following eigenfunction

$$\psi(x) = \frac{C}{\cosh \kappa x},$$

where $C$ is the normalization constant, and $\kappa$ is a real constant. Calculate the function $U(x)$ and the state’s eigenenergy $E$.

1.14. Calculate the density $dN/dE$ of traveling-wave states in large rectangular potential wells of various dimensions: $d = 1, 2, \text{ and } 3$.

1.15. Use the finite-difference method with steps $a/2$ and $a/3$ to find as many eigenenergies as possible for a 1D particle in the infinitely deep, hard-wall 1D potential well of width $a$. Compare the results with each other, and with the exact formula.\(^{70}\)

\(^{70}\) You may like to start from reading about the finite-difference method - see, e.g., CM Sec. 8.5 or EM Sec. 2.11.
Chapter 2. 1D Wave Mechanics

The simplest, 1D version of wave mechanics enables a quantitative discussion of many important quantum-mechanical effects. The order of their discussion in this chapter is dictated mostly by the mathematical convenience – going from the simplest potential profiles to more complex ones, so that we may build upon the previous results. However, I would advise the reader to focus more not on the math, but rather on the variety of the non-classical physical phenomena it describes, ranging from the particle penetration to classically-forbidden regions, to quantum-mechanical tunneling, to the metastable state decay, to covalent bonding and quantum oscillations, to energy bands and gaps.

2.1. Basic relations

As was discussed at the end of Chapter 1, in several cases (in particular, at strong confinement within the \([y, z]\) plane), the general (3D) Schrödinger equation may be reduced to the 1D equation, similar to Eq. (1.92):

\[
\frac{i\hbar}{\partial t} \frac{\partial^2 \Psi(x,t)}{\partial x^2} = -\frac{\hbar^2}{2m} \frac{\partial^2 \Psi(x,t)}{\partial x^2} + U(x,t)\Psi(x,t).
\]

(2.1)

It is important, however, to remember that according to the discussion in Sec. 1.8, \(U(x,t)\) in this equation is generally an effective potential energy, which may include the energy of the lateral motion, while \(\Psi(x,t)\) may be just one factor in the complete wavefunction \(\Psi(x,t)\chi(y,z)\). If the transverse factor \(\chi(y,z)\) is normalized to 1, then the integration of Eq. (1.22a) over the 3D space within a segment \([x_1, x_2]\) gives the following probability to find the particle on this segment:

\[
W(t) = \int_{x_1}^{x_2} |\Psi(x,t)|^2 dx.
\]

(2.2)

If the particle under analysis is definitely somewhere inside the system, the normalization of its 1D wavefunction \(\Psi(x,t)\) is provided by extending the integral (2) to the whole axis \(x\):

\[
\int_{-\infty}^{\infty} w(x,t) dx = 1, \quad \text{where } w(x,t) = |\Psi(x,t)|^2.
\]

(2.3)

A similar integration of Eq. (1.23) shows that the expectation value of any observable depending only on the coordinate \(x\) (and possibly time), may be expressed as

\[
\langle A \rangle(t) = \int_{-\infty}^{\infty} \Psi^*(x,t) A(x,t) \Psi(x,t) dx.
\]

(2.4)

It is also useful to introduce the notion of the probability current along the \(x\)-axis (a scalar):

\[
I(x,t) = \int j_x dy dz = \frac{\hbar}{m} \text{Im} \left( \Psi^* \frac{\partial}{\partial x} \Psi \right) = \frac{\hbar}{m} \left| \Psi(x,t) \right|^2 \frac{\partial \phi}{\partial x},
\]

(2.5)

where \(j_x\) is the \(x\)-component of the current density vector \(j(r,t)\). Then the continuity equation (1.48) for the segment \([x_1, x_2]\) takes the form
The above formulas are the basis for the analysis of 1D problems of wave mechanics, but before proceeding to particular cases, let me deliver on my earlier promise to prove that the Heisenberg’s uncertainty relation (1.35) is indeed valid for any wavefunction $\Psi(x, t)$. For that, let us consider an evidently positive (or at least non-negative) integral

$$J(\lambda) \equiv \int_{-\infty}^{+\infty} \left| x\Psi + \lambda \frac{\partial \Psi}{\partial x} \right|^2 dx \geq 0, \quad (2.7)$$

where $\lambda$ is an arbitrary real constant, and assume that at $x \to \pm \infty$ the wavefunction vanishes, together with its first derivative – as we will see below, a very common case. Then the left-hand side of Eq. (7) may be recast as

$$\int_{-\infty}^{+\infty} \left| x\Psi \right|^2 dx + \lambda \int_{-\infty}^{+\infty} \left( \frac{\partial \Psi^*}{\partial x} \right) \left( \frac{\partial \Psi}{\partial x} \right)^* dx + \lambda^2 \int_{-\infty}^{+\infty} \left( \frac{\partial \Psi}{\partial x} \right)^* \frac{\partial \Psi}{\partial x} dx. \quad (2.8)$$

According to Eq. (4), the first term in the last form of Eq. (8) is just $\langle x^2 \rangle$, while the second and the third integrals may be worked out by parts:

$$\int_{-\infty}^{+\infty} \left( x\frac{\partial \Psi^*}{\partial x} + \frac{\partial \Psi}{\partial x} \Psi^* \right) dx = \left| x\Psi \right|^2 \left. \right|_{-\infty}^{+\infty} = \int_{-\infty}^{+\infty} \frac{\partial \Psi\Psi^*}{\partial x} dx = \int_{-\infty}^{+\infty} \frac{\partial}{\partial x} \left( x\Psi \Psi^* \right) dx = \left. x\Psi \Psi^* \right|_{-\infty}^{+\infty} - \int_{-\infty}^{+\infty} \Psi\Psi^* dx = -1, \quad (2.9)$$

$$\int_{-\infty}^{+\infty} \frac{\partial \Psi}{\partial x} \frac{\partial \Psi^*}{\partial x} dx = \left. \frac{\partial^2 \Psi}{\partial x^2} \Psi^* \right|_{-\infty}^{+\infty} - \int_{-\infty}^{+\infty} \Psi^* \frac{\partial^2 \Psi}{\partial x^2} dx = -\int_{-\infty}^{+\infty} \Psi^* \frac{\partial^2 \Psi}{\partial x^2} dx = \frac{1}{\hbar^2} \int_{-\infty}^{+\infty} \Psi^* \frac{\partial \Psi}{\partial x} dx = \frac{\langle p_x^2 \rangle}{\hbar^2}. \quad (2.10)$$

As a result, Eq. (7) takes the following form:

$$J(\lambda) = \langle x^2 \rangle - \lambda + \lambda^2 \frac{\langle p_x^2 \rangle}{\hbar^2} \geq 0, \quad \text{i.e.} \quad \lambda^2 + a\lambda + b \geq 0, \quad \text{with} \quad a \equiv -\frac{\hbar^2}{\langle p_x^2 \rangle}, \quad b \equiv \frac{\hbar^2}{\langle p_x^2 \rangle} \langle x^2 \rangle. \quad (2.11)$$

This inequality should be valid for any real $\lambda$, so that the corresponding quadratic equation, $\lambda^2 + a\lambda + b = 0$, can have either one (degenerate) real root – or no real roots at all. This is only possible if its determinant, Det $= a^2 - 4b$, is non-positive, leading to the following requirement:

$$\langle x^2 \rangle \langle p_x^2 \rangle \geq \frac{\hbar^2}{4}. \quad (2.12)$$

In particular, if $\langle x \rangle = 0$ and $\langle p_x \rangle = 0$, then according to Eq. (1.33), Eq. (12) takes the form

---

1 Equality (13) may be proved even if $\langle x \rangle$ and $\langle p_x \rangle$ are not equal to zero, by making the following replacements, $x \to x - \langle x \rangle$, $\partial / \partial x \to \partial / \partial x + i\langle p \rangle / \hbar$, in Eq. (7), and then repeating all the calculations – which in this case become somewhat bulky. In Chapter 4, equipped with the bra-ket formalism, we will derive a more general uncertainty relation, which includes the Heisenberg’s relation (13) as a particular case, in a more efficient way.
which, according to the definition (1.34) of the r.m.s. uncertainties, is equivalent to Eq. (1.35).

Now let us notice that the Heisenberg’s uncertainty relation looks very similar to the 
commutation relation between the corresponding operators:

\[
[\hat{x}, \hat{p}_x] \equiv (\hat{x}\hat{p}_x - \hat{p}_x\hat{x})\Psi = -\frac{i\hbar}{\partial x} \left( x\Psi - \frac{i\hbar}{\partial x} (x\Psi) \right) = i\hbar \Psi.
\]  
(2.14a)

Since this relation is valid for any wavefunction \( \Psi(x, t) \), we may represent it as an operator equality:

\[
[\hat{x}, \hat{p}_x] = i\hbar \neq 0.
\]  
(2.14b)

In Sec. 4.5 we will see that the relation between Eqs. (13) and (14) is just a particular case of a general relation between the expectation values of non-commuting operators, and their commutators.

2.2. Free particle: Wave packets

Let us start our discussion of particular problems with the free 1D motion, i.e. with \( U(x, t) = 0 \). From Eq. (1.29), it is evident that in the 1D case, a similar “fundamental” (i.e. a particular but the most important) solution of the Schrödinger equation (1) is a sinusoidal (“monochromatic”) wave

\[
\Psi_0(x, t) = \text{const} \times \exp\left\{i(k_0x - \omega_0t)\right\}.
\]  
(2.15)

According to Eqs. (1.32), it corresponds to a particle with an exactly defined momentum\(^2\) \( p_0 = \hbar k_0 \) and energy \( E_0 = \hbar \omega_0 = \hbar^2 k_0^2 / 2m \). However, for this wavefunction, the product \( \Psi^*\Psi \) does not depend on either \( x \) or \( t \), so that the particle is completely delocalized, i.e. the probability to find it the same along all axis \( x \), at all times.

In order to describe a space-localized state, let us form, at the initial moment of time \( t = 0 \), a wave packet of the type shown in Fig. 1.6, by multiplying the sinusoidal waveform (15) by some smooth envelope function \( A(x) \). As the most important particular example, consider the Gaussian wave packet

\[
\Psi(x, 0) = A(x)e^{ik_0x}, \quad \text{with } A(x) = \frac{1}{(2\pi)^{1/4}(\delta x)^{1/2}} \exp\left\{-\frac{x^2}{(2\delta x)^2}\right\}.
\]  
(2.16)

(By the way, Fig. 1.6a shows exactly such a packet.) The pre-exponential factor in this envelope function has been selected in the way to have the initial probability density,

\[
